The Lower Klamath Project License Surrender Draft Environmental Impact Report is being made available to the public in accordance with the California Environmental Quality Act. Public Comments are due on Tuesday, February 26, 2019.

Visit Lower Klamath Project License Surrender Project Web Site (https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/low er_klamath_ferc14803.shtml) where you can:

- View and download an electronic copy of the Draft EIR.
- View or download a list of libraries and other locations where hardcopies of the Draft EIR are available for review.

To receive future email notifications regarding the Lower Klamath Project, please subscribe to the “Lower Klamath Project License Surrender” email subscription list under “Water Rights”.
Instructions on how to sign up for the State Water Board’s Email Subscription List are outlined below:

1. Visit: http://www.waterboards.ca.gov/resources/email_subscriptions/swrcb_subscribe.shtml#rights
2. Provide your name and email in the required fields.
3. In the categories below the email and name fields, select “Water Rights,” then “Lower Klamath Project License Surrender.”
4. Click on the "Subscribe" button.
5. An email will be sent to you. You must respond to the email message(s) to confirm your membership on the selected list(s).

EXECUTIVE SUMMARY

On September 23, 2016, the Klamath River Renewal Corporation (KRRC) applied to the Federal Energy Regulatory Commission (FERC) to remove the dams and associated facilities that together form the Lower Klamath Project (FERC Project No. 14083). The KRRC's goal is to create a free-flowing Klamath River and provide for volitional fish passage in the Klamath River currently occupied by the Lower Klamath Project. The Lower Klamath Project consists of four dams: (J.C. Boyle; Copco No. 2; Copco No. 1; and Iron Gate) and their associated facilities (e.g., powerhouses, penstocks and power lines). The Lower Klamath Project (FERC Project No. 14803) is currently part of the Klamath Hydroelectric Project (FERC Project No. 2082), which is owned and operated by PacifiCorp. The Klamath Hydroelectric Project also includes several additional hydropower facilities (e.g., Fall Creek, East Side, West Side and Keno).

Also on September 23, 2016, the KRRC applied to the California State Water Resources Control Board (State Water Board) for water quality certification for the Proposed Project, pursuant to section 401 of the Clean Water Act. The State Water Board's water quality certification addresses water quality in California. The State Water Board is the lead agency for the California Environmental Quality Act (CEQA), which requires analysis of the environmental impacts of projects that can affect the environment. This Environmental Impact Report (EIR) was prepared to conform with CEQA. It focuses primarily on impacts related to actions proposed for the California portion of the Proposed Project. Actions at the J.C. Boyle Dam complex, located in Klamath County, Oregon, and other actions of the Proposed Project in Oregon, are described in general terms, but the discussion of actions in Oregon are limited to those with the potential to adversely impact the California environment. Oregon's Department of Environmental Quality issued a separate water quality certification for the Proposed Project that addresses water quality impacts in Oregon, including removal of the J.C. Boyle Dam complex. FERC and other federal agencies will analyze impacts of the Proposed Project in both states.

Proposed Project Location

The Lower Klamath Project is located on, and adjacent to, the Klamath River in Siskiyou County, California, and in Klamath County, Oregon (Figure ES-1). The State Water Board has identified the Project Boundary as inclusive of the Proposed Project "Limits of Work", as well as PacifiCorp owned and managed lands immediately surrounding the Lower Klamath Project ("Parcel B lands"), that would be transferred as part of the Proposed Project (Figure ES-2). The nearest city to the California portion of the Proposed Project is Yreka, which is located 20 miles southwest of the downstream end of the Proposed Project. The California portion of the Proposed Project includes the following three dams and associated facilities: Copco No. 1 Dam (River Mile [RM] 201.8), Copco No. 2 Dam (RM 201.5), and Iron Gate Dam (RM 193.1). For purposes of analyses conducted in this EIR, the California portion of the Klamath River system has been divided into four (4) reaches as follows: Hydroelectric Reach, Middle Klamath River, Lower Klamath River, and Klamath River Estuary (Figure ES-1).

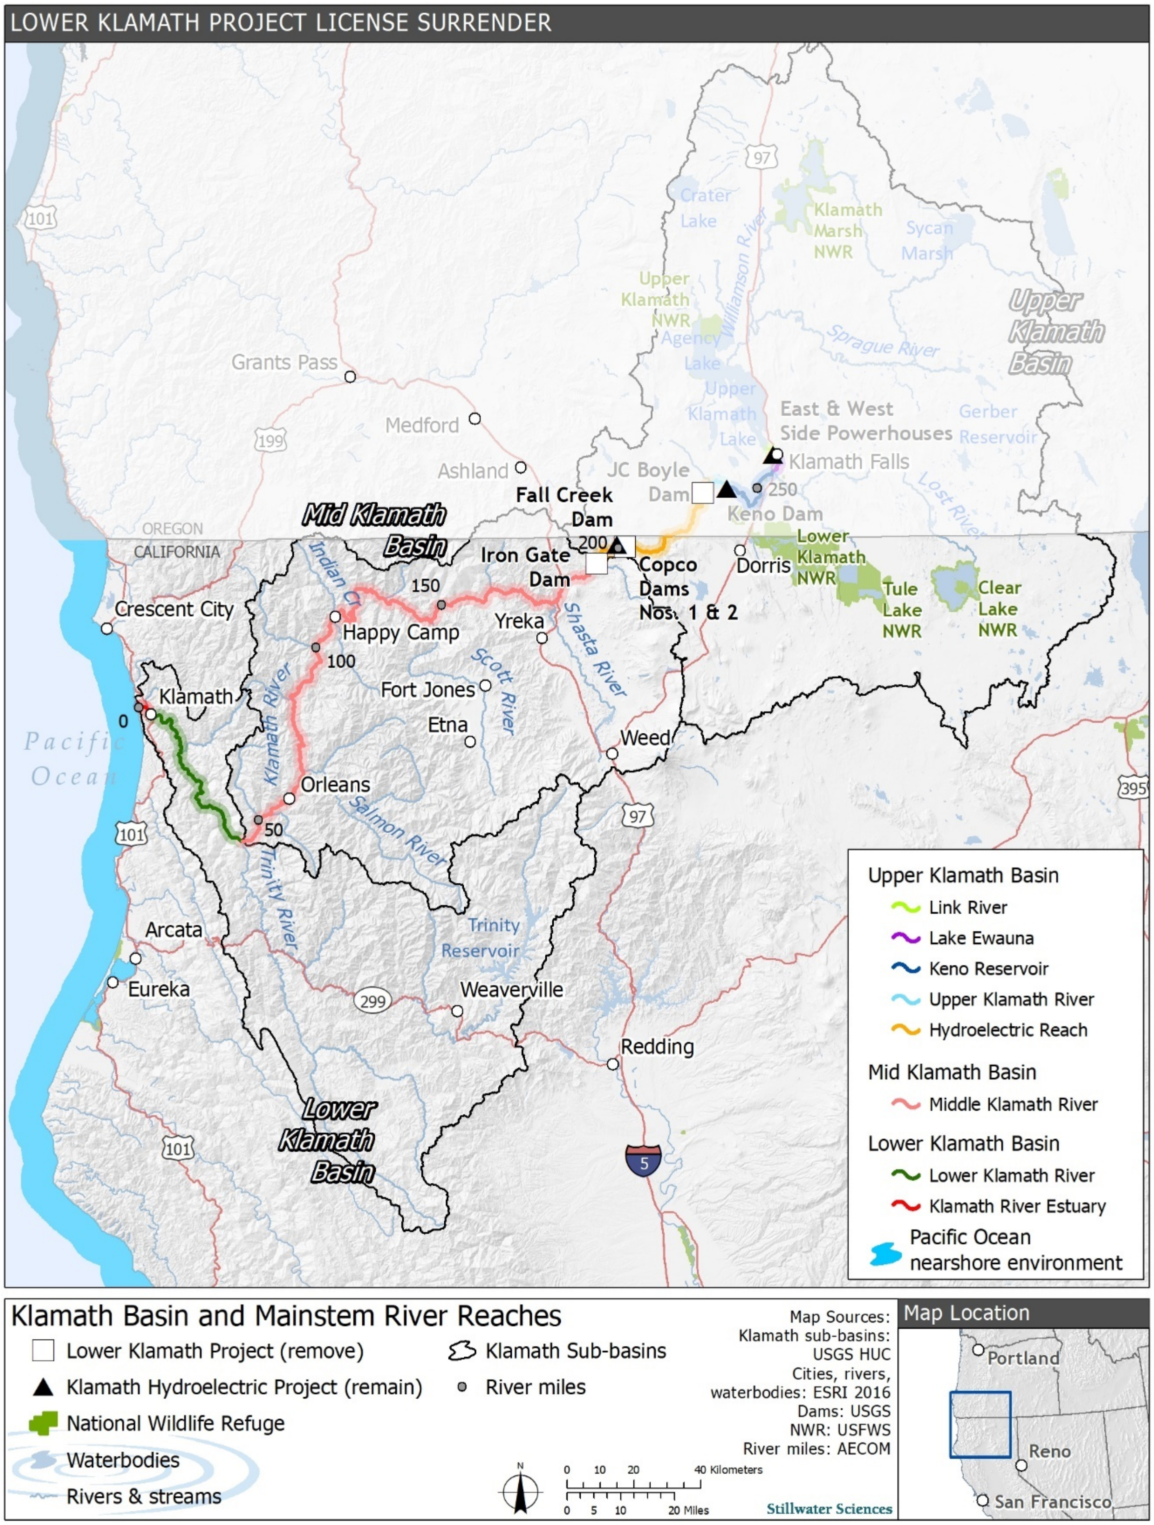

Figure ES-1. Klamath Basin and Mainstem River Reaches.

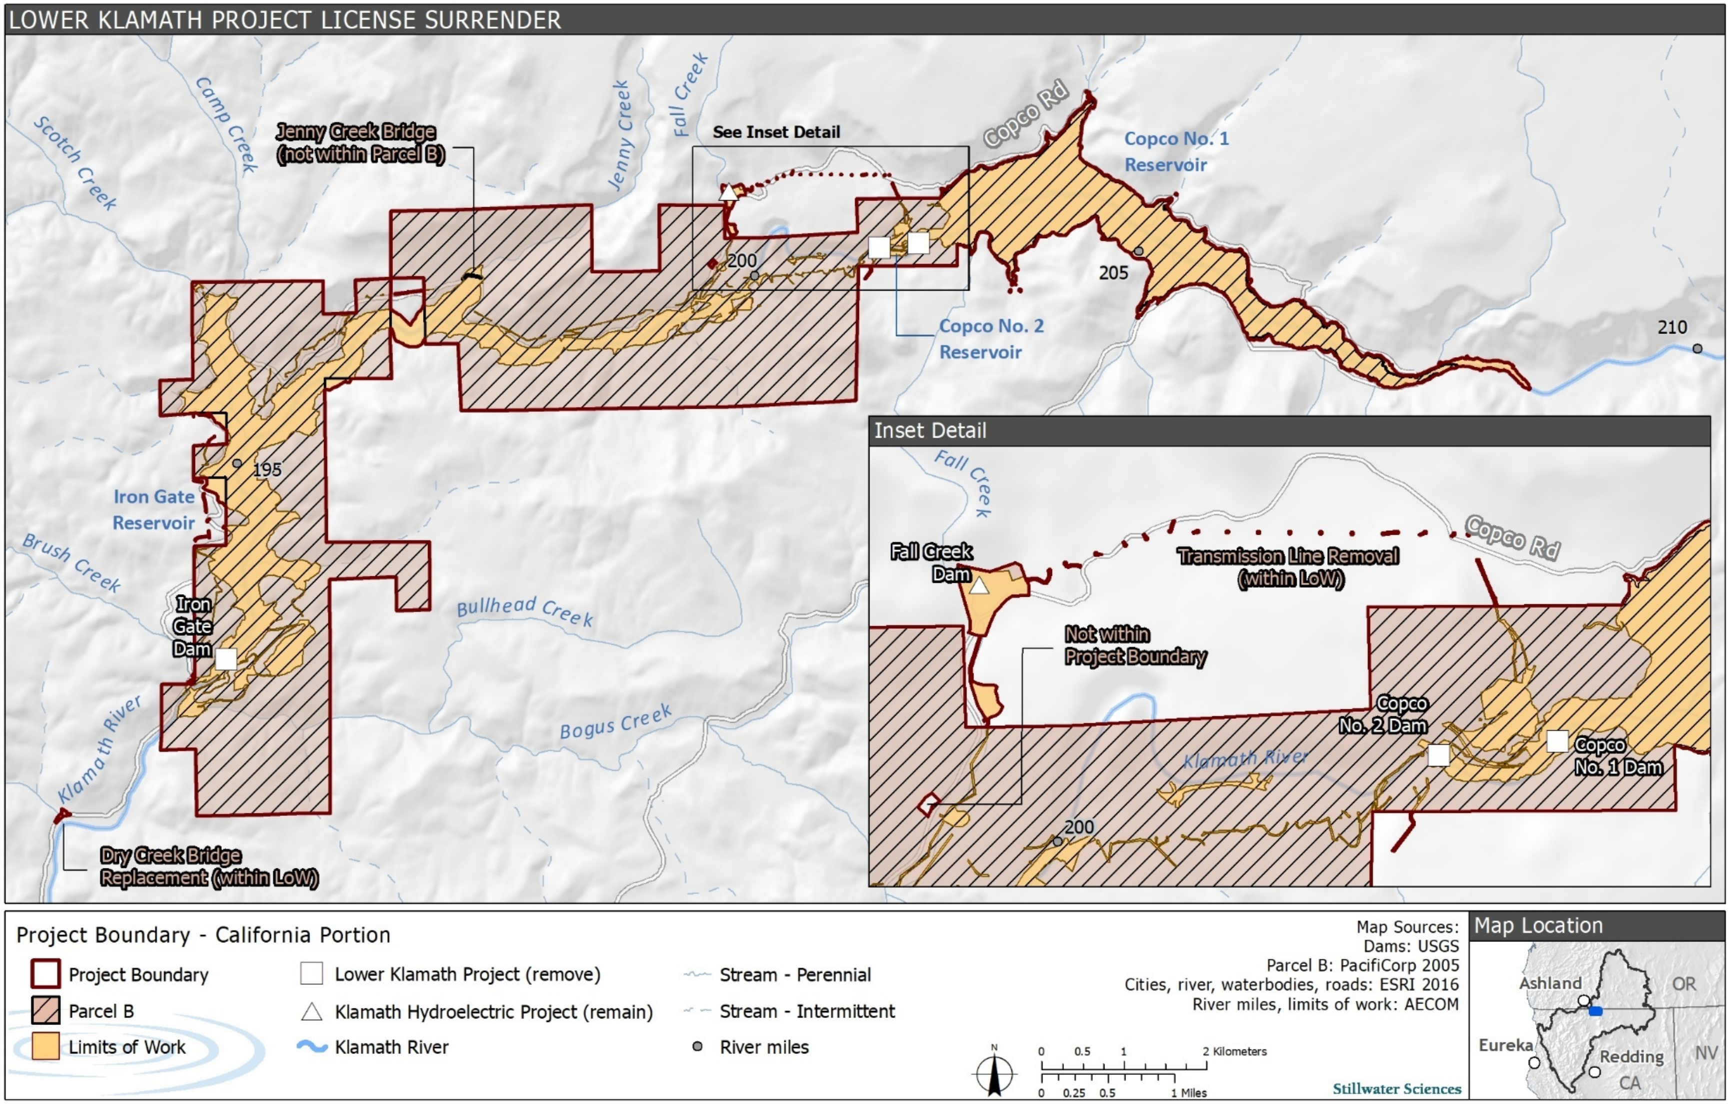

Figure ES-2. Proposed Project Boundary – California Portion.

Proposed Project Objectives

The State Water Board has identified the following Proposed Project objectives, as required under CEQA Guidelines, section 15124, subdivision (b):

In a timely manner:

1. Improve the long-term water quality conditions associated with the Lower Klamath Project in the California reaches of the Klamath River, including water quality impairments due to *Microcystis aeruginosa* and associated toxins, water temperature, and levels of biostimulatory nutrients.
2. Advance the long-term restoration of the natural fish populations in the Klamath Basin, with particular emphasis on restoring the salmonid fisheries used for subsistence, commerce, tribal cultural purposes, and recreation.
3. Restore volitional anadromous fish passage in the Klamath Basin to viable habitat currently made inaccessible by the Lower Klamath Project dams.
4. Ameliorate conditions underlying high disease rates among Klamath River salmonids.

The objectives further the underlying purpose of the Proposed Project, which is the timely improvement of water quality related to the Lower Klamath Project within and downstream of the current Hydroelectric Reach and the restoration of anadromous access upstream of Iron Gate Dam (the current barrier to anadromy).

Proposed Project

Dam and Powerhouse Deconstruction

The Proposed Project includes the deconstruction of the J.C. Boyle Dam and Powerhouse, Copco No. 1 Dam and Powerhouse, Copco No. 2 Dam and Powerhouse, and Iron Gate Dam and Powerhouse, as well as associated features. Associated features vary by powerhouse, but generally include: powerhouse intake structures, embankments and sidewalls, penstocks and supports, decks, piers, gate houses, fish ladders and holding facilities, pipes and pipe cradles, spillway gates and structures, diversion control structures, tunnels, aprons, sills, tailrace channels, footbridges, powerhouse hazardous materials, transmission lines, switchyards, a remnant cofferdam near Copco No. 2 Dam, portions of the Iron Gate Fish Hatchery, and various buildings. To access the dams for deconstruction, the KRRC would perform a controlled reservoir drawdown using both existing and modified infrastructure. Dam demolition would occur over approximately four months using multiple techniques, including blasting and hydraulic excavators. In addition, road maintenance, improvements and rehabilitation; culvert replacements; and bridge protection, strengthening, or replacement, would occur at numerous locations within the Proposed Project Limits of Work to support construction activities.

Anticipated import materials include gravel, sheetpile or H-piles, topsoil, seed and mulch materials, ready-mix concrete, reinforcing steel, mechanical equipment materials for the road, bridge and culvert improvements/replacements, and signage. Staging areas and disposal sites would also be created for each of the dams within the Proposed Project Limits of Work, and offsite waste disposal would likely be hauled to the Yreka Transfer

Station (Class III sanitary landfill). Hazardous materials would be handled and disposed of in accordance with applicable regulations.

Reservoir Drawdown

Copco No. 1 Reservoir would be drawn down first (November–March of dam removal year 1)[1], followed by J.C. Boyle (Oregon) and Iron Gate reservoirs (January–March of dam removal year 2). Copco No. 2 Reservoir is substantially smaller than the other three dams and the KRRC proposes to drawdown this reservoir after Copco No. 1 Dam has been breached to final grade in May of dam removal year 2. The proposed drawdown period was designed to: (1) balance the water quality impacts of dam removal across different life stages of aquatic species in the Middle and Lower Klamath River reaches; (2) use naturally high winter flows to flush sediments trapped in the reservoirs as quickly as possible; and (3) permit power generation revenues for the period specified in the Klamath Hydroelectric Settlement Agreement (KHSA). For all reservoirs, the minimum drawdown rate would be two feet per day, and the maximum drawdown rate would be five feet per day, until drained.

The maximum average flow releases would be: 138 cfs at J.C. Boyle Dam (Oregon), 762 cfs at Copco No. 1 Dam, and 822 cfs at Iron Gate Dam. These releases correspond to three percent, 13 percent, and 14 percent of the two-year peak flow in the Klamath River, and one percent, seven percent, and six percent of the 10-year peak flow in the Klamath River, respectively. These maximum rates would occur during dry periods, with slower drawdown (lower flow releases) occurring during storm events. During Iron Gate Dam removal, the embankment dam crest would be retained at a level to accommodate the passage of a 100-year flood event.

Power generation at Copco No. 1 Dam would end after the reservoir reaches the minimum operating level at reservoir surface elevation 2,604.5 feet, in November of dam removal year 1. If power generating equipment proves capable under sediment-laden conditions, power generation at Copco No. 2 Dam could continue until May of dam removal year 2. At J.C. Boyle (Oregon) and Iron Gate dams, power generation would cease on January 1 of dam removal year 2.

Reservoir Sediment Deposits and Erosion During Drawdown

There would be an estimated 15.1 million cubic yards (14.6 million tons) of sediment stored in the J.C. Boyle, Copco No. 1, and Iron Gate reservoirs by 2020 (USBR 2012). Between 2020 and 2021 (i.e., dam removal year 2, when drawdown is anticipated to primarily occur) the sediment volume present behind the dams would increase by approximately 81,300 cubic yards in Copco No. 1 Reservoir and approximately 100,000 cubic yards in Iron Gate Reservoir based on estimates of annual sedimentation rates for each reservoir (USBR 2012). The increase in sediment volume between 2020 and 2021 would be an order of magnitude less than the uncertainty of the 2020 total sediment volume estimates, so the 2020 sediment volumes provide a reasonable estimate for 2021 and thus for the Proposed Project. Copco No. 2 Reservoir does not retain

[1] The Proposed Project schedule is broken down into calendar years: pre-dam removal years 1−3, dam removal year 1, dam removal year 2, and post-dam removal years 1 through 10. See Table 2.7-1 for detailed schedule of Proposed Project activities.

appreciable amounts of sediment, because of its smaller size and location, and would not appreciably contribute to sediment transport during the drawdown of the reservoirs.

Approximately 85 percent of the sediment stored behind the reservoirs is fine (silt and clay), which would be easily eroded during drawdown, and only approximately 15 percent is coarse (sand and larger). Approximately 36 to 57 percent of the total sediment stored in J.C. Boyle, Copco No. 1, and Iron Gate reservoirs by 2021 is expected to be eroded and transported downstream during the drawdown period and the year following dam removal (i.e., short-term), which is equivalent to 5.4 to 8.6 million cubic yards (1.2 to 2.3 million tons). The range in the estimated volume of sediment eroded from each reservoir is primarily dependent upon whether the prevailing hydrology during reservoir drawdown corresponds to a dry hydrologic year or a wet hydrologic year, with less erosion expected in a dry year. The majority of the erosion would occur during the reservoir drawdown process and would be a combination of direct erosion of sediment by moving water, slumping of the fine sediment along the reservoir sides toward the river, and sediment jetting of some areas of reservoir-deposited sediments during drawdown. The short-term (i.e., two years following dam removal) effects of the Proposed Project on dam-released sediment and sediment resupply would likely extend from Iron Gate Dam to approximately Cottonwood Creek (USBR 2012). Most of the fine sediment is expected to be transported in suspension to the ocean shortly after being eroded. Fine sediment erosion would result in elevated suspended sediment concentrations downstream of Iron Gate Dam in the short term (Stillwater Sciences 2010, USBR 2012). Coarse sediment transport would occur more slowly and would be dependent on the frequency and magnitude of mobilizing flows and attenuation by channel storage.

Restoration within the Reservoir Footprint

The following sequence describes the activities that would be implemented in the former reservoir footprints to manage remaining sediment deposits and restore habitat.

- *Pre-dam removal* (pre-dam removal year 3, and dam removal year 1): collect and propagate seed and control invasive plants.
- *Reservoir drawdown* (January to March, dam removal year 2): revegetate exposed reservoir areas during and following drawdown by hydroseeding with a pioneer seed mix that contains common native plant species and sterile wheat mixed with a mycorrhizal inoculant and is capable of dealing with poor soil conditions, inclement weather, and complex hydrology, and by installing acorns, shrub seedlings, and pole cuttings. Permanent wildlife-friendly cattle exclusion fencing would be installed around the reservoir restoration areas where they abut grazing lands prior to drawdown, or shortly after the pioneer seeding.
- *Post-drawdown first summer/fall* (dry season immediately after drawdown during dam removal year 2): monitor and rectify any non-natural fish passage barriers, conduct additional fall overseeding on exposed areas, install riparian trees and shrubs, and install an irrigation system in the Bank Riparian Zone that would provide water for the duration of the KRRC maintenance and monitoring period.
- *Post-dam removal* (post-dam removal year 1): maintain vegetation, continue to remove and treat invasive exotic vegetation, install floodplain and off-channel habitat features, such as large wood. Monitor and rectify any non-natural fish passage barriers in mainstem and tributaries.

- *Establishment period* (post-dam removal years 2 through 5): continued monitoring and maintenance of vegetation, removal of invasive exotic vegetation, fish passage monitoring, and enhancement of habitat features as needed.
- *Long term* (post-dam removal years 5 through 10): continued monitoring and adaptive management, removal of invasive exotic vegetation, and fish passage monitoring. Vegetation restoration would be monitored for five years, or until the relevant performance criteria associated with minimizing invasive exotic vegetation, enhancing native plant diversity, and survival of planted trees and shrubs, have been met.

Restoration of Upland Areas Outside of the Reservoir Footprint

The following activities would be implemented in upland areas outside of the reservoirs' footprints:

- *Pre-dam removal:* active management of invasive exotic vegetation, which may include grazing, manual weed extraction, solarization (covering ground areas with black visqueen), tilling, and use of herbicides. Additionally, native plants would be prepared by collecting seeds and working with local nurseries to grow trees and shrubs.
- *Construction/deconstruction period*: protection of native trees.
- *Post-dam removal*: restoration of upland disposal, staging, temporary access, infrastructure demolition, and former recreation areas, including activities such as addressing compaction and broadcast-seeding with a native seed mix. Soils would be disked and ripped in preparation for planting. A temporary irrigation system may be installed in upland areas, if required.

Fish Hatcheries

During demolition, some Iron Gate Hatchery facilities located at the base of Iron Gate Dam would be removed, along with the cold-water supply and aerator for the hatchery. However, operational components of Iron Gate Hatchery would be retained and modified to continue operations at a reduced rate for just Chinook salmon and to eliminate coho salmon production. The nearby Fall Creek Hatchery, located at Fall Creek just upstream of Iron Gate Reservoir, would be reopened to maintain the current Iron Gate coho salmon production and some Chinook salmon production. The Iron Gate and Fall Creek hatcheries would remain in operation for eight years following removal of the dams, at which point the hatcheries would cease operations

City of Yreka Water Supply Pipeline Relocation

The City of Yreka receives its water supply from Fall Creek, a tributary to the Klamath River in the Upper Klamath Basin, approximately 23 miles northeast of the City of Yreka. At the upstream end of Iron Gate Reservoir, the pipeline crosses the reservoir and is minimally buried in the reservoir bed. To prevent damage to the pipeline, a replacement pipe crossing would be installed before dam removal and reservoir drawdown. The replacement pipe crossing would consist of one of the following three options:

- A new buried pipeline by micro-tunneling in the immediate vicinity of the existing pipeline crossing.

- A new aerial pipeline on a dedicated utility pipe crossing in the immediate vicinity of the existing pipeline crossing.
- A combination of a new buried pipeline and an aerial pipeline crossing on the existing timber traffic bridge along Daggett Road located approximately 2,000 feet upstream of the existing pipeline crossing.

Other Project Components

Other Proposed Project components include:

- ***Aquatic Resource Measures*** – surveys and protection measures for mainstem spawning and outmigrating juveniles; delayed release of hatchery fish from Iron Gate Fish Hatchery to avoid poor water quality; and surveys and relocation of suckers and freshwater mussels.
- ***Terrestrial Resource Measures*** – stabilization of remaining sediments and restoration of reservoir and other disturbed areas for habitat restoration; and surveys and avoidance and minimization measures for nesting birds, bald and golden eagles, special-status bats, northern spotted owl, and special-status plants.
- ***Transportation and Traffic*** – improve roads, bridges and culverts affected by the Proposed Project construction and ongoing maintenance.
- ***Recreation*** – implementation of a Recreation Plan, which includes removal of numerous existing recreation facilities, and restoration with native vegetation before, during and after dam removal at J.C. Boyle Reservoir, Copco No. 1 Reservoir, Iron Gate Reservoir, and dispersed recreation sites; initiates process to add new river-based recreation opportunities.
- ***Downstream Flood Control*** – maintain existing flood protection.
- ***Management and Other Plans*** – Cultural Resources Plan, Traffic Management Plan, Water Quality Monitoring Plan, Groundwater Well Management Plan, Fire Management Plan, Hazardous Material Management Plan, Emergency Response Plan, and Noise and Vibration Control Plan.

Land Disposition

Before dam removal, PacifiCorp would transfer most of the lands immediately surrounding the Lower Klamath Project ("Parcel B lands") to the KRRC. The Proposed Project provides that, after dam removal, the KRRC would transfer Parcel B lands to California or Oregon or to a designated third-party for public interest purposes, as described under KHSA Section 7.6.4.

Summary of Proposed Project Effects, Potential Impacts, and Potential Cumulative Impacts

Table ES-1 (located after the Executive Summary *References*) summarizes the potential impacts examined in this EIR. For each potential impact, it lists the significance of the potential impact for the Proposed Project (and for each of the alternatives analyzed), and whether these potential impacts would be short term or long term. The table also notes mitigation measures that could reduce the severity of potentially significant impacts.

The largest number of adverse impacts under the Proposed Project would be impacts due to reservoir drawdown (and the resulting sediment discharge) and from dam removal activities; however, many of these impacts would be reduced through proposed mitigation for the resource areas listed above. Additionally, many of these impacts would be short term. Mitigation measures are listed in Table ES-1. All mitigation measures would be included in a Mitigation, Monitoring, and Reporting Program (MMRP).

Effects with No Significant Impact (with or without Mitigation)

As shown in Table ES-1, most of the potential impacts assessed in this EIR would result in no significant impact or no significant impact with mitigation. The Proposed Project itself, or the Proposed Project with proposed mitigation measures, would result in no significant impact for one or more impacts in all resource areas.

Effects Found to be Beneficial

A summary, by resource area, of effects found to be beneficial for the Proposed Project is provided below. These effects are also summarized in Table ES-1, along with effects found to be beneficial for the alternatives.

Water Quality

- Short-term and long-term water temperature improvements in the Hydroelectric Reach and the Middle Klamath River to the confluence with the Salmon River;
- Short-term and long-term elimination of summer and fall extremes in dissolved oxygen concentrations in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam;
- Short-term and long-term decreases in summer and fall pH and daily pH fluctuations in the Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam; and
- Short-term and long-term reduction of chlorophyll-a and algal toxins for the Hydroelectric Reach, the Middle and Lower Klamath River, and the Klamath River Estuary.

Aquatic Resources

- Long-term effects on in coho salmon critical habitat quality and quantity;
- Long-term effects on Chinook and coho salmon Essential Fish Habitat (EFH) quality and quantity;

- Long-term beneficial effects on the fall-run Chinook salmon population due to increased habitat quality and quantity;
- Long-term beneficial effects on the spring-run Chinook salmon population due to increased habitat quality and quantity;
- Long-term beneficial effects on the coho salmon population due to increased habitat quality and quantity;
- Long-term beneficial effects on the steelhead population due to increased habitat quality and quantity;
- Long-term beneficial effects on the Pacific lamprey population due to increased habitat quality and quantity;
- Long-term beneficial effects on the redband trout population due to increased habitat quality and quantity;
- Short-term and long-term beneficial effects on species interactions between introduced resident fish species and native aquatic species due to short- and long-term changes in habitat quality and quantity; and
- Long-term beneficial effects on benthic macroinvertebrate habitat quality.

Phytoplankton and Periphyton

- Long-term change in the spatial extent, temporal duration, transport, or concentration of nuisance and/or noxious phytoplankton blooms and concentrations of algal toxins in the Hydroelectric Reach, Middle and Lower Klamath River, and Klamath River Estuary.

Terrestrial Resources

- Long-term beneficial effects on riparian habitat downstream of the Lower Klamath Project due to sediment deposition and the creation of new surfaces for colonization;
- Long-term beneficial effects on willow flycatcher from additional riparian habitat in the former location of Copco No. 1 and Iron Gate reservoirs;
- Long-term beneficial effects on special-status amphibians and reptiles in riverine habitats from improved water quality;
- Long-term beneficial effects on benthic macroinvertebrates due to increased habitat availability and improved habitat quality;
- Long-term beneficial effects on deer from an increase in winter range habitat;
- Long-term beneficial effects on rare natural communities, wetlands, and riparian vegetation from herbicide use during reservoir restoration that would improve habitat conditions by reducing competition from invasive species;
- Effects on wildlife from increased habitat for salmonid spawning, production, and migration and increase in prey and overall nutrient distribution;
- Long-term effects on wildlife from increased wildlife movement opportunities; and
- Long-term effects on terrestrial wildlife from an increase in the distribution of salmon-derived nutrients upstream of Iron Gate, Copco No. 1 and Copco No. 2 dams.

Flood Hydrology

- Long-term decrease in the risk of dam failure resulting in flooding of areas downstream of the Lower Klamath Project.

Geology, Soils, and Mineral Resources

- Long-term increase in sediment supply and transport, creating a more dynamic and mobile riverbed within the Hydroelectric Reach and downstream of Iron Gate Dam.

Historical Resources and Tribal Cultural Resources

- Klamath Riverscape Contributing Aspect – long-term beneficial effects on the Klamath River fishery of predicted increases in fish production and health from dam removal and the long-term benefits on much of the key tribal trust species (e.g., Chinook salmon, coho salmon, steelhead, and Pacific lamprey) resulting from improved river ecosystem function and increased habitat access; and
- Klamath Riverscape Contributing Aspect – long-term increase in the ability of tribes to access and use the Middle and Lower Klamath River for ceremonial and other purposes due to improvements in riverine water quality and reductions in seasonal blue-green algae blooms in Copco No. 1 and Iron Gate reservoirs.

Recreation

- Increased recreational fishing opportunities due to increased habitat access for salmonids and improved water quality; and
- Long-term beneficial effects on California Klamath Wild and Scenic River resources due to a return to more natural conditions and improved water quality, and scenic, wildlife, fishery, and recreation river values.

Significant Unavoidable Adverse Impacts

Below is a summary, by resource area, of impacts found to be 'significant and unavoidable' with or without mitigation (Table ES-1). Please note, the KRRC proposes to further develop Proposed Project actions relating to certain state and local regulatory requirements for several resource areas that fall outside of State Water Board's water quality certification authority. The State Water Board anticipates implementation of additional measures (e.g., good neighbor agreements between the KRRC and relevant state or local agencies, recommended measures in this EIR, and any modifications developed through the FERC process that provide the same or better level of protection for the resource in question) would reduce impacts. The EIR notes where such protection would eliminate the potential for a significant impact. However, the State Water Board cannot ensure implementation of good neighbor agreements, recommended measures included in this EIR, or modifications anticipated to be developed through the FERC process. Therefore, the State Water Board has identified impacts that rely on implementation of such agreements or recommended measures in this EIR as significant and unavoidable.

Water Quality

- Short-term increases in suspended sediments in the Hydroelectric Reach, Middle and Lower Klamath River, Klamath River Estuary, and the Pacific Ocean nearshore environments due to release of sediments currently trapped behind the Lower Klamath Project dams;
- Short-term increases in oxygen demand and reductions in dissolved oxygen due to release of sediments currently trapped behind the Lower Klamath Project dams in the Hydroelectric Reach and Middle Klamath River from Iron Gate Dam to the Salmon River; and
- Short-term increases in water temperature and reductions in dissolved oxygen in Fall Creek downstream of Fall Creek Hatchery due to hatchery operations.

Aquatic Resources

- Short-term impacts on native freshwater mussels (*Anodonta spp.*) due to elevated suspended sediment concentrations (SSCs) during reservoir drawdown and long-term impacts due to elimination of reservoir habitat in the Hydroelectric Reach and relatively stable flow regime in the Middle Klamath River immediately downstream of Iron Gate Dam.

Phytoplankton and Periphyton

- Potential for short-term and long-term increases in the growth of nuisance periphyton species along the margins of the newly created low gradient river channels in the Hydroelectric Reach.

Terrestrial Resources

- Short-term impacts on special-status plants from construction-related activities within the Limits of Work;
- Short-term and long-term impacts on special-status wetland plants surrounding the reservoirs due to removal of Copco No. 1, Copco No. 2, and Iron Gate reservoirs;
- Short-term impacts on special-status mammals (bats, gray wolf, American badger) from construction-related activities within the Limits of Work;
- Short-term impacts on nesting birds from construction-related noise and habitat removal within and surrounding the Limits of Work;
- Short-term impacts on willow flycatcher from construction-related noise disturbance and habitat removal at Copco No. 1 and Iron Gate reservoirs;
- Short-term impacts on bald and golden eagles from construction-related noise and nesting habitat alterations at Copco No. 1, Copco No. 2, and Iron Gate reservoirs;
- Short- and long-term impacts on special-status bats, maternity roosts, and hibernacula from construction noise and loss of roosting habitat at existing Lower Klamath Project facilities; and
- Short-term impacts on sensitive habitats and special-status terrestrial wildlife and plant species from construction activities on Parcel B lands.

Flood Hydrology

- Long-term change in the Federal Emergency Management Agency (FEMA) 100-year floodplain inundation extent from Iron Gate Dam (RM 193) to Humbug Creek (RM 174), potentially exposing existing structures, which cannot feasibility be moved or elevated, to a substantial risk of flood damage and/or loss.

Air Quality

- Short-term exceedances of the Siskiyou County Air Pollution Control District total daily emissions thresholds for NO_x, PM_{10}, and $PM_{2.5}$[2] during dam removal construction activities.

Historical Resources and Tribal Cultural Resources

- Exposure of or damage to known Tribal Cultural Resources and historic-period archaeological sites through pre-dam removal ground-disturbing construction and disposal activities and increased access to sensitive areas;
- Shifting, erosion, and exposure of known or unknown, previously submerged Tribal Cultural Resources and historic-period archaeological sites, due to reservoir drawdown;
- Erosion or flood disturbance to Tribal Cultural Resources and historic-period archaeological sites located along the Middle Klamath River from Iron Gate Dam to Humbug Creek;
- Physical disturbance of known or unknown tribal cultural resources and historic-period archaeological sites that directly overlap with locations where blasting and other removal techniques would occur;
- Physical disturbance of known Tribal Cultural Resources and historic-period archaeological sites from ground disturbance associated with reservoir restoration, recreation site removal and/or development, disposal site restoration, and ongoing road and recreation site maintenance;
- Increased potential for looting of Tribal Cultural Resources during and following drawdown at Iron Gate, Copco No. 1 and Copco No. 2 reservoirs;
- Exposure or disturbance to known or unknown Tribal Cultural Resources within the reservoir footprints immediately following reservoir drawdown and prior to vegetation establishment/full stabilization of sediment deposits because of erosion caused by high-intensity and/or duration precipitation events;
- Impacts to Tribal Cultural Resources as a result of dam removal from increased looting opportunities and from surface and subsurface erosion of Tribal Cultural Resources;
- Impacts to the historical significance of the Klamath River Hydroelectric Project District due to facilities removal; and

[2] Nitrogen oxides (NO_x), particulate matter with a diameter of 10 microns or less (PM_{10}), and particulate matter with a diameter of 2.5 microns or less ($PM_{2.5}$).

Public Services

- Increases in public service response times for emergency fire, police, and medical services due to construction and demolition activities, including construction-related traffic; and
- Substantial increase in response times for suppressing wildland fires where suitable replacement water sources cannot be identified in close proximity to a fire in a location for which the Lower Klamath Project reservoirs would otherwise have been the nearest water source.

Aesthetics

- Short-term visual changes resulting from reservoir drawdown, including temporarily bare/unvegetated banks;
- Long-term visual changes resulting from new recreation facilities; and
- Short-term impacts to nighttime views in the area from new sources of substantial light or glare from construction or security lighting.

Recreation

- Changes to or loss of river conditions that support whitewater boating in the Hell's Corner reach in the upper portion of the Hydroelectric Reach.

Hazards and Hazardous Substances

- Construction-related traffic may interfere with emergency response on rural roads surrounding the Lower Klamath Project.
- Substantial increase in public's risk of loss, injury or death associated with wildland fires where suitable replacement water sources cannot be identified in close proximity to a fire in a location for which the Lower Klamath Project reservoirs would otherwise have been the nearest water source.

Transportation and Traffic

- Increase in traffic in excess of the capacity or design of the road improvements or impairment of the safety or performance of the circulation system, including transit, roadways, bicycle lanes or pedestrian paths;
- Conflict with an applicable congestion management program for designated roads or highways that would result in increased risk of harm to the public;
- Substantially increasing hazards due to a design feature or incompatible uses associated with construction-related traffic that would result in an increased risk of harm to the public;
- Inadequate emergency access that would result in an increased risk of harm to the public; and
- Conflict of construction-related activities with public transit, bicycle, or pedestrian facilities, or decrease of the performance or safety of such facilities resulting in an increased risk of harm to the public.

Noise

- Short-term exceedance of Siskiyou County General Plan criteria for maximum allowable noise levels from construction equipment;
- Short-term increases in daytime and nighttime noise levels affecting residents near Copco No.1 Dam due to construction activities;
- Short-term increases in nighttime noise levels affecting residents near Iron Gate Dam due to construction activities;
- Short-term increase in noise levels affecting residential areas near Copco No. 1 and Iron Gate reservoirs due to restoration activities;
- Short-term increase in vibration levels affecting residential areas near Copco No.1, Copco No. 2, and Iron Gate dams due to blasting activities during removal of the dams.

There are no significant and unavoidable impacts under the Proposed Project for the following resource areas: groundwater, water supply/water rights, greenhouse gas emissions, geology, soils, and mineral resources, paleontologic resources, land use and planning, agricultural and forestry resources, population and housing, and utilities and service systems.

Cumulative Impacts

CEQA requires determination of whether the combined impact of the Proposed Project and other projects causing related impacts is significant and adverse, and whether the incremental impact of the Proposed Project is cumulatively considerable. Using a list of past, present, and probable future projects within the Klamath Basin, the following impacts are assessed as “cumulatively considerable”:

Water Quality

- Short-term increases in suspended sediments under the Proposed Project in combination with the 2017 court-ordered flushing and emergency dilution flows; and
- Short-term water quality effects of the Proposed Project in combination with wildfires.

Air Quality

- Short-term increases in criteria air pollutant emissions under the Proposed Project in combination with forest and wildfire management projects.

Public Services

- Short-term public services effects from the Proposed Project in combination with non-project activities.

Hazards and Hazardous Substances

- Short-term and long-term hazards (fire-fighting water access) from the Proposed Project in combination with non-project activities.

Transportation and Traffic

- Short-term and long-term traffic and transportation effects from the Proposed Project in combination with non-project activities.

There are no cumulatively considerable impacts for other resource areas.

Alternatives to the Proposed Project

No Project Alternative

The No Project Alternative describes the environment should the KRRC's Proposed Project − to decommission the four dams and associated facilities − not proceed. There is significant uncertainty about the long-term disposition of the Lower Klamath Project facilities if the KRRC's Proposed Project does not proceed.

During the short term (i.e., 0−5 year period), the Lower Klamath Project (i.e., J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams and associated facilities) and the remaining Klamath Hydroelectric Project facilities (East Side, West Side, Keno, and Fall Creek) would continue to operate under annual licenses issued by FERC until the disposition of Lower Klamath Project facilities could be determined through the FERC relicensing process. This would include the potential of another settlement agreement under that process. This timeframe also includes time for completion of any necessary planning or studies to undertake facilities modifications. The current annual license issued for Lower Klamath Project facilities under PacifiCorp's annual FERC licenses for the Klamath Hydroelectric Project (Project No. 2082) has no requirements for additional fish passage or implementation of the prescriptions that are currently before FERC in the Klamath Hydroelectric Project relicensing process.

Additionally, in the short term, the No Project Alternative would not result in any change from the existing management conditions, except regarding flow and certain interim water quality and habitat measures as noted in this paragraph. The 2017 court-ordered flushing and emergency dilution flow releases downstream of Iron Gate Dam (U.S. District Court 2017) would modify flow releases compared to the existing condition. Some KHSA Interim Measures (IMs) would cease.

In addition to the KHSA IMs, there are various efforts in the Klamath Basin to improve water quality, which are discussed in Cumulative Effects (Section 3.24). The effects of these efforts, including efforts aimed at meeting Klamath River total maximum daily loads (TMDLs) are not analyzed for the short term under No Project Alternative because the basin response to the restoration measures to meet the TMDLs during the short term is too speculative.

In the short term, the No Project Alternative would not meet the Proposed Project's underlying objectives. In the long term, the impacts and ability of the No Project Alternative to meet project objectives and purposes are speculative, but they would be within the range of the alternatives and the Proposed Project evaluated in this EIR.

Partial Removal Alternative

In the Partial Removal Alternative, portions of J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams and associated facilities would be removed to ensure a free-flowing Klamath River and year-round volitional fish passage in the Hydroelectric Reach (under all river stages and flow conditions). Ancillary facilities associated with J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dam complexes that do not affect Klamath River flows or volitional fish passage would be secured for public safety (e.g., sealing or fencing to prevent entry, removal of hazardous materials) and abandoned in place. In general, the ancillary facilities to be retained under the Partial Removal Alternative include the Copco No. 1 Powerhouse, penstocks, and intake structure, the Copco No. 2 Powerhouse, steel penstocks and supports, and intake structure, and the lower portion of the Iron Gate Powerhouse, as well as the mechanical and electrical equipment associated with each powerhouse. All other aspects would occur as described under the Proposed Project: dam and powerhouse deconstruction, reservoir drawdown, erosion of reservoir sediment deposits during drawdown, restoration in the reservoir footprint, restoration of upland areas, hatchery operations, City of Yreka water supply pipeline relocation, aquatic and terrestrial resource measures, road and bridge improvements/replacements, culvert replacements, recreation facilities removal, traffic management, groundwater well monitoring and replacement, fire management, hazardous material management, emergency response, and noise and vibration control measures.

This alternative would meet the underlying purpose, and all the objectives, of the Proposed Project. Under the Partial Removal Alternative, the construction footprint would be slightly reduced, and the impact to the historical built environment would be reduced as compared with the Proposed Project. Should this alternative be pursued, the responsibility for long-term maintenance of remaining facilities is unknown.

Continued Operations with Fish Passage Alternative

In the Continued Operations with Fish Passage Alternative, the J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams and associated facilities would be relicensed by FERC for continued operations with changes to allow for upstream and downstream fish passage and updated flow requirements consistent with fishway prescriptions. This alternative would include volitional year-round upstream and downstream fish passage at the dams, and an increase of minimum flows in the J.C. Boyle Bypass Reach and the Copco No. 2 Bypass Reach. Conditions would include flows required by the NMFS and USFWS 2013 Joint Biological Opinion for the Klamath Irrigation Project (2013 BiOp Flows), 2017 court-ordered flushing and emergency dilution flows, and design and implementation of a Reservoir Management Plan. KHSA Interim Measures (IMs) (KHSA Section 1.2.4) would not continue under the Continued Operations with Fish Passage Alternative. Actions consistent with IMs designed for water quality improvements are analyzed in this alternative as part of the Reservoir Management Plan. Additionally, the "California Klamath Restoration Fund/Coho Enhancement Fund" restoration actions, described under the No Project Alternative (see Table 4.2-1), would continue.

This alternative would not meet one of Proposed Project's objectives because it does not adequately address Project-related long-term water quality impairments. It also would only partially further the underlying purpose of the Proposed Project because it would not result in timely improvement of water quality related to the Proposed Project within and downstream of the current Hydroelectric Reach; however, it would further the underlying purpose of providing fish passage upstream of Iron Gate Dam. Because the dams and reservoirs would remain, they would still continue as an impairment to migration that is not present under the Proposed Project. Compared to the Proposed Project, this alternative would avoid potential impacts associated with sediment release, dam removal, and riverine restoration. It would also continue hydropower production at close to existing levels, and it would reduce the level of construction and its associated impacts (as construction activities would mainly be associated with fish ladders rather than dam decommissioning). However, while this alternative would further the underlying purpose and related objectives of providing fish passage upstream of Iron Gate Dam, fish survival through fishways would be reduced as compared to through un-dammed stream reaches. Further, this alternative would not improve other water quality conditions that are stressors for fish and other resources. Thus, this alternative would further the underlying purpose and Proposed Project objectives to some extent, but not to the same extent as the Proposed Project.

Three Dam Removal Alternative

This alternative would remove the three California Lower Klamath Project dams (Copco No. 1, Copco No. 2, and Iron Gate) and associated facilities, but J.C. Boyle Dam and associated facilities would remain in place. J.C. Boyle Dam would operate under the conditions that federal agencies had imposed in the FERC proceedings for the continued relicensing of the Klamath Hydroelectric Project (which is currently on hold). The main changes to J.C. Boyle Dam facilities and operations would be: construction of new fish ladders for upstream and downstream fish passage; new fish screens; elimination of peaking operations; elimination of whitewater recreation flows; changed bypass release requirements; and any conditions imposed by the Oregon Department of Environmental Quality as part of its water quality certification[3] of J.C. Boyle Dam and its associated facilities. The flow-related measures would reduce power generation at J.C. Boyle Dam relative to existing conditions. The alternative assumes that USBR's flow release requirements for Iron Gate Dam would continue to be required as federal Endangered Species Act requirements (i.e., 2013 BiOp Flows and 2017 court-ordered flushing and emergency dilution flows). This alternative considers conditions with and without the 2017 court-ordered flushing and emergency dilution flows for potential impacts related to fish disease.

As compared to the Proposed Project, retaining J.C. Boyle Dam would somewhat reduce the amount and duration of short-term sediment release during reservoir drawdown, although it would not change the determinations of significance or associated mitigation measures. Compared to the Proposed Project, retaining J.C. Boyle Dam results in no meaningful difference in the significance determinations or associated mitigation measures related to construction impacts, because the differing construction efforts would occur in Oregon and any impacts would be substantially diluted in California. This alternative would allow some level of non-peaking hydropower production to continue, but it would be less than under the existing condition or the Continued Operation with Fish Passage Alternative. However, while this alternative would further the underlying purpose and related objectives of providing fish passage, fish survival through fishways would be reduced as compared to passage through un-

[3] This alternative does not make any assumptions about potential Oregon water quality certification conditions.

dammed stream reaches. Thus, the Three Dam Removal Alternative would further the underlying purpose and Proposed Project objectives, but not to the same extent as the Proposed Project.

Two Dam Removal Alternative

This alternative would remove the Copco No. 1 and Iron Gate dams and associated facilities in California, while the J.C. Boyle Dam in Oregon and the Copco No. 2 Dam in California would remain in place. J.C. Boyle Dam would operate under the conditions that federal agencies had imposed in the FERC proceedings for the continued relicensing of the Klamath Hydroelectric Project (which is currently on hold). The main changes to J.C. Boyle facilities and operations would be: construction of new fish ladders for upstream and downstream fish passage; new fish screens; elimination of peaking operations; elimination of whitewater recreation flows; changed bypass release requirements; and any conditions imposed by the Oregon Department of Environmental Quality as part of its water quality certification[4] of J.C. Boyle Dam and its associated facilities. The main changes to Copco No. 2 would be: an increase of minimum flows for the Bypass Reach; installation of upstream and downstream fish passage facilities; and any conditions imposed by the State Water Board as part of its water quality certification of Copco No. 2 and its associated facilities[4]. Flow-related requirements would reduce power generation at J.C. Boyle Dam relative to existing conditions.

This alternative assumes that USBR's flow requirements would be the same as those required under the current federal Endangered Species Act requirements (i.e., 2013 BiOp Flows and 2017 court-ordered flushing and emergency dilution flows) and considers conditions with and without the 2017 court-ordered flushing and emergency dilution flows for potential impacts related to fish disease.

Retaining J.C. Boyle and Copco No. 2 dams would reduce the amount and duration of short-term sediment release and it would reduce construction and waste disposal in California, thus reducing the associated significant impacts compared to the Proposed Project. This alternative would also allow some non-peaking hydropower production to continue – less than under the existing condition or Continued Operation with Fish Passage Alternative, but more than under the Three Dam Removal Alternative. However, while this alternative would further the underlying purpose and related objectives of providing fish passage, fish survival through fishways would be reduced as compared to passage through un-dammed stream reaches. Thus, the Two Dam Removal Alternative would further the underlying purpose and Proposed Project objectives, but not to the same extent as the Proposed Project.

[4] This alternative does not make any assumptions about potential Oregon and California water quality certification conditions.

No Hatchery Alternative

The No Hatchery Alternative is the same as the Proposed Project, except that modification and operation of Fall Creek Hatchery would not occur, and the Iron Gate Hatchery operations would end upon dam removal instead of continuing with reduced production for eight years following removal of the dams, as under the Proposed Project. Under this alternative, all production of salmonids would be discontinued after hatchery releases occur in the fall of dam removal year 1 and the reduced production goals for the Proposed Project would not occur. Construction activities would include all those identified under the Proposed Project, except that: Iron Gate Hatchery facilities would be completely removed; and, Fall Creek Hatchery would not be refurbished and would not reopen. Water diversions to operate the hatcheries would not be needed. This alternative would reduce construction-related impacts associated with the reopening of Fall Creek Hatchery, modifications to provide water, and installation of a new fish ladder at Iron Gate Hatchery.

The No Hatchery Alternative would further the underlying purpose and objectives, although the alternative would not meet Objective 2 (to advance the long-term restoration of the natural fish population in the Klamath Basin, with particular emphasis on restoring the salmonid fisheries used for subsistence, commerce, tribal cultural purposes, and recreation) as quickly as under the Proposed Project.

Public Involvement and Agency Consultation

The State Water Board solicited public and agency input for the Lower Klamath Project and Alternatives, in accordance with CEQA Guidelines Section 15082. The *Notice of Preparation and Scoping Meetings for an Environmental Impact Report for the Lower Klamath Project License Surrender (NOP)* was issued for a 42-day public comment period (December 22, 2016 to February 1, 2017). The State Water Board held three public scoping meetings (in Arcata, Sacramento, and Yreka) in January 2017 to solicit input (see the *Scoping Report* attached as Appendix A). A total of 1,418 oral and written comments were received. Seven comment emails or letters were received after the close of the comment period and were included in the *Scoping Report*.

In addition to the formal scoping process, the State Water Board has consulted with and/or obtained comments from various Native American Tribes, state and federal public agencies, affected local agencies, and stakeholders, including, but not limited to:

- CALFIRE
- California Coastal Commission
- California Department of Fish and Wildlife (CDFW) Region 1 (includes participation in KRRC Technical Workgroup Inter-agency Meetings)
- California Natural Resources Agency
- National Marine Fisheries Service (includes participation in KRRC Technical Workgroup Inter-agency Meetings)
- Native American Tribes – Shasta Nation, Shasta Indian Nation, Yurok Tribe, Karuk and Hoopa Valley Tribes
- Oregon Department of Environmental Quality
- Siskiyou County

- United States Bureau of Reclamation (USBR)
- United States Fish and Wildlife Service (USFWS) (includes participation in KRRC Technical Workgroup Inter-agency Meetings)
- United States Geological Survey

Areas of Controversy

CEQA Guidelines Section 15123 requires disclosure of the controversial project issues known to the Lead Agency, including those raised by agencies and the public. Table ES-2 highlights controversies raised by agencies and the public during the scoping period and other forums. Additional information concerning these areas of controversy and others can be found in the Scoping Report (Appendix A of this EIR). Opinions and issues raised by agencies and members of the public do not necessarily represent the position of the State Water Board.

Table ES-2. Areas of Controversy and Issues Raised by Agencies and the Public.

Topic	Issue Raised and Area of Controversy	EIR Section(s), If Applicable
Geographic Scope of EIR	The geographic scope of the EIR's area of analysis.	Sections 1.1 through 1.4, as well as individual areas of analysis in each Section 3 resource area
Range of Alternatives of EIR	Concern that alternatives besides the Proposed Project be addressed, including a dams-in alternative	Section 4
Fisheries and Aquatic Resources	The potential for the Proposed Project to improve fisheries in the Klamath Basin, and the range of historic fisheries.	Section 3.3.2.1
	Concern that sediment release during dam removal will have significant and deleterious effects on the aquatic environment from Iron Gate Dam to the Pacific Ocean during the period of dam removal.	Sections 3.3.5.1 and Appendix E
	Loss of sucker habitat in reservoirs	Sections 3.3.2.1 and Potential Impact 3.3-13
Water Quality	The short- and long-term water quality impacts associated with the Proposed Project. Water quality related concerns include the amount, toxicity, and fate and transport of sediment behind the dams; duration of short-term impacts; and the consequences of conversion of the system from reservoirs to riverine.	Section 3.2
Water for Agriculture, Fire Suppression, and Environmental Uses	Concern that removal of the Project dams will adversely impact irrigation in the Scott and Shasta river basins.	Section 3.8.2.2
	Reservoirs serve as a water source for fighting regional wildland fires. Potential for reduced water sources for fire suppression efforts with loss of the reservoirs.	Section 3.17.5, Potential Impact 3.17-3 Sections 3.21.5, Potential Impact 3.21-8
	Concern regarding loss of water provided from the reservoirs for additional summer instream flows.	Section 3.3.5.5
	Concern regarding loss of agricultural irrigation supply to farmers in the upper basin areas of California and Oregon.	Section 3.8.2.1 and Section 3.8.5, Potential Impact 3.8-2
	Concern regarding changes in groundwater table and associated water supply with loss of the reservoirs.	Section 3.7.5
Flood Hydrology	Concern regarding changes to flow regulation and flood control.	Section 3.6.2.3 and Section 3.6.5, Potential Impact 3.6-1, 3.6-3, and 3.6-4
Loss of Renewable Power Supply	Concern that loss of the Project will result in the loss of renewable power.	Section 3.10.2, Potential Impacts 3.10-1 and 3.10-2

Topic	Issue Raised and Area of Controversy	EIR Section(s), If Applicable
Regional Economic Impacts	Concern regarding lost power generation and impacts to local real estate.	Section 5.4
	Concern regarding ongoing impacts to commercial fisheries due to negative effects of dams on habitat quantity and quality	Section 5.4
Upper Klamath Basin	Analysis needs to include consideration of the Oregon dams and the Upper Klamath Basin Irrigation Project.	Throughout, particularly Sections 3.2, 3.3, 3.8, and 3.24
Loss of Reservoir Environment	Dam removal would result in a loss of reservoirs, affecting individuals that live on or near the reservoirs and who value the reservoirs' aesthetic and recreational values.	Section 3.19.2 and Section 3.19.5, Potential Impacts 3.19-1, 3.19-4, 3.19-5 Section 3.20.2.3 and Section 3.20.5, Potential Impact 3.20-2
Environmental Law Compliance	Concern that dam removal is premature and/or a pre-determined outcome.	Sections 1.1 through 1.5 and all impact analyses considered in Sections 3 and 4
Changes in Recreational Uses, including Types and Amounts of Whitewater Boating	Peaking flows from operation of the hydroelectric project currently allow for commercial whitewater boating in mid- to late-summer. Concern regarding loss of whitewater boating flows.	Section 3.20.2.2 and Section 3.20.5, Potential Impact 3.20-5
Siskiyou County Advisory Election Vote November 2, 2010 (Measure G).	The Siskiyou County ballot asked, "Should the Klamath River Dams (Iron Gate, Copco 1, and Copco 2) and associated hydroelectric facilities be removed – Yes or No?" 78.84 percent of voters expressing an opinion voted No to dam removal, while 21.86 percent voted Yes.	While this is not an environmental impact the State Water Board acknowledges vote in Section 2.6.1
Traffic and Road Conditions	Concern that there may be construction-related impacts to local traffic and road conditions, and effects on emergency response times.	Section 3.22

Please refer to the Scoping Report (Appendix A of this EIR) for further information on issues identified by agencies and the public during the public scoping process. The Scoping Report can also be found online at: http://www.swrcb.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/scoping_report.pdf. Scoping Report appendices are available separately on the Lower Klamath Project webpage. The State Water Board's Proposed Project webpage has other pertinent descriptions and links to documents and is available online at: http://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/lower_klamath_ferc14803.shtml.

Issues to be Resolved

CEQA Guidelines Section 15123 requires disclosure of issues to be resolved.

It is clear that the Klamath River has significantly degraded water quality and aquatic resources, and that these ongoing impacts stem from multiple factors including operation of the hydroelectric facilities. It is also clear that removal of the Lower Klamath Project dams and associated facilities under the Proposed Project is a large undertaking that would itself involve negative as well as positive environmental consequences, particularly in the short term. The degree of environmental impacts and benefits for the proposed restoration project are issues to be resolved, as is the potential for mitigation of impacts both within and outside of the State Water Board's purview.

Based solely on a comparison to the existing condition (summarized in Table ES-1), the alternative with the least number of unmitigable adverse environmental impacts would be the Continued Operations with Fish Passage Alternative. However, the Proposed Project is a restoration project aimed at improving the aquatic ecosystem in the Klamath River over the long term. Therefore, in identifying the environmentally superior alternative in this context, it makes sense to evaluate the degree of benefit that the alternatives provide above the current degraded condition, as well as the duration and severity of negative impacts. Based on the potential impacts and effects identified in this EIR (summarized in Table ES-1), the Proposed Project would result in significantly more identified benefits for environmental resources than the Continued Operations with Fish Passage Alternative, including all of the benefits listed above under *Effects Found to be Beneficial*. Further, the majority of the unmitigable adverse impacts identified under the Proposed Project would occur in the short term, during reservoir drawdown and construction activities associated with hydroelectric facilities removal. In looking at the range of benefits and impacts the State Water Board has identified the Proposed Project as the environmentally superior alternative.

The KRRC proposes to further develop Proposed Project actions relating to certain state and local regulatory requirements for several resource areas that fall outside of State Water Board's water quality certification authority. The State Water Board anticipates implementation of additional measures (e.g., good neighbor agreements between the KRRC and relevant state or local agencies, recommended measures in this EIR, and any modifications developed through the FERC process that provide the same or better level of protection for the resource in question) would reduce impacts. The EIR notes where such protection would eliminate the potential for a significant impact. However, the State Water Board cannot ensure implementation of good neighbor agreements, recommended measures included in this EIR, or modifications anticipated to be developed through the FERC process. Therefore, the State Water Board has identified impacts that rely on implementation of such agreements or recommended measures in this EIR as significant and unavoidable.

Table ES-1. Summary of Impacts and Mitigation Measures.

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Water Quality								
Potential Impact 3.2-1. Short-term and long-term alterations in water temperatures due to conversion of the reservoir areas to a free-flowing river.								
Hydroelectric Reach to the confluence with the Salmon River	S	L	PP, PR, 2R, 3R, NH					
Middle Klamath River downstream from the Salmon River, Lower Klamath River, Klamath River Estuary, Pacific Ocean nearshore environment	S	L		PP, PR, 2R, 3R, NH				
Potential Impact 3.2-2. Short-term and long-term alterations in seasonal water temperatures in the Klamath River Estuary due to morphological changes induced by dam removal sediment release and subsequent deposition in the estuary.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.2-3. Increases in suspended sediments due to release of sediments currently trapped behind the dams.								
	S			NP, CO			PP, PR, 2R, 3R, NH	
		L		PP, PR, CO, 2R, 3R, NH				
Potential Impact 3.2-4. Increases in suspended material from stormwater runoff due to pre-construction, dam deconstruction and removal, and restoration activities in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam.								
	S				WQ-1, TER-1, HZ-1	PP, PR, 2R, 3R, NH		
Potential Impact 3.2-5. Long-term alterations in mineral (inorganic) suspended material from the lack of continued interception and retention by the dams.								
		L		PP, PR, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.2-6. Long-term alterations in algal-derived (organic) suspended material from the lack of continued interception and retention by the dams.								
		L		PP, PR, 2R, 3R, NH				
Potential Impact 3.2-7. Short-term increases in sediment-associated nutrients due to release of sediments currently trapped behind the dams.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.2-8. Long-term alterations in nutrients from the lack of interception and retention by the dams and conversion of the reservoir areas to a free-flowing river.								
Annual interception and retention of total nutrients		L		PP, PR, 2R, 3R, NH				
Potential seasonal release of dissolved nutrients		L	PP, PR, 2R, 3R, NH					
Potential Impact 3.2-9. Short-term increases in oxygen demand and reductions in dissolved oxygen due to release of sediments currently trapped behind the dams.								
Hydroelectric Reach and Middle Klamath River from Iron Gate Dam to the Salmon River	S			NP, CO			PP, PR, 2R, 3R, NH	
Middle Klamath River downstream from the Salmon River, Lower Klamath River, Klamath River Estuary	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.2-10. Long-term alterations in dissolved oxygen concentrations and daily variability due to conversion of the reservoir areas to a free-flowing river.								
Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam (daily fluctuations)		L		PP, PR, 2R, 3R, NH				
Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam (elimination of summer and fall extremes)		L	PP, PR, 2R, 3R, NH					
Hydroelectric Reach and Middle Klamath River (winter and spring)		L		PP, PR, 2R, 3R, NH				
Lower Klamath River, Klamath River Estuary, and Pacific Ocean nearshore environment		L		PP, PR, 2R, 3R, NH				

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.2-11. Alterations in pH and daily pH fluctuations due to a conversion of the reservoir areas to a free-flowing river.								
Hydroelectric Reach at Oregon-California state line	S	L		PP, PR, 2R, 3R, NH				
Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam	S	L	PP, PR, 2R, 3R, NH					
Middle Klamath River, Klamath River Estuary, Pacific Ocean nearshore environment	S	L		PP, PR, 2R, 3R, NH				
Potential Impact 3.2-12. Alterations in chlorophyll-a and algal toxins due to a conversion of the reservoir areas to a free-flowing river.								
	S	L	PP, PR, 2R, 3R, NH					
Potential Impact 3.2-13. Human exposure to inorganic and organic contaminants due to release and exposure of reservoir sediment deposits.								
	S	L			WQ-2, WQ-3	PP, PR, 2R, 3R, NH		
Potential Impact 3.2-14. Freshwater aquatic species exposure to inorganic and organic contaminants due to release of sediments currently trapped behind the dams.								
	S	L		PP, PR, 2R, 3R, NH				
Potential Impact 3.2-15. Short-term increases in inorganic and organic contaminants from hazardous materials associated with construction and restoration activities in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam.								
	S				WQ-1, TER-1, HZ-1	PP, PR, 2R, 3R, NH		
Potential Impact 3.2-16. Short-term impacts to aquatic biota from herbicide application during restoration of the reservoir areas.								
	S				WQ-4	PP, PR, 2R, 3R, NH		

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.2-17. Short-term and long-term influence of changes in Iron Gate and Fall Creek hatchery production on Klamath River and Fall Creek water quality.								
Water quality in the Middle Klamath River downstream of Iron Gate Hatchery	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Water temperature and dissolved oxygen in Fall Creek downstream of Fall Creek Hatchery	S			NP, CO, NH			PP, PR, 2R, 3R	
Water quality (except water temperature and dissolved oxygen) in Fall Creek downstream of Fall Creek Hatchery		L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.2-18. Short-term impacts on water quality from construction activities on Parcel B lands.								
	S	L			WQ-1, TER-1, HZ-1	PP, PR		
Potential Impact 4.2.2-1 Seasonal alterations in water temperature due to continued impoundment of water in the reservoirs.								
J.C. Boyle Peaking Reach from the Oregon-California state line to Copco No. 1 Reservoir	S	L	CO	NP (S only)				
Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam and the Middle Klamath River to the confluence with the Salmon River	S	L		NP (S only), CO				
Middle Klamath River downstream of the confluence with the Salmon River, the Lower Klamath River, and the Klamath River Estuary, and the Pacific Ocean nearshore environment	S	L		NP (S only), CO				
Potential Impact 4.2.2-2. Seasonal increases in algal-derived (organic) suspended material due to continued impoundment of water in the reservoirs.								
Hydroelectric Reach from J.C. Boyle Reservoir to the upstream end of Copco No. 1 Reservoir	S	L		NP (S only), CO				
Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam, the Middle and Lower Klamath River, and the Klamath River Estuary	S	L		NP (S only), CO				

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**									
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 4.2.2-3 Increases in suspended material due to implementation of 2017 court-ordered flushing and emergency dilution flows downstream of Iron Gate Dam.									
	S	L		NP (S only), CO				
Potential Impact 4.4.2-1. Short-term increases in suspended material and contaminants from stormwater runoff due to construction activities associated with replacement and construction of new fish passage facilities.									
Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam	S			CO	WQ-1, TER-1, HZ-1			
Potential Impact 4.2.2-4. Annual interception and retention of nutrients and seasonal release of nutrients due to continued impoundment of water in the reservoirs.									
Hydroelectric Reach and Middle Klamath River (annual interception and retention of nutrients)	S	L		NP (S only), CO				
Hydroelectric Reach and the Middle Klamath River (seasonal release of nutrients)	S	L		NP (S only), CO				
Potential Impact 4.2.2-5. Seasonal low dissolved oxygen concentrations due to continued impoundment of water in the reservoirs.									
Hydroelectric Reach and the Middle Klamath River	S	L		NP (S only), CO				
Middle Klamath River downstream of Seiad Valley, the Lower Klamath River, and the Klamath River Estuary	S	L		NP (S only), CO				
Potential Impact 4.2.2-6. Seasonal high pH and daily pH fluctuations due to continued impoundment of water in the reservoirs.									
Hydroelectric Reach and the Middle Klamath River	S	L		NP (S only), CO				
Middle Klamath River downstream of Seiad Valley the Lower Klamath River, and the Klamath River Estuary	S	L		NP (S only), CO				
Potential Impact 4.2.2-7. Seasonal increases in chlorophyll-*a* and algal toxins due to continued impoundment of water in the reservoirs.									
Hydroelectric Reach from J.C. Boyle Reservoir to upstream end of Copco No. 1 Reservoir	S	L		NP (S only), CO				
Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam, the Middle and Lower Klamath River, and the Klamath River Estuary	S	L		NP (S only), CO				

Potential Impacts
PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impact 4.2.2-8. Human and freshwater aquatic species' exposure to inorganic and organic contaminants due to continued impoundment of water in the reservoirs.								
	S	L		NP (S only), CO				
Aquatic Resources								
Potential Impact 3.3-1. Effects on coho salmon critical habitat quality and quantity due to short-term sediment releases and long-term changes in habitat quality and quantity due to dam removal.								
	S				AQR-1 and AQR-2	PP, PR, 2R, 3R, NH		
		L	PP, PR, 2R, 3R, NH					
Potential Impact 3.3-2. Effects on southern resident killer whale critical habitat quality due to short-term and long-term alterations to salmon populations due to dam removal.								
	S	L		PP, PR, 2R, 3R, NH				
Potential Impact 3.3-3. Effects on eulachon critical habitat quality due to short-term sediment releases due to dam removal.								
	S	L		PP, PR, 2R, 3R, NH				
Potential Impact 3.3-4. Effects on Chinook and coho salmon Essential Fish Habitat (EFH) quality and quantity due to short-term sediment releases and long-term changes in habitat quality and quantity due to dam removal.								
	S				AQR-1 and AQR-2	PP, PR, 2R, 3R, NH		
		L	PP, PR, 2R, 3R, NH					
Potential Impact 3.3-5. Effects on groundfish Essential Fish Habitat (EFH) quality due to short-term sediment releases and long-term changes in habitat quality due to dam removal.								
	S	L		PP, PR, 2R, 3R, NH				
Potential Impact 3.3-6. Effects on pelagic fish Essential Fish Habitat (EFH) quality due to short-term sediment releases and long-term changes in habitat quality due to dam removal.								
	S	L		PP, PR, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative

	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.5-10. Short-term impacts on special-status amphibian, reptiles, and mammals from construction activities. *								
Amphibians and reptiles	S			NP	TER-2 and TER-3	PP, PR, CO, 2R, 3R, NH		
Mammals	S			NP			PP, PR, CO, 2R, 3R, NH	

Potential Impacts
PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impact 3.5-11. Short-term impacts on nesting birds from construction-related noise and habitat alterations. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.5-12. Effects on willow flycatcher from short-term construction-related noise and short-term and long-term habitat alterations. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Riparian habitat in the former location of Copco No. 1 and Iron Gate reservoirs		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 3.5-13. Short-term impacts on bald and golden eagles from construction-related noise and habitat alterations. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.5-14. Short-term and long-term impacts on bats from construction noise and loss of roosting habitat. *								
	S	L		NP (S only)			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.5-15. Short-term and long-term impacts on northern spotted owl and critical habitat from construction-related noise and habitat alterations.								
	S	L		PP, NP (S only) PR, CO, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.5-16. Effects on special-status amphibians and reptiles in riverine habitats from short-term high suspended sediment concentrations and flows and long-term changes in water quality.								
Pacific tailed frog, southern torrent salamander, northern red-legged frog, and western pond turtle	S			PP, NP, PR, CO, 2R, 3R, NH				
Foothill yellow-legged frog egg masses, if present	S			CO, NP			PP, PR, 2R, 3R, NH	
All special-status amphibians and reptiles		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 3.5-17. Effects on benthic macroinvertebrates from short-term dewatering and sedimentation and long-term alterations to habitat.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 3.5-18. Short-term impacts on amphibian and reptile in riverine habitats from sedimentation.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.5-19. Impacts on native amphibians from loss of reservoir habitat.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.5-20. Short-term and long-term impacts on western pond turtle and amphibians from reduced BMI populations.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative									
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.5-21. Short-term and long-term impacts on birds and bats from loss of aquatic reservoir and shoreline vegetative habitat.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.5-22. Short-term and long-term impacts on western pond turtle from loss of aquatic habitat.								
	S	L		NP (S only), CO	TER-4	PP, PR, 2R, 3R, NH		
Potential Impact 3.5-23. Long-term effects on deer from alterations to winter range habitat.								
		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 3.5-24. Effects on terrestrial species from herbicide use during reservoir restoration activities.								
Special-status plants and wildlife	S			PP, NP, PR, CO, 2R, 3R, NH				
Rare natural communities, wetlands, and riparian vegetation		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 3.5-25. Effects on wildlife from increased habitat for salmonids and changes in hatchery production.								
	S	L	PP, PR, 2R, 3R, NH	NP (S only), NH, CO				

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.5-26. Impacts on special-status wildlife from Bogus Creek flow diversions.								
	S			NP, NH, CO	AQR-3	PP, PR, 2R, 3R		
Potential Impact 3.5-27. Impacts on special-status wildlife from Fall Creek flow diversions.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.5-28. Impacts on sensitive habitats and special-status terrestrial wildlife and plant species from construction activities on Parcel B lands. *								
		L			WQ-1, TER-1, and TER-4			PP, PR, 2R, 3R, NH, CO
Potential Impact 3.5-29. Long-term effects on wildlife from alteration of wildlife movement corridors.								
Increased wildlife movement opportunities		L	PP, PR, 2R, 3R, NH	CO				
Wildlife-friendly fencing		L		PP, PR, 2R, 3R, NH				
Potential Impact 3.5-30. Long-term effect on terrestrial wildlife from an increase in the distribution of salmon-derived nutrients upstream of Iron Gate, Copco No. 1 and Copco No. 2 dams.								
		L	PP, PR, NH, CO	2R, 3R				
Potential Impact 4.2.5-1. Effects of 2017 court-ordered flushing and emergency dilution flows released from Iron Gate Dam on foothill yellow-legged frog and western pond turtle breeding.								
Hydroelectric Reach (foothill yellow-legged frogs)	S						NP, CO	
Hydroelectric Reach (western pond turtles)	S			NP, CO				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Flood Hydrology								
Potential Impact 3.6-1 Reservoir drawdown and dam removal could result in short-term increases in downstream surface water flows and result in exposing people and/or structures to a substantial risk of damage, loss, injury, or death involving flooding.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.6-2 Under the Proposed Project recreational facilities currently located on the banks of the existing reservoirs would be removed following drawdown and could change flood hydrology.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.6-3. The long-term FEMA100-year floodplain inundation extent downstream from Iron Gate Dam could change between river miles 193 and 174, potentially exposing people and/or structures to a substantial risk of damage, loss, injury, or death involving flooding.								
Exposing structures to a substantial risk of damage due to flooding		L					PP, PR, 2R, 3R, NH	
Exposing people and/or structures to a substantial risk of flooding related to flood forecasting		L		PP, PR, 2R, 3R, NH				
Potential Impact 3.6-4. The FEMA 100-year floodplain inundation extent downstream from J.C. Boyle Dam could change between the California-Oregon state line and Copco No. 1 Reservoir, potentially exposing people and/or structures to a substantial risk of damage, loss, injury, or death involving flooding.								
		L		PP, PR, 2R, 3R, NH				

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Potential Impact 3.6-5. The release of sediment stored behind the Lower Klamath Project dams and resulting downstream sediment deposition under the Proposed Project could result in potentially exposing people and/or structures to a substantial risk of damage, loss, injury, or death involving flooding.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.6-6. Dam failure could flood areas downstream of the Lower Klamath Project.								
	S			PP, NP, PR, 2R, 3R, NH, CO				
		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 4.2.6-1. The FEMA 100-year floodplain inundation extent downstream from Iron Gate Dam could change due to 2017 flow requirements, potentially exposing people and/or structures to a substantial risk of damage, loss, injury, or death involving flooding.								
	S	L		NP (S only), CO				
Potential Impact 4.2.6-2. The FEMA 100-year floodplain inundation extent downstream from J.C. Boyle Dam could change due to 2017 flow requirements between the California-Oregon state line and Copco No. 1 Reservoir, potentially exposing people and/or structures to a substantial risk of damage, loss, injury, or death involving flooding.								
	S	L		NP (S only), CO				
Groundwater Resources								
Potential Impact 3.7-1. Groundwater levels in existing wells adjacent to the reservoirs could decline in response to the decrease in reservoir surface-water elevations if the dams, and therefore reservoirs, are removed.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.7-2. The Proposed Project could interfere with groundwater recharge and adversely affect surface water conditions in the Klamath River.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Water Supply/Water Rights								
Potential Impact 3.8-1 Dam removal could change the amount of surface water flow available for diversion under existing water rights in the mainstem Klamath River within the Hydroelectric Reach and downstream from Iron Gate Dam.								
	S	L		PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.8-2. Dam removal could change the amount of surface water flow available for diversion from Upper Klamath Lake and/or Keno Reservoir to California water users in the USBR Klamath Irrigation Project.								
	S	L		PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.8-3. Release of stored sediment during reservoir drawdown could change Klamath River geomorphology and affect water intake pumps downstream from Iron Gate Dam.								
	S			NP, CO	WSWR-1	PP, PR, 2R, 3R, NH		
Potential Impact 3.8-4. Relocation of the City of Yreka water supply pipeline after drawdown of Iron Gate Reservoir could affect water supply.								
	S			NP, CO	WSWR-2	PP, PR, 2R, 3R, NH		
Potential Impact 3.8-5. Removal and potential replacement of recreational facilities currently located on the banks of the existing reservoirs could affect water supply and/or water rights.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 4.2.8-1. Water availability changes from coordinated operations under 2017 flow requirements.								
	S	L		NP (S only), CO				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Air Quality								
Potential Impact 3.9-1. Conflict with or obstruct implementation of the California Regional Haze Plan.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.9-2. Exceedance of the Siskiyou County Air Pollution Control District emissions thresholds in Rule 6.1 (Construction Permit Standards for Criteria Air Pollutants).								
	S			NP, CO			PP, PR, 2R, 3R, NH	
Potential Impact 3.9-3. Short-term cumulative increase in criteria pollutants for which the Siskiyou County Air Pollution Control District is non-attainment.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.9-4. Short-term exposure of sensitive receptors to substantial toxic air contaminant concentrations.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.9-5. Short-term exposure to objectionable odors near construction sites.								
	S			PP, NP, PR, CO, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Greenhouse Gas Emissions								
Potential Impact 3.10-1. Generation of greenhouse gas emissions, either directly or indirectly, that would exceed 10,000 MT CO2e.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.10-2. Conflict with an applicable plan, policy, or regulation adopted for the purpose of reducing GHG emissions.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Geology, Soils, and Mineral Resources								
Potential Impact 3.11-1. Reservoir drawdown could result in changes to geologic hazards, such as seismic or volcanic activity.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.11-2. Soil disturbance associated with heavy vehicle use, excavation, and grading.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.11-3. Reservoir drawdown could result in hillslope instability in reservoir rim areas.								
J.C. Boyle Reservoir	S			PP, NP, PR, CO, NH				
Copco No. 1 Reservoir	S			NP, CO	GEO-1	PP, PR, 2R, 3R, NH		
Iron Gate Reservoir	S			PP, NP, PR, CO, 2R, 3R, NH				

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage;** **2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.11-4. Reservoir drawdown could result in short-term instability of embankments at the earthen dams (Iron Gate and J.C. Boyle).								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.11-5. Reservoir drawdown could result in substantial short-term sediment deposition in the Klamath River downstream of Iron Gate Dam due to erosion of reservoir sediment deposits and a long-term change in sediment supply and transport due to dam removal.								
Middle Klamath River to confluence with Cottonwood Creek	S			NP, CO			PP, PR, 2R, 3R, NH	
Middle Klamath River downstream of Cottonwood Creek, Lower Klamath River, Klamath River Estuary, Pacific Ocean nearshore environment	S			PP, NP, PR, CO, 2R, 3R, NH				
Hydroelectric Reach, Middle and Lower Klamath River, Klamath River Estuary		L	PP, PR, 2R, 3R, NH	CO				
Pacific Ocean nearshore environment		L		PP, PR, CO, 2R, 3R, NH				
Potential Impact 3.11-6. Reservoir drawdown could result in increased bank erosion in the Klamath River downstream of Iron Gate Dam.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.11-7. Reservoir drawdown could reduce or eliminate the availability of a known mineral resource or a locally-important mineral resource recovery site.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Historical Resources and Tribal Cultural Resources								
Potential Impact 3.12-1. Pre-dam-removal activities that involve disturbance of the landscape, including construction or improvement of associated roads, bridges, water supply lines, staging areas, disposal sites, hatchery modifications, recreation site removal and/or development, and culvert construction and improvements could result in potential exposure of or damage to known Tribal Cultural Resources through ground-disturbing construction and disposal activity and increased access to sensitive areas								
	S	L		NP (S only)	TCR-1, TCR-2, TCR-3, TCR-4			PP, PR, CO, 2R, 3R, NH
Potential Impact 3.12-2. Drawdown of Iron Gate, Copco No. 1, and Copco No. 2 reservoirs could result in shifting, erosion, and exposure of known or unknown, previously submerged Tribal Cultural Resources								
	S	L		NP (S only), CO	TCR-1, TCR-2, TCR-3, TCR-4			PP, PR, 2R, 3R, NH
Potential Impact 3.12-3. Reservoir drawdown could result in erosion or flood disturbance to Tribal Cultural Resources located along the Klamath River								
Hydroelectric Reach between J.C. Boyle Dam and Copco No. 1 Reservoir	S	L		PP, NP, PR, CO, 2R, 3R, NH				
Middle Klamath River from Iron Gate Dam to Humbug Creek	S	L		NP, CO	TCR-1, TCR-2, TCR-3			PP, PR, 2R, 3R, NH
Middle Klamath River downstream of Humbug Creek and Lower Klamath River excluding the Yurok Reservation (approximately RM 0 to RM 45)	S	L		PP, NP, PR, CO, 2R, 3R, NH				
Yurok Reservation (approximately RM 0 to RM 45) along Lower Klamath River and Klamath River Estuary	S	L		NP, CO	TCR-5	PP, PR, 2R, 3R, NH		

Potential Impacts
PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impact 3.12-4. Project activities associated with removal of Iron Gate, Copco No. 1, and Copco No. 2 dams could result in physical disturbance to known or unknown Tribal Cultural Resources from blasting or other removal techniques								
	S	L		NP (S only)	TCR-1, TCR-2, TCR-3, TCR-4			PP, PR, CO, 2R, 3R, NH
Potential Impact 3.12-5. Ground disturbance associated with reservoir restoration, recreation site removal and/or development, and disposal site restoration could physically disturb known Tribal Cultural Resources. Additionally, ongoing road and recreation site maintenance has the potential to disturb known Tribal Cultural Resources								
	S	L		NP (S only)	TCR-1, TCR-2, TCR-3, TCR-4			PP, PR, CO, 2R, 3R, NH
Potential Impact 3.12-6. During and following reservoir drawdown activities at Iron Gate, Copco No. 1, and Copco No. 2 reservoirs there is an increased potential for looting of Tribal Cultural Resources (short term and long term).								
Iron Gate Reservoir and Copco No. 1 Reservoir	S	L		NP, CO	TCR-2, TCR-4			PP, PR, 2R, 3R, NH
Copco No. 2 Reach	S	L		NP, CO	TCR-2, TCR-4			PP, PR, 3R, NH
Potential Impact 3.12-7. Short-term erosion caused by high-intensity and/or duration precipitation events could cause exposure of or disturbance to known or unknown Tribal Cultural Resources within the reservoir footprints immediately following reservoir drawdown and prior to vegetation establishment/full stabilization of sediment deposits								
	S			NP, CO	TCR-1, TCR-2, and TCR-3		PP, PR, 2R, 3R, NH	
Potential Impact 3.12-8. Long-term (post-removal) impacts to Tribal Cultural Resources as a result of dam removal from increased looting opportunities and from surface and subsurface erosion of Tribal Cultural Resources								
Prior to land transfer		L		CO			PP, PR, 2R, 3R, NH	
After land transfer		L			TCR-1, TCR-2, TCR-3, TCR-6, TCR-7, and TCR-8	PP, PR, 2R, 3R, NH		

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Potential Impact 3.12-9. Klamath Cultural Riverscape Contributing Aspect – Combined effects on the Klamath River fishery of dam removal, changes in hatchery production, and increased habitat for salmonids								
	S			PP, NP, PR, CO, 2R, 3R, NH				
		L	PP, PR, 2R, 3R, NH	CO				
Potential Impact 3.12-10. Klamath Cultural Riverscape Contributing Aspect: Ability of tribes to use the Middle and Lower Klamath River for ceremonial and other purposes due to alterations in riverine water quality and changes in the extent of nuisance and/or noxious blue-green algae blooms.								
	S	L	PP, PR, 2R, 3R, NH	NP (S only), CO				
Potential Impact 3.12-11. Potential impacts to Copco No. 1 Dam, Copco No. 2 Dam, and Iron Gate Dam, their associated hydroelectric facilities, and the Klamath River Hydroelectric Project District as a whole.								
J.C. Boyle Reservoir and associated hydroelectric facilities	S	L		NP (S only), CO			PP, PR, NH	
Copco No. 1 Dam and associated hydroelectric facilities	S	L		NP (S only), CO			PP, PR, 2R, 3R, NH	
Copco No. 2 Dam and associated hydroelectric facilities	S	L		NP (S only), CO			PP, PR, 3R, NH	
Iron Gate Dam and associated hydroelectric facilities	S	L		NP (S only), CO			PP, PR, 2R, 3R, NH	
Klamath River Hydroelectric Project District	S	L		NP (S only), CO			PP, PR, 2R, 3R, NH	

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.12-12 Potential impacts to submerged historic-period archaeological sites upon reservoir drawdown and exposure providing new access opportunities for artifact collecting and unauthorized excavation								
	S	L		NP (S only), CO	TCR-2 and TCR-3			PP, PR, 2R, 3R, NH
Potential Impact 3.12-13. Drawdown of Iron Gate, Copco No. 1, and Copco No. 2 reservoirs could shift, erode, or expose historic-period archaeological resources resulting in increased potential for damage and looting								
	S	L		NP (S only), CO	TCR-2 and TCR-3			PP, PR, 2R, 3R, NH
Potential Impact 3.12-14. Reservoir drawdown could result in short-term erosion or flood disturbance to historic-period cultural resources located along the Klamath River								
Middle Klamath River from Iron Gate Dam to Humbug Creek	S			NP, CO	TCR-3			PP, PR, 2R, 3R, NH
Hydroelectric Reach excluding Iron Gate Dam, Middle Klamath River downstream of Humbug Creek, Lower Klamath River, Klamath River Estuary	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.12-15. Project activities associated with removal of Iron Gate, Copco No. 1, and Copco No. 2 dams could result in physical disturbance to historic-period cultural resources from blasting or other removal techniques								
	S			NP	TCR-3			PP, PR, CO, 2R, 3R, NH
Potential Impact 3.12-16. Ground disturbance associated with reservoir restoration, recreation site removal and/or development, and disposal site restoration could physically disturb historic-period cultural resources. Additionally, ongoing road and recreation site maintenance may have the potential to disturb known historic-period cultural resources								
	S			NP	TCR-2 and TCR-3			PP, PR, CO, 2R, 3R, NH

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Paleontologic Resources								
Potential Impact 3.13-1. The Proposed Project could result in substantial adverse effects on, or destruction of, High Potential Paleontologic Resources through exposure or slope failure.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Land Use and Planning								
Potential Impact 3.14-1. Removal of the reservoirs, construction-related traffic, and/or land transfer could change connectivity between areas of a community.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.14-2. The Proposed Project would not conflict with an applicable land use plan, policy, or regulation adopted for the purpose of avoiding or mitigating an environmental effect in a manner that would prevent the avoidance or mitigation result sought to be achieved by the plan, policy, or regulation.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Agriculture and Forestry Resources								
Potential Impact 3.15-1. Conversion of farmland to non-agricultural use or conflict with Williamson Act land or agricultural zoning.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.15-2. Conversion of forest lands to non-forest use or conflict with forest zoning.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Potential Impact 3.15-3. Indirect conversion of farmland to non-agricultural use or forest land to non-forest use.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.15-4. Other changes in the existing environment that could result in conversion of farmland to non-agricultural use or conversion of forest land to non-forest use.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Population and Housing								
Potential Impact 3.16-1. Inducing substantial unplanned population growth in an area, either directly or indirectly.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Potential Impact 3.16-2. Displacement of substantial numbers of existing people or housing, necessitating the construction of replacement housing elsewhere.								
	S	L		PP, NP (S only), PR, CO, 2R, 3R, NH				
Public Services								
Potential Impact 3.17-1. Increased public service response times for emergency fire, police, and medical services due to construction and demolition activities. *								
	S			NP	HZ-1			PP, PR, CO, 2R, 3R, NH

Potential Impacts
PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative

Geographic or Other Additional Information (as needed)	Time Frame[1]		Beneficial	No Significant Impact[2]	Mitigation	No Significant Impact with Mitigation	Significant and Unavoidable	Significant and Unavoidable with Mitigation
Potential Impact 3.17-2. The Proposed Project's elimination of a long-term water source for wildfire services could substantially increase the response time for suppressing wildfires. *								
	S			PP, NP, PR, CO, 2R, 3R, NH				
		L		CO				PP, PR, 2R, 3R, NH
Potential Impact 3.17-3. Potential effects on school services and facilities.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Utilities and Service Systems								
Potential Impact 3.18-1. The Proposed Project could result in the construction of new wastewater treatment facilities or expansion of existing facilities, due to inadequate capacity to serve the Proposed Project's anticipated demand or where the construction of such facilities could cause significant environmental impacts.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.18-2. The Proposed Project could require or result in the construction of new stormwater drainage facilities or expansion of existing facilities, the construction of which could cause significant environmental impacts.								
	S			PP, PR, CO, 2R, 3R, NH				
Potential Impact 3.18-3. The Proposed Project could exceed permitted landfill capacity to accommodate the project's solid waste disposal needs.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.18-4. The Proposed Project could violate applicable statutes and regulations related to solid waste.								
	S			PP, NP, PR, CO, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative

Hazards and Hazardous Materials								
Potential Impact 3.21-1. Proposed construction-related activities could result in substantial exposure to hazardous materials through the routine transport, use, or disposal of hazardous materials.								
	S			NP	HZ-1	PP, PR, CO, 2R, 3R, NH		
Potential Impact 3.21-2. Proposed construction-related activities could result in substantial exposure to hazardous materials through reasonably foreseeable upset and accident conditions involving the release of hazardous materials into the environment.								
	S			NP	HZ-1	PP, PR, CO, 2R, 3R, NH		
Potential Impact 3.21-3. Proposed construction-related activities could result in substantial exposure to hazardous materials through emissions or handling of substances or waste within one-quarter mile of an existing or proposed school.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.21-4. The Proposed Project could be located on a site which is included on a list of hazardous materials sites compiled pursuant to Government Code Section 65962.5 and, as a result, could result in substantial exposure to hazardous materials.								
	S			NP	HZ-1	PP, PR, CO, 2R, 3R, NH		
Potential Impact 3.21-5. The Proposed Project could result in, for a project located within an airport land use plan or, where such a plan has not been adopted, within two miles of a public airport or public use airport, a substantial safety hazard for people residing or working in the project area due to a risk of traffic accidents.								
	S			PP, NP, PR, CO, 2R, 3R, NH				

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.21-6. The Proposed Project could result in, for a project within the vicinity of a private airstrip, a substantial safety hazard for people residing or working in the project area due to a risk of traffic accidents.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.21-7. Proposed construction-related activities could impair implementation of, or physically interfere with, an adopted emergency response plan or emergency evacuation plan. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.21-8. Proposed construction-related activities and/or removal of the Lower Klamath Project reservoirs could substantially increase the public's risk of loss, injury or death associated with wildland fires.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
		L		CO			PP, PR, 2R, 3R, NH	
Transportation and Traffic								
Potential Impact 3.22-1. Proposed construction-related traffic could potentially result in a substantial increase in traffic in excess of the capacity or design of the road improvements or impairs the safety or performance of the circulation system, including transit, roadways, bicycle lanes and pedestrian paths. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.22-2. Proposed construction-related traffic could potentially conflict with an applicable congestion management program, including, but not limited to level of service standards and travel demand measures, or other standards established by the county congestion management agency for designated roads or highways that would result in increased risk of harm to the public. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.22-3. Proposed construction-related traffic could result in substantially increasing hazards due to a design feature (e.g., sharp curves or narrow lanes) or incompatible uses (e.g., oversized construction equipment) that would result in an increased risk of harm to the public. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.22-4. The Proposed Project could result in inadequate emergency access that would result in an increased risk of harm to the public. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.22-5. Construction-related activities could potentially conflict with adopted policies, plans, or programs regarding public transit, bicycle, or pedestrian facilities, or otherwise decrease the performance or safety of such facilities resulting in an increased risk of harm to the public. *								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.22-6. The Proposed Project could potentially result in a change in air traffic patterns, including either an increase in traffic levels or a change in location that results in substantial safety risks.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Noise								
Potential Impact 3.23-1. Use of standard construction equipment could exceed Siskiyou County General Plan criteria for maximum allowable noise levels from construction equipment.								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.23-2. Construction activities at Copco No. 1 Dam could cause short-term increases in daytime and nighttime noise levels affecting nearby residents.								
	S			NP			PP, PR, CO, 2R, 3R, NH	

Potential Impacts PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage; 2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.23-3. Construction activities at Copco No. 2 Dam could cause short-term increases in noise levels affecting nearby residents.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.23-4. Construction activities at Iron Gate Dam could cause short-term increases in nighttime noise levels affecting nearby residents.								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.23-5. Reservoir restoration activities at Copco No. 1 and Iron Gate could result in short-term increases in noise levels affecting nearby residents.								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.23-6. Blasting activities at Copco No. 1, Copco No. 2, and Iron Gate Dams could increase daytime vibration levels affecting nearby residents.								
	S			NP			PP, PR, CO, 2R, 3R, NH	
Potential Impact 3.23-7. Transporting waste to off-site landfills and construction worker commutes could cause increases in traffic noise along haul routes affecting nearby residents.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.23-8. Construction activities associated with the Downstream Flood Control project component (moving or elevating legally established structures with flood risk) could produce noise and vibration associated with construction activities.								
	S			PP, NP, PR, CO, 2R, 3R, NH				
Potential Impact 3.23-9. Construction activities associated with implementation of Mitigation Measure WSWR-1 (modify water intakes) could produce noise and vibration associated with construction activities.								
	S			PP, NP, PR, CO, 2R, 3R, NH				

Potential Impacts **PP = Proposed Project; NP = No Project Alternative; PR = Partial Removal Alternative; CO = Continued Operations with Fish Passage;** **2R = Two Dam Removal Alternative; 3R = Three Dam Removal Alternative; NH = No Hatchery Alternative**								
Geographic or Other Additional Information (as needed)	**Time Frame[1]**		**Beneficial**	**No Significant Impact[2]**	**Mitigation**	**No Significant Impact with Mitigation**	**Significant and Unavoidable**	**Significant and Unavoidable with Mitigation**
Potential Impact 3.23-10. Construction activities associated with the deepening or replacement of existing groundwater wells adjacent to the reservoirs could produce noise and vibration affecting nearby residents.								
	S			PP, NP, PR, CO, 2R, 3R, NH				

[1] S = short term potential impact; L = long term potential impact; time frames for "S" and "L" are defined by alternative and resource area.

[2] No significant impact - potential effect either would not cause any adverse alterations to existing conditions or would cause alterations but they would not result in a significant adverse effect (includes determinations of no impact, less than significant impact, no change from existing adverse conditions, no change from existing conditions).

* Indicates a *Significant and Unavoidable Impact* that would be reduced to *No Significant Impact with Mitigation* if one or more Recommended Measures were to be implemented. Due to federal preemption the State Water Board cannot guarantee the implementation of Recommended Measures.

This page left blank intentionally.

1 INTRODUCTION

1.1 Authorization, Purpose, and Use of EIR

The Klamath River Renewal Corporation (KRRC) has applied to the Federal Energy Regulatory Commission (FERC) to decommission and remove the four Lower Klamath Project dams and associated facilities to create a free-flowing Klamath River and provide for volitional fish passage in the Klamath River.

FERC is the federal agency that licenses the construction, operation, and decommissioning of most non-federal hydroelectric dams in the United States. The KRRC has applied to FERC to surrender the hydropower license for the Lower Klamath Project. Under section 401 of the federal Clean Water Act, the KRRC has applied to the State Water Resources Control Board (State Water Board) for certification of whether − and under what conditions − the proposed dam removal can comply with California's water quality standards. FERC incorporates the terms of any water quality certification into the licenses or surrender orders it issues.

The State Water Board is the Lead Agency responsible for complying with the California Environmental Quality Act (CEQA)[5] for the Lower Klamath Project License Surrender (Proposed Project). This environmental impact report (EIR) was prepared in conformance with CEQA. CEQA requires the Lead Agency to prepare an EIR when there is substantial evidence that a project could have a significant effect on the environment.

This EIR focuses on impacts related to actions proposed in the California portion of the Lower Klamath Project (FERC Project No. 14803) located along the Klamath River in Siskiyou County, California, including the Copco No. 1, Copco No. 2, and Iron Gate dam complexes. Actions at the J.C. Boyle dam complex, located in Klamath County, Oregon, and other actions of the Proposed Project in Oregon will be described in general terms, but the discussion of environmental impacts in this EIR will be limited to those with the potential to adversely impact the California environment. On September 7, 2018, Oregon's Department of Environmental Quality (ODEQ) issued a water quality certification based on a separate certification application for the Lower Klamath Project that addresses water quality impacts in Oregon from the Proposed Project, including removal of the J.C. Boyle dam complex. FERC and other federal agencies are analyzing impacts of the Proposed Project in both states.

The purpose of this EIR is to inform the public and decision makers of the significant environmental effects of the Proposed Project, to identify possible ways to minimize those effects, and to describe reasonable alternatives that would feasibly attain most, if not all of the basic objectives of the Proposed Project (Section 2.1 *Project Objectives*).

The EIR process is specifically designed to evaluate and disclose the potentially significant direct, indirect, and cumulative effects of the Proposed Project, and to describe reasonable alternatives to the Proposed Project that could avoid or reduce those effects, while feasibly attaining most, if not all, of the Proposed Project's basic objectives (Section 2.1 *Project Objectives*).

[5] Public Resources Code, sections 21000 et seq.

1.1.1 CEQA Guidance Regarding State Boundaries

Public Resources Code, section 21080, subdivision (b) (14), establishes that CEQA does not apply to "*any project or portion thereof located in another state which will be subject to environmental impact review pursuant to the National Environmental Policy Act (NEPA) of 1969* (42 U.S.C. Sec. 4321 et seq.) or similar state laws of that state. Any emissions or discharges that would have a significant effect on the environment in this state are subject to [CEQA]."

Since the Proposed Project is required to comply with NEPA, this EIR does not evaluate portions of the Proposed Project in Oregon. There are two exceptions to this approach:

1. This EIR evaluates portions of the Proposed Project in Oregon for which the impacts may cross into California and potentially affect California resources. These impacts are evaluated starting at the Oregon-California state line. For example, removal of J.C. Boyle Dam in Oregon, which is part of the Proposed Project and some alternatives, would affect hydrology and water quality in California.
2. This EIR examines potential significant Project-related impacts to California environmental resources (e.g., anadromous fish) that move into Oregon and subsequently move back into California as a result of the Proposed Project or alternatives.

1.2 Brief Introduction to the Proposed Project

The Proposed Project is a restoration project on the Klamath River to decommission and remove four hydroelectric dams and implement of a range of associated measures. The Proposed Project includes removal of the dams and associated facilities, road improvements, modifications to hatcheries, restoration activities, and measures to address some of the potential environmental and quality-of-life impacts of the restoration project. The hydroelectric dams proposed for removal are Copco No. 1 Dam ([River Mile [RM] 201.8), Copco No. 2 Dam (RM 201.5), and Iron Gate Dam (RM 193.1) in Siskiyou County, California and J.C. Boyle Dam (RM 229.8), in Klamath County, Oregon (see Figure 2.2-1). Together, these dams and their associated facilities constitute the Lower Klamath Project (FERC Project No. 14803). Please see Section 2 *Proposed Project* for more detailed information.

1.3 Scope and Content of the EIR

This EIR evaluates the environmental impacts of the Proposed Project relative to a number of environmental issue areas. This EIR provides information in accordance with CEQA Guidelines sections 15120 to 15132, as follows.

Volume I

Section 1 Introduction – This section introduces the EIR with information on: authorization, purpose, and use of the EIR; brief introduction to the Proposed Project; scope and content of the EIR; EIR process overview; and public involvement and agency consultation during preparation of the EIR.

Section 2 Project Description – This section provides a summary description of the Proposed Project, including Proposed Project objectives; location; existing features; surrounding land ownership, land use, and land cover; background information on Klamath Basin water conflicts, the relationship between the Proposed Project and other local hydroelectric facilities, Klamath Basin settlement agreements, and prior/related environmental reviews; Proposed Project components including, but not limited to, schedule, deconstruction activities, restoration activities, and operation of hatcheries; and intended uses of the EIR.

Section 3 Environmental Setting, Potential Impacts, and Mitigation Measures – This section provides a description of the environmental setting for all relevant issue areas. Significance criteria for the impact analyses are presented by issue area. As applicable, the issue areas address compliance with relevant plans. Each resource area analyzes potential impacts, along with potential mitigation measures for significant impacts. This section evaluates the impacts as either having no significant impact, no significant impact with mitigation, significant and unavoidable impact, significant and unavoidable with mitigation, or a beneficial effect. The potential incremental impacts of the Proposed Project when combined with other closely related past, present, and reasonably foreseeable future projects (i.e., cumulative impacts) are also analyzed in this section.

Section 4 Alternatives – This section provides a discussion of the selection of a range of reasonable alternatives to the Proposed Project. For each alternative carried forward for analysis in this EIR, the potential environmental impacts are analyzed by resource area, including analysis of potential mitigation measures for significant impacts.

Section 5 Other CEQA Considerations – This section provides an evaluation of irreversible and irretrievable commitment of resources and potential growth-inducing impacts and discusses consideration of social and economic factors under CEQA.

Volume II

Technical Appendices – This volume includes all technical appendices to the EIR.

1.4 EIR Process Overview

As Lead Agency, the State Water Board made the determination to prepare an EIR based on a preliminary evaluation of the potential environmental effects of the Proposed Project. The State Water Board issued a Notice of Preparation on December 22, 2016 (please see Section 1.5.1 *Scoping Meetings* for a description of scoping and other meetings to solicit public and agency input).

Stillwater Sciences[6], the State Water Board's CEQA contractor, then prepared working draft documents at the direction of State Water Board staff. State Water Board staff reviewed these working drafts, and comments and revisions were incorporated to constitute the Draft EIR.

This Draft EIR is being circulated for agency and public review. The comment period concludes at 12:00 p.m. on February 26, 2019. During the comment period, the State Water Board will also hold four public meetings on the Draft EIR, as described in the Notice of Availability of a Draft EIR. The State Water Board will review all comments received on the Draft EIR and will prepare written responses to comments raising significant environmental issues, consistent with the requirements of CEQA Guidelines section 15088. The Final EIR will include responses to comments and any changes to the Draft EIR. Written responses will be sent to those public agencies that provided timely comments on the EIR at least 10 days prior to certification of the Final EIR.

The State Water Board will review and consider the EIR, including comments and responses prior to making a decision on issuance of a water quality certification. If the State Water Board concludes that the EIR reflects the State Water Board's independent judgment and has been prepared in accordance with CEQA and the CEQA Guidelines, the State Water Board will certify the Final EIR (CEQA Guidelines section 15090). The State Water Board will make findings regarding each significant effect identified in the EIR (Pub. Resc. Code, sec. 21081). The State Water Board will consider the information in the EIR, along with any other available information, in making its decision on whether and under what conditions to issue water quality certification for the Lower Klamath Project (CEQA Guidelines section 15121).

1.5 Public Involvement and Agency Consultation in Preparing Draft EIR

The State Water Board received invaluable input from public stakeholders and other federal, state, and local agencies and Native American Tribes in the development of its Draft EIR.

As part of the environmental review process, the State Water Board issued its *Notice of Preparation and Scoping Meetings for an Environmental Impact Report for the Lower Klamath Project License Surrender* (NOP) on December 22, 2016. The NOP was out for a 42-day public comment period from December 22, 2016 to February 1, 2017 (see also Appendix A). The State Water Board held three public scoping meetings in the cities of Arcata, Sacramento, and Yreka in January 2017 to solicit public and stakeholder input. The State Water Board notified all relevant agencies on the State Clearinghouse list of potential responsible and trustee agencies, as well as interested groups, organizations, and individuals, that the State Water Board would prepare an EIR for the Proposed Project, and published notice of the scoping meetings and of issuance of the Notice of Preparation in the Siskiyou Daily, Eureka Times Standard, and Sacramento Bee.

The State Water Board also engaged in robust consultation with other public agencies and Native American Tribes, as detailed below in Section 1.5.3.

[6] Stillwater Sciences is the primary consultant firm developing this EIR at the direction of the State Water Board. Additional consultants supporting Stillwater Sciences include SHN Engineers and Geologists, and William Rich and Associates.

The State Water Board issued a Scoping Report (see Appendix A), which documents the scoping process, including the NOP, the content of the public scoping meetings and all comments received. A summary of the scoping meetings and environmental issues raised during this public involvement process follows.

1.5.1 Scoping Meetings

The State Water Board recognizes the complex and controversial nature of the proposed Lower Klamath Project; that different communities along the Klamath River have different input to provide, and that travel for community members might be difficult. In this context, valuable community input may have been lost under CEQA's minimum requirement of one scoping meeting. To facilitate community input, the State Water Board conducted three scoping meetings during the NOP comment period.

Table 1.5-1. Public Scoping Meetings – Dates and Locations.

Arcata, CA
January 12, 2017 (5:00 pm–7:00 pm) D Street Neighborhood Center 1301 D Street Arcata, CA 95521
Sacramento, CA
January 20, 2017 (10:00 am–12:00 pm) CalEPA Building – Byron Sheet Auditorium 1001 I Street, 2nd Floor Sacramento, CA 95814
Yreka, CA
January 26, 2017* (5:00 pm–7:00 pm) Best Western Miner's Inn – Convention Center, Auditorium 122 E. Miner Street Yreka, CA 96097

* The Yreka public scoping meeting was originally scheduled for January 10, 2017. On January 9, 2017, the State Water Board canceled the Yreka scoping meeting due to inclement weather and a strong advisory against travel from the National Oceanic and Atmospheric Administration's National Weather Service. On January 10, 2017, the State Water Board rescheduled the Yreka scoping meeting for January 26, 2017.

1.5.2 Scoping Comments

The State Water Board received 83 oral and eight written comments during the public scoping meetings, as well as over 1,300 written comments submitted via email or letter. All comments referenced in the Scoping Report were considered in development of the EIR.

The Scoping Report summarizes the issues raised under each of the topics and provides the text of both oral and written comments (Appendix A, Scoping Report, section 4.2). Scoping comments addressed a wide range of environmental and other issues, which are listed below:

- Overall EIR scope
- Environmental baseline
- KRRC's Proposed Project
- No Project Alternative
- Other project alternatives suggested during scoping
- Incorporation of findings from past studies
- Fish/fisheries
- Water quality
- Water supply
- Hydrology
- Sediment
- Recreation
- Economics
- Property value
- Tribal cultural and historical resources
- Paleontologic resources
- Energy production and greenhouse gases
- Wildlife
- Riparian habitat
- Agriculture
- Public health and safety
- Aesthetics
- Environmental law compliance
- Cumulative impact analysis
- Source data and information
- Other comments
- Comments not relating to the scope or content of the EIR

1.5.3 Agency and Tribal Consultation

Consistent with CEQA Guidelines, section 21104(a), as part of the EIR development, the State Water Board consulted with and obtained comments from public agencies that have expertise related to the Proposed Project, and the county in the Proposed Project location. Similarly, consistent with Public Resources Code section 21080.3.1, the State Water Board consulted with California Native American Tribes traditionally and culturally affiliated with the geographic area of the Proposed Project who requested consultation. A short description of the consultations with each agency and tribes is outlined below:

CALFIRE:

- Hosted a conference call with CALFIRE staff on November 6, 2018, to discuss Lower Klamath Project dam removal and current firefighting methods in Siskiyou County.

California Coastal Commission

- Attended a public meeting with Coastal Commission staff on April 13, 2017, and associated email communications.

California Department of Fish and Wildlife (CDFW)

- Regular in-person meetings and coordination calls, including participation in KRRC Technical Workgroup Inter-agency meetings.

California Natural Resources Agency

- Regular coordination calls.

National Marine Fisheries Service (NMFS)

- Coordination calls, as needed, including participation in KRRC Technical Workgroup Inter-agency meetings.

Native American Tribes

- Series of tribal consultation meetings under Assembly Bill 52[7] with Shasta Nation, Shasta Indian Nation, and Yurok Tribe.
- In-person meetings with the Karuk Tribe and Hoopa Valley Tribe

North Coast Regional Water Quality Control Board

- Various meetings and emails.
- Attended in-person North Coast Regional Water Quality Control Board meeting in City of Weed on April 19, 2018, with State Water Board Member Steve Moore.

Oregon Department of Environmental Quality

- Regular telephonic communications.

[7] Statutes 2014, Chapter 532, Gatto.

Siskiyou County

- July 11, 2017 – State Water Board staff and State Water Board member Steve Moore, attended a public meeting of the Siskiyou County Board of Supervisors and presented on the status of the Draft EIR.
- April 19, 2018 – in-person meeting with County's designated contact and consultants.
- August 14, 2018 – State Water Board staff attended a public meeting of the Board of Supervisors and presented on the status of the draft EIR.

United States Bureau of Reclamation (USBR)

- Coordination calls, as needed.

United States Fish and Wildlife Service (USFWS)

- Coordination calls, as needed, including participation in KRRC Technical Workgroup Inter-agency meetings.

United States Geological Survey (USGS)

- Coordination calls, as needed.

2 PROPOSED PROJECT

This chapter describes the Lower Klamath Project License Surrender (Proposed Project) pursuant to the requirements of CEQA Guidelines Section 15124.

2.1 Project Objectives

The State Water Board has identified the following Proposed Project objectives, as required under CEQA Guidelines, section 15124, subdivision (b):

In a timely manner:

1. Improve the long-term water quality conditions associated with the Lower Klamath Project in the California reaches of the Klamath River, including water quality impairments due to *Microcystis aeruginosa* and associated toxins, water temperature, and levels of biostimulatory nutrients.
2. Advance the long-term restoration of the natural fish populations in the Klamath Basin, with particular emphasis on restoring the salmonid fisheries used for subsistence, commerce, tribal cultural purposes, and recreation.
3. Restore volitional anadromous fish passage in the Klamath Basin to viable habitat currently made inaccessible by the Lower Klamath Project dams.
4. Ameliorate conditions underlying high disease rates among Klamath River salmonids.

These objectives further the underlying purpose of timely improving water quality related to the Lower Klamath Project within and downstream of the current Hydroelectric Reach and restoring anadromous access upstream of Iron Gate Dam (the current barrier to anadromy).

2.2 Project Location

The Proposed Project is located on the Klamath River in Siskiyou County, California and in Klamath County, Oregon (Figure 2.2-1). The nearest city to the California portion of the Proposed Project is Yreka, which is located 20 miles southwest of the downstream end of the Proposed Project.

The California portion of the Proposed Project includes the following three dams and associated facilities: Iron Gate Dam (RM 193.1), Copco No. 1 Dam (RM 201.8), and Copco No. 2 Dam (RM 201.5). The Klamath Basin—comprised of the Upper Klamath Basin, Mid-Klamath Basin, and Lower Klamath Basin—and the mainstem Klamath River reaches are shown in Figure 2.2-2. For purposes of this draft EIR, the California portion of the Klamath River system has been divided into four (4) reaches as follows: Hydroelectric Reach, Middle Klamath River, Lower Klamath River, and Klamath River Estuary. The Hydroelectric Reach extends into Oregon, where upstream reaches of the Klamath River also include the Upper Klamath River, Keno Reservoir, Lake Ewauna, and Link River (Figure 2.2-3).

The State Water Board has identified the Project Boundary as inclusive of the Proposed Project “Limits of Work” as well as PacifiCorp lands immediately surrounding the Lower Klamath Project (“Parcel B lands”) that would be transferred as part of the Proposed

Project. The boundary for the entire Proposed Project, including the Oregon portion of the Proposed Project surrounding the J.C. Boyle Dam and associated facilities and the California portion of the Proposed Project surrounding the Iron Gate, Copco No. 1, and Copco No. 2 dams and associated facilities, are shown in Figure 2.2-4. The California portion of the Project Boundary is shown in Figure 2.2-5. The transfer and disposition of Parcel B lands under the Proposed Project is discussed further in Section 2.7.10 *Land Disposition and Transfer* of this EIR.

Throughout this EIR, information concerning the Oregon portion of the Proposed Project is provided for context, although CEQA does not apply to impacts or actions Oregon except to the extent that there are emissions or discharges that would significantly impact the California environment (see also Section 1.1.1 *CEQA Guidance Regarding State Boundaries*).

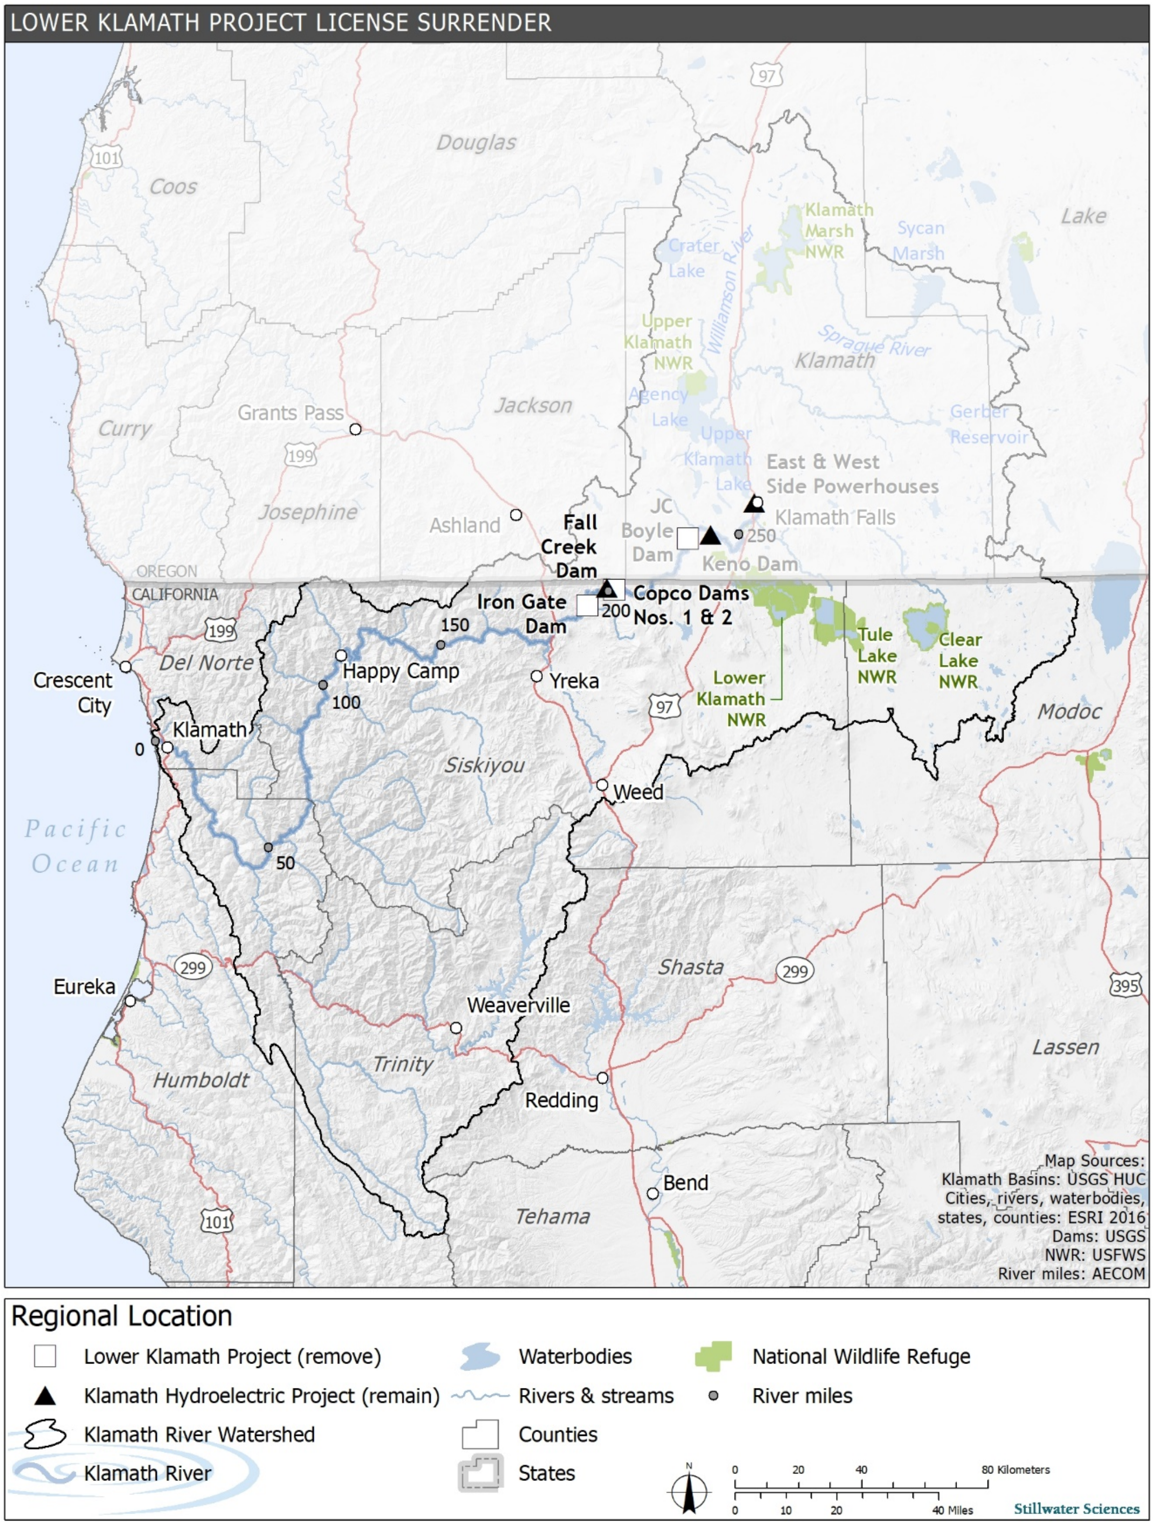

Figure 2.2-1. Regional Location.

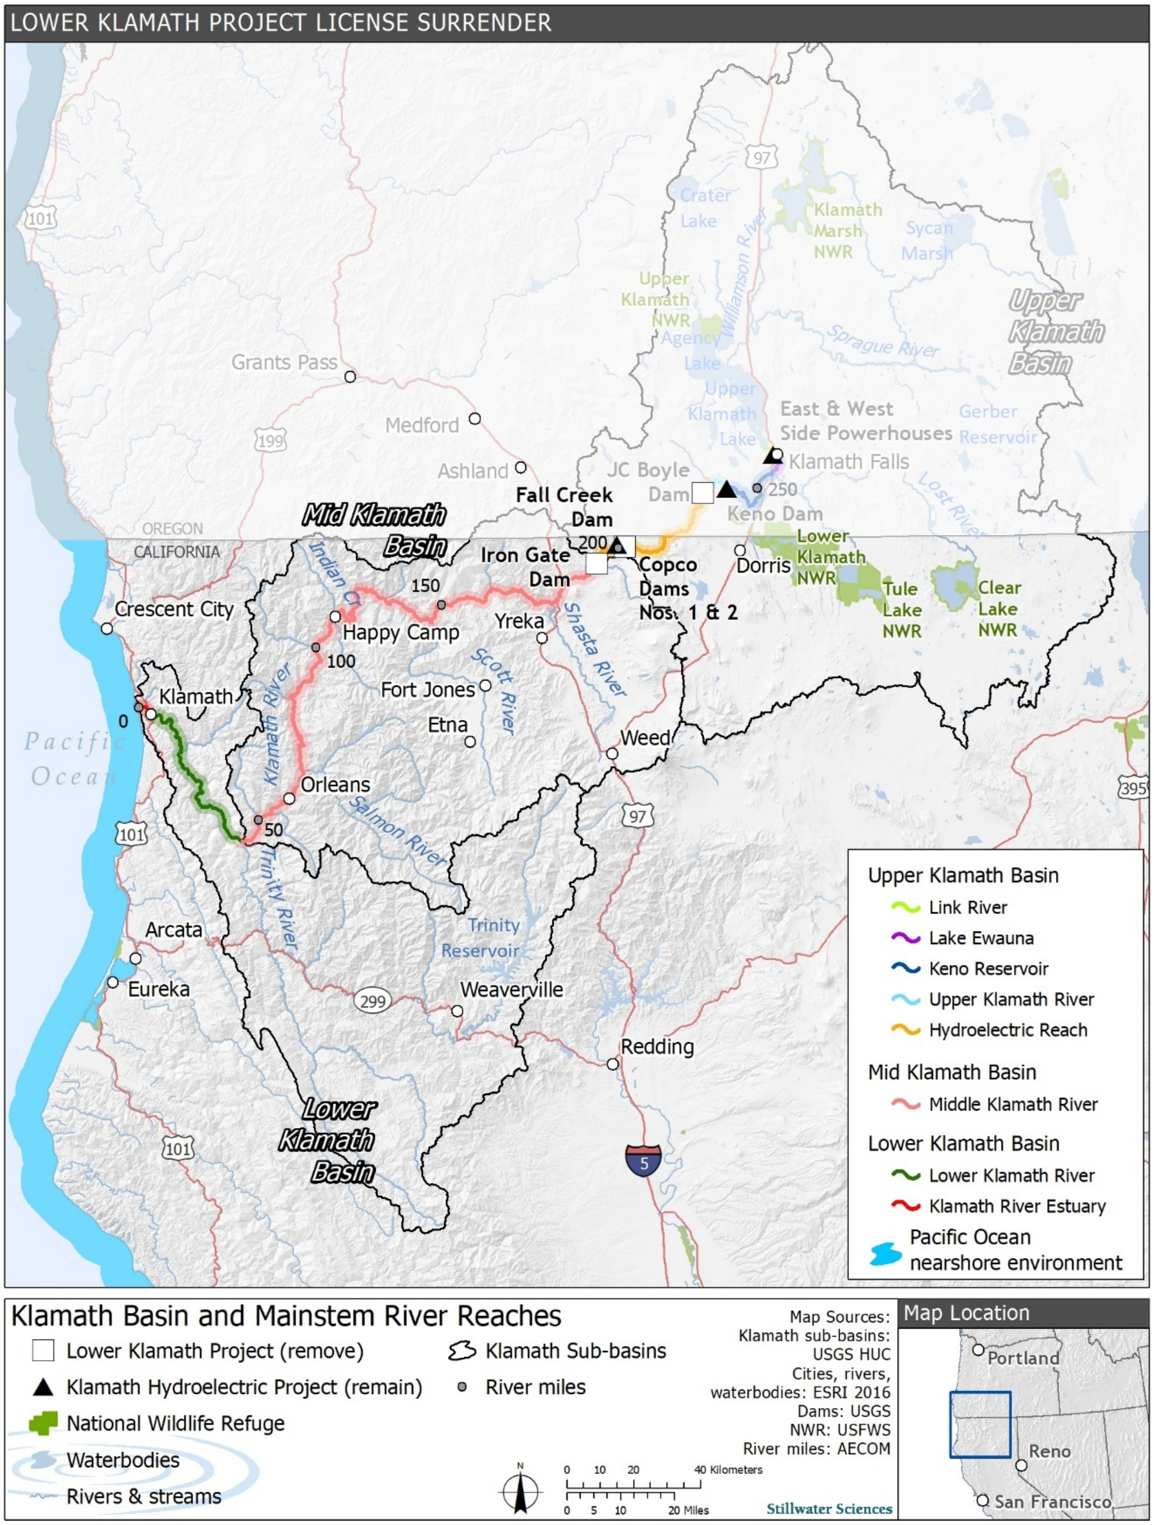

Figure 2.2-2. Klamath Basin and Mainstem River Reaches.

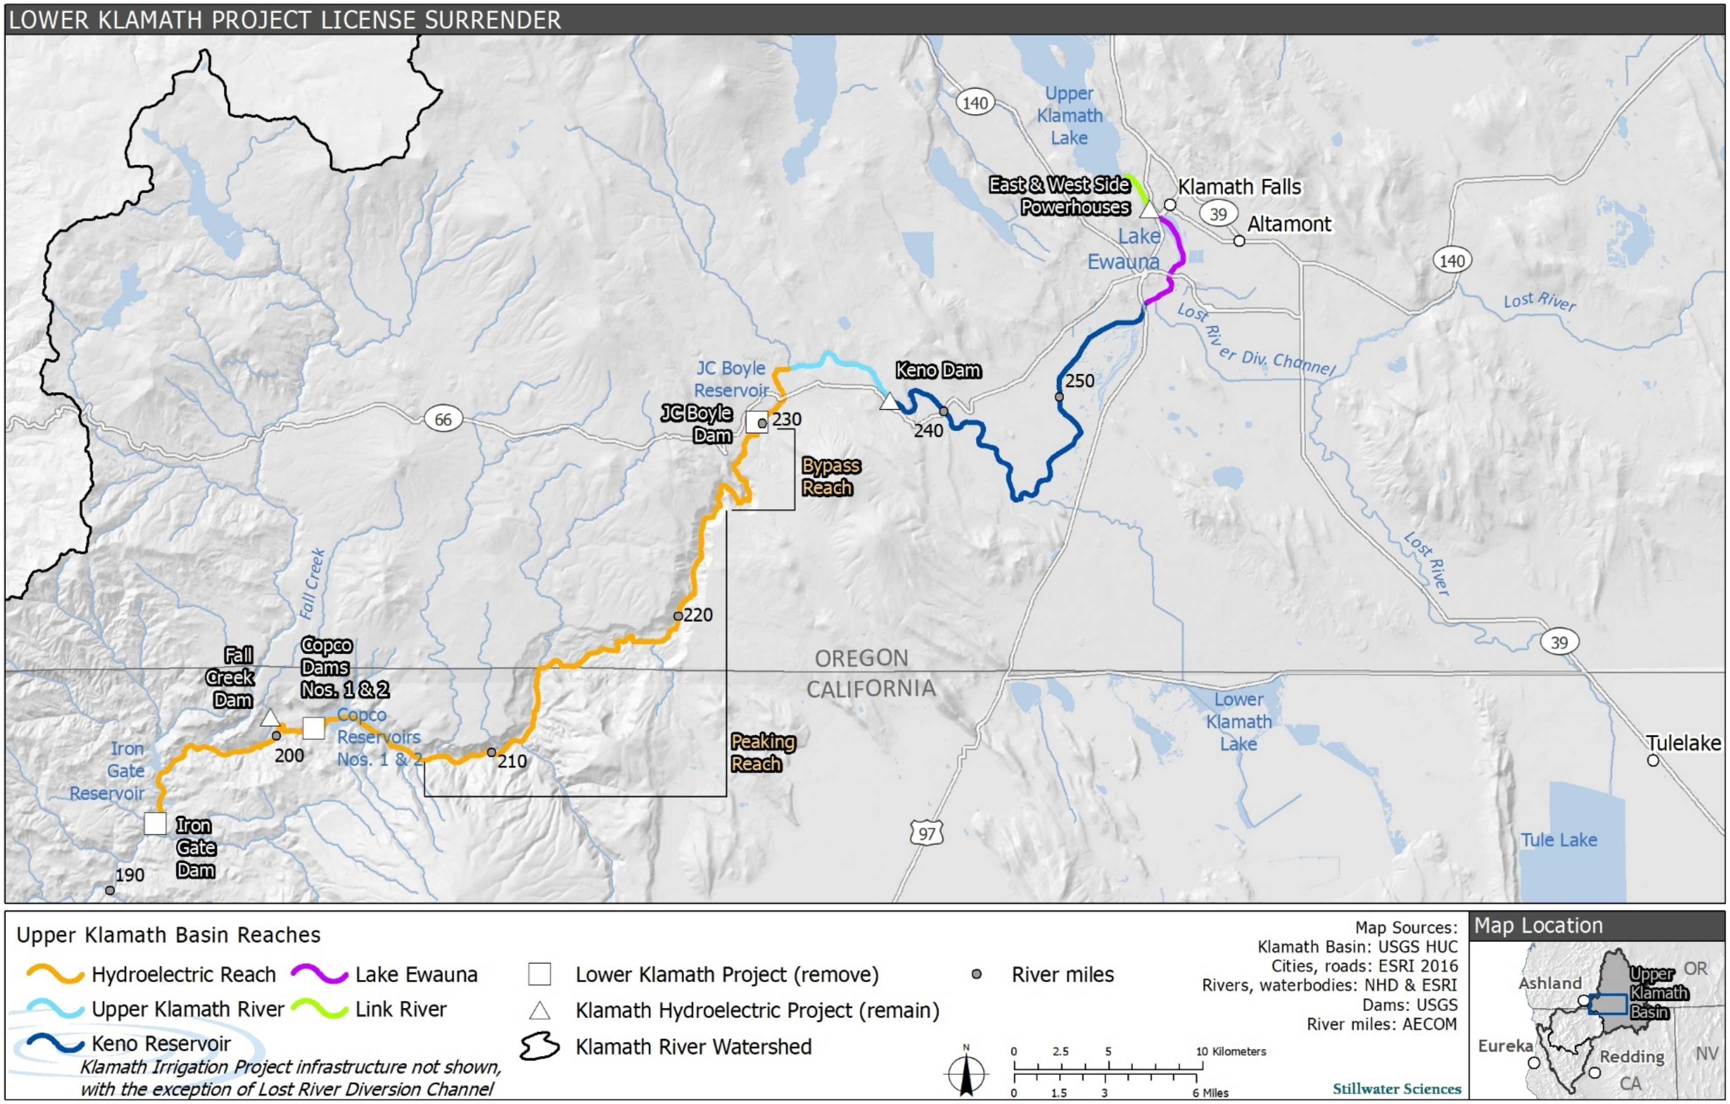

Figure 2.2-3. Upper Klamath Basin Reaches.

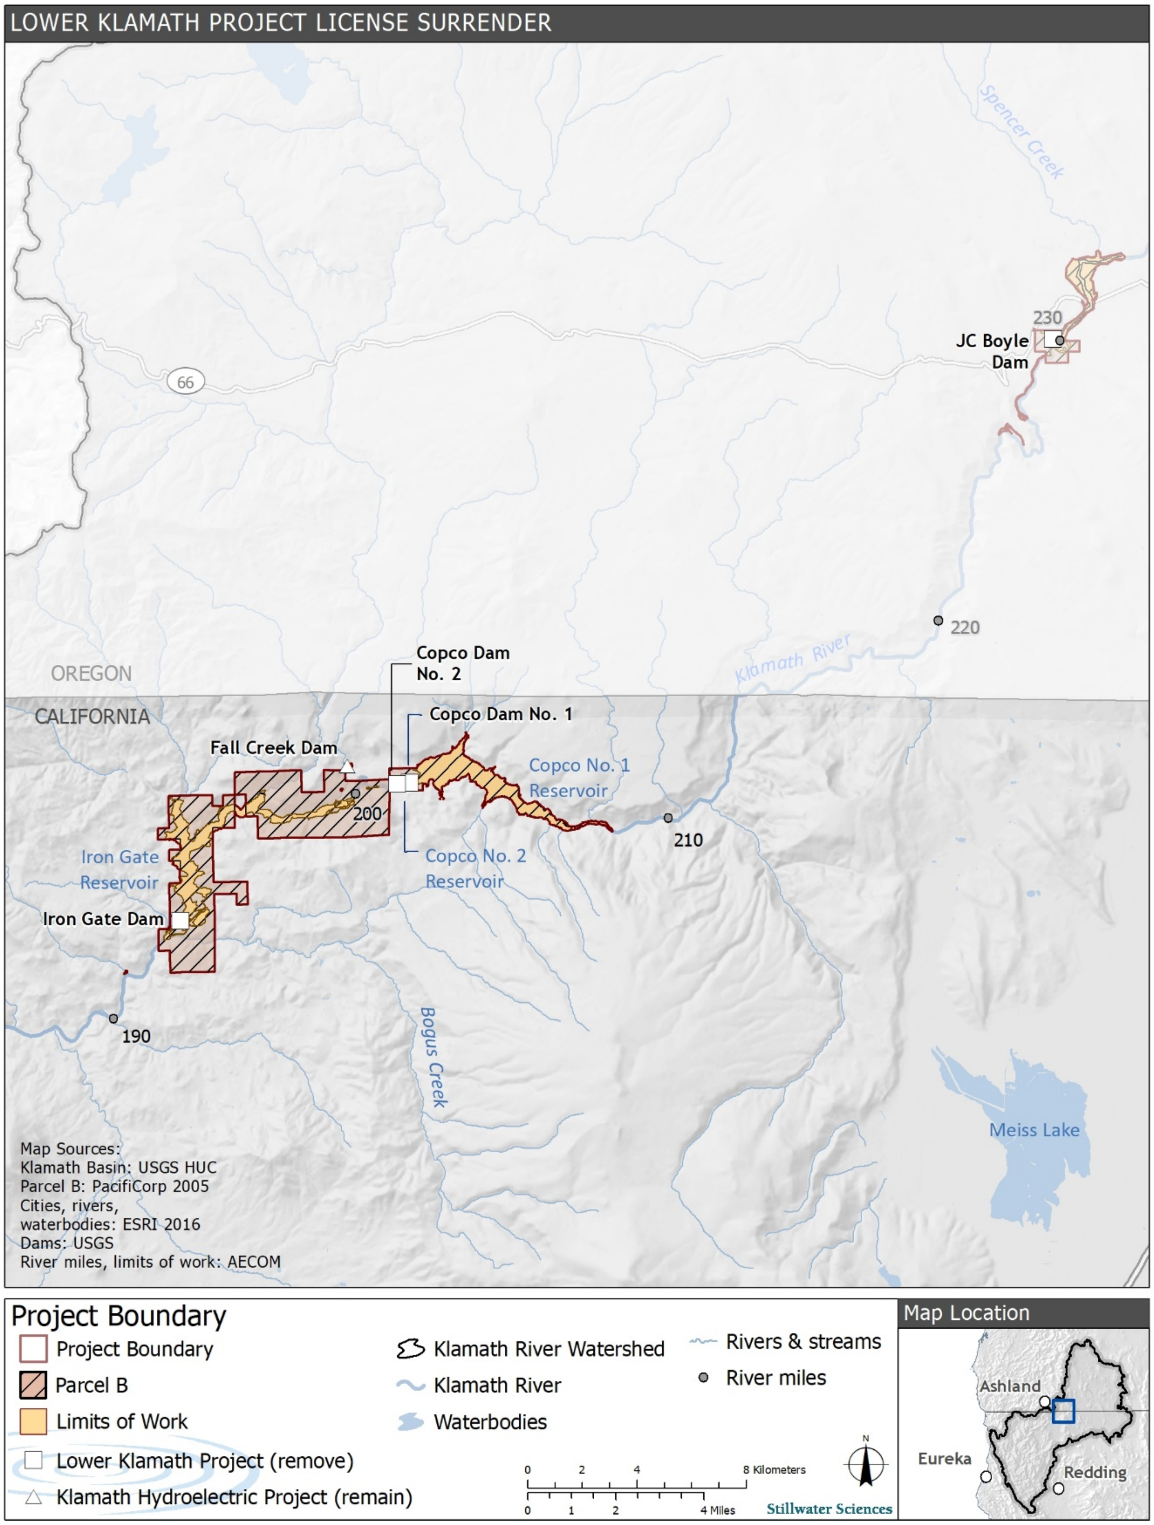

Figure 2.2-4. Proposed Project Boundary.

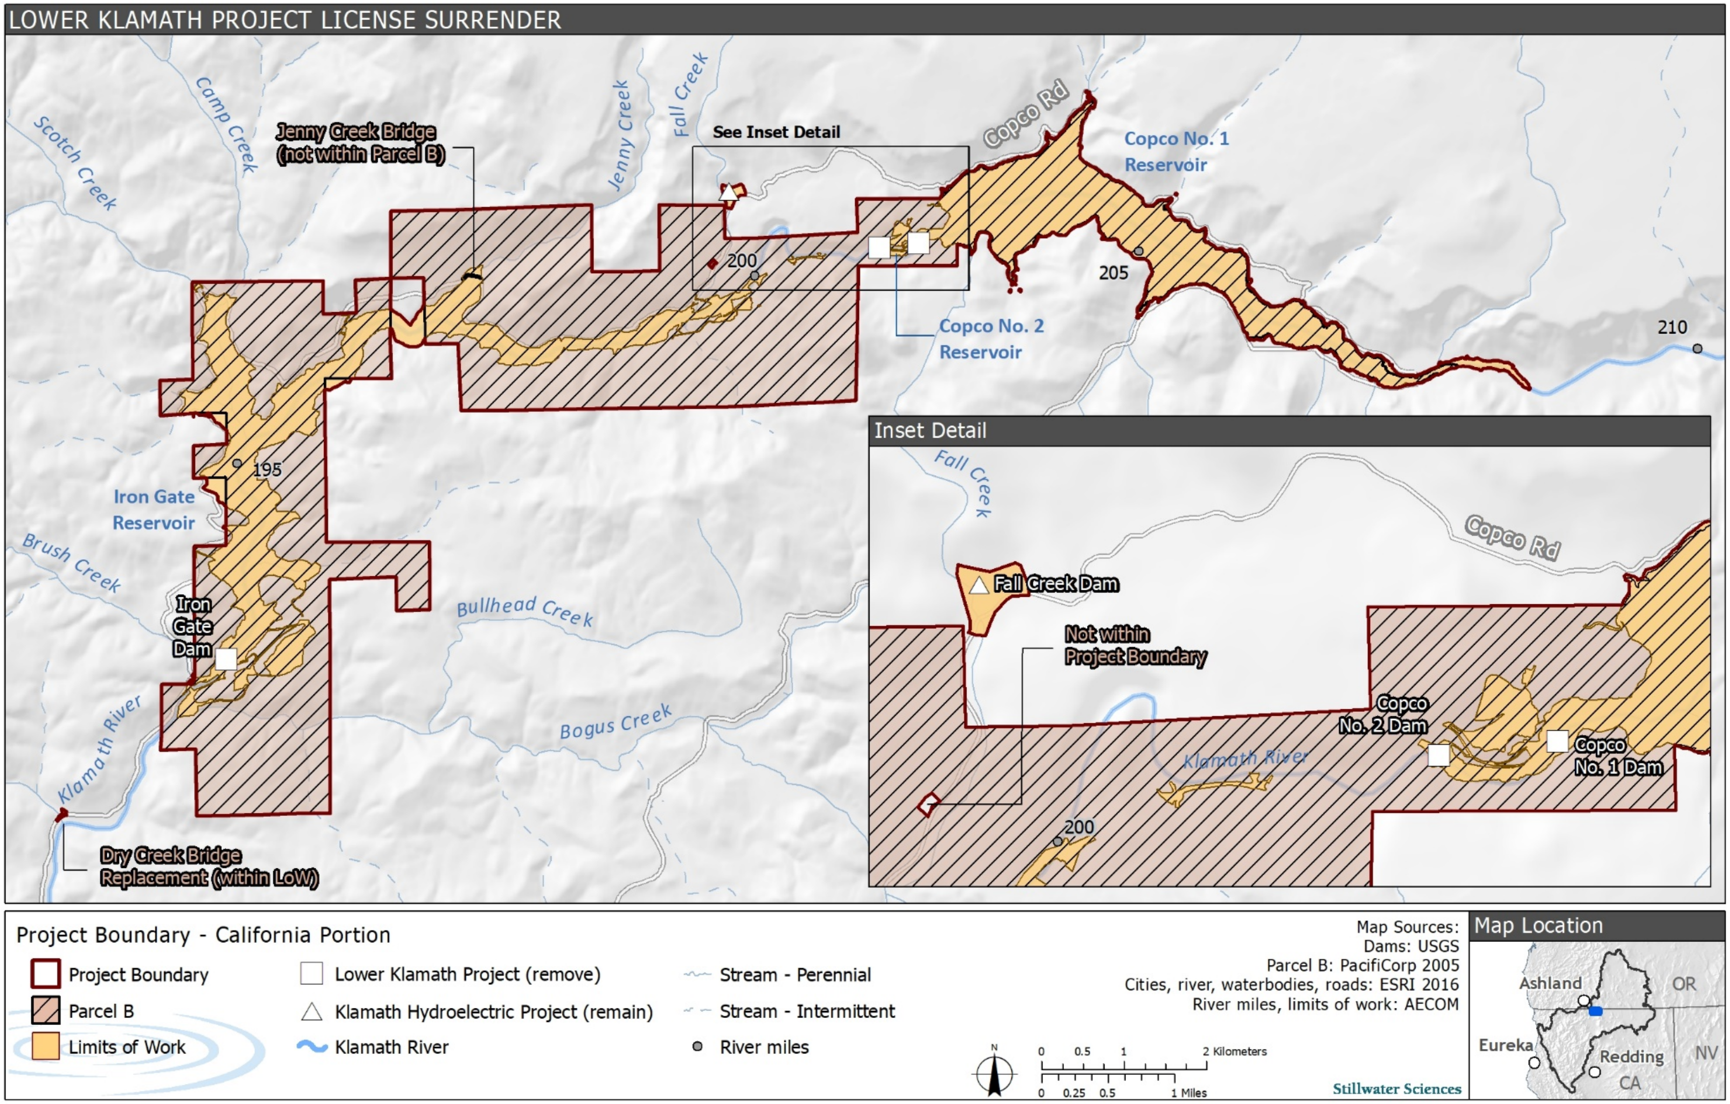

Figure 2.2-5. Proposed Project Boundary – California Portion.

2.3 Existing Lower Klamath Project Features

Basic features of the Lower Klamath Project (e.g., dams and powerhouse components) are summarized in Table 2.3-1 and described in the following sections. A brief description of J.C. Boyle Dam and its associated facilities, which are located in Oregon, is provided to inform any evaluations of impacts to resources in California that are affected by the portion of the Proposed Project that is in Oregon (see also Section 1.1.1 *CEQA Guidance Regarding State Boundaries*).

Table 2.3-1. Lower Klamath Project Dam and Powerhouse Components.

	J.C. Boyle	Copco No. 1	Copco No. 2	Iron Gate
Dam type	Concrete and earthfill embankment	Concrete	Concrete	Earthfill embankment
Dam maximum height	68 feet	133 feet	32 feet	189 feet
Dam crest length	430 feet	410 feet	305 feet	740 feet
Reservoir surface area	350 acres	972 acres	N/A	942 acres
Reservoir storage volume	2,267 acre-feet	33,724 acre-feet	70 acre-feet	50,941 acre-feet
Type of facility to allow water to flow past dam	Overflow spillway with control gates and diversion culvert	Overflow spillway with larger control gate and modified diversion tunnel	Overflow spillway with control gates	Uncontrolled overflow spillway and diversion tunnel

Source: Appendix B: *Definite Plan*. Note that component dimensions have been adjusted from those reported in FERC 2007 and USBR 2012a based on available data (e.g., as-built drawings, aerial photographs, topographic information).

2.3.1 J.C. Boyle Dam and Associated Facilities

The J.C. Boyle Dam (RM 229.8) and associated facilities are in Oregon on the mainstem of the Klamath River at the upstream end of the Hydroelectric Reach. J.C. Boyle Dam is a 68-foot tall concrete and earthfill dam that was completed in 1958. The dam impounds approximately 2,267-acre feet of water in a narrow reservoir with a surface area of approximately 350 acres, with a fish ladder along its concrete spillway[8] (Figure 2.3-1). J.C. Boyle Reservoir supplies water through a conveyance system that extends 2.5 miles from the dam to a 98-megawatt (MW) powerhouse. Water diversions for hydropower generation at J.C. Boyle Dam create a sub-reach of the Hydroelectric Reach called the Bypass Reach, which is located immediately downstream of the dam and extends to the powerhouse at RM 225.2 (Figure 2.3-1). The Bypass Reach contains less flow than other sections of the Klamath River due to water diversions for J.C. Boyle hydropower operations. Article 34 of the 1957 amended license requires a reasonable minimum flow, which was later set to 100 cfs by FERC, to be maintained in the Bypass

[8] The existing concrete upstream fish ladder on the north side of the J.C. Boyle Dam spillway does not meet current design criteria and must be replaced because of its configuration and poor structural condition (2012 KHSA EIS/EIR).

Reach. After diverted water runs through the J.C. Boyle power generation facilities, it rejoins the Klamath River (RM 225.2).

Another sub-reach of the Hydroelectric Reach is located downstream of the J.C. Boyle Powerhouse and is referred to as the Peaking Reach because the powerhouse is generally operated as a peaking facility to generate power during peak demand periods. During peaking operations, water stored in J.C. Boyle Reservoir is diverted around the Bypass Reach to the powerhouse to provide enough flow to generate hydropower and to take advantage of the cost difference between peak and off-peak power generation. Peaking occurs at J.C. Boyle Powerhouse when there is not sufficient river flow to sustain continuous hydropower operations, especially during the summer and fall low flow period. Power demand peaks during weekday afternoons in the summer, thus peaking power generation occurs in the late afternoons and early evenings to meet this demand. J.C. Boyle Reservoir refills during the night when power demand is minimal. Figure 2.3-2 illustrates early summer flows in 2011 as an example of how peaking operations affect flow downstream from the powerhouse, fluctuating rapidly to meet demand and peaking operations for power generation. During peaking operations, the rise or fall of the Klamath River is increased or decreased gradually at a rate not to exceed 9 inches per hour at a point located 0.5 miles downstream of the J.C. Boyle Powerhouse. Peaking operations result in a rise or fall of the river over a period of three to four hours. The Peaking Reach crosses from Oregon into California and ends at the Copco No. 1 Reservoir (RM 208.3).

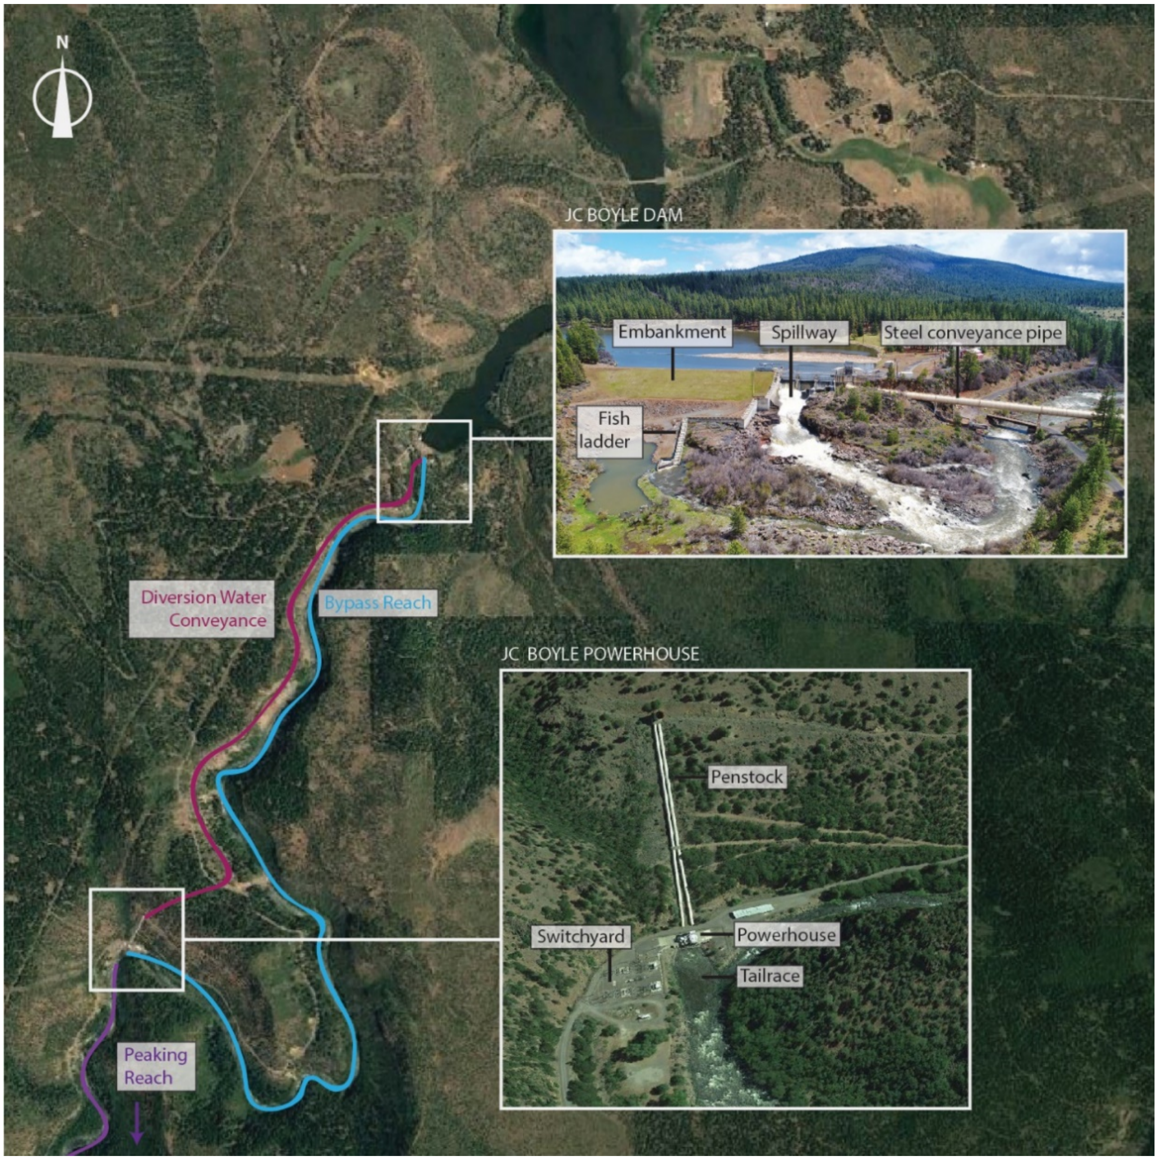

Figure 2.3-1. J.C. Boyle Dam and Associated Facilities.

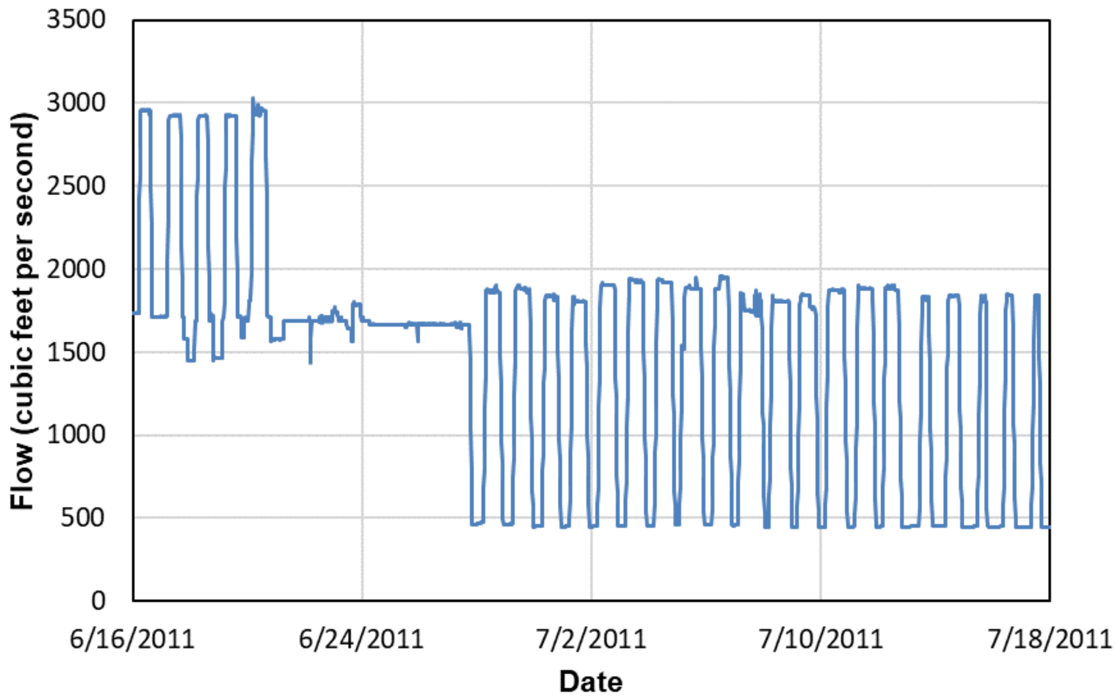

Figure 2.3-2. Example Flows in Peaking Reach downstream from J.C. Boyle Powerhouse (USGS station 11510700). Source: USGS 2011.

2.3.2 Copco No. 1 Dam and Associated Facilities

The Copco No. 1 dam and associated facilities (Figure 2.3-3) are located on the Klamath River between RM 201.8 and RM 208.3 in Siskiyou County, California. Copco No. 1 Dam was completed in 1918. The dam and associated facilities consist of the following:

1. A 33,724-acre-feet reservoir (Copco No. 1 Reservoir);
2. A 135-foot tall concrete gravity arch dam with a gated spillway (Copco No. 1 Dam);
3. A diversion tunnel capable of diverting approximately 12,000 cubic feet per second (cfs), but currently is non-operational and unable to divert any flow;
4. A switchyard with 3.03 miles of 69-kV transmission lines;
5. A water conveyance system consisting of a powerhouse intake structure, two gate houses on the right abutment, and three steel penstock pipes: one 10-foot diameter, 172-foot long, one 10-foot diameter, 194-foot long, and one 14-foot diameter, 228-foot long penstock pipes;
6. An approximately 9,800-square foot, 20-MW Copco No. 1 Powerhouse; and
7. The developed reservoir-associated recreation facilities Mallard Cove and Copco Cove. Each facility has one boat launch, one dock, and two toilets. Mallard Cove has eight picnic tables and parking for approximately 25 vehicles, while Copco Cove has two picnic tables and parking for approximately five vehicles.

There is no bypass reach for this dam.

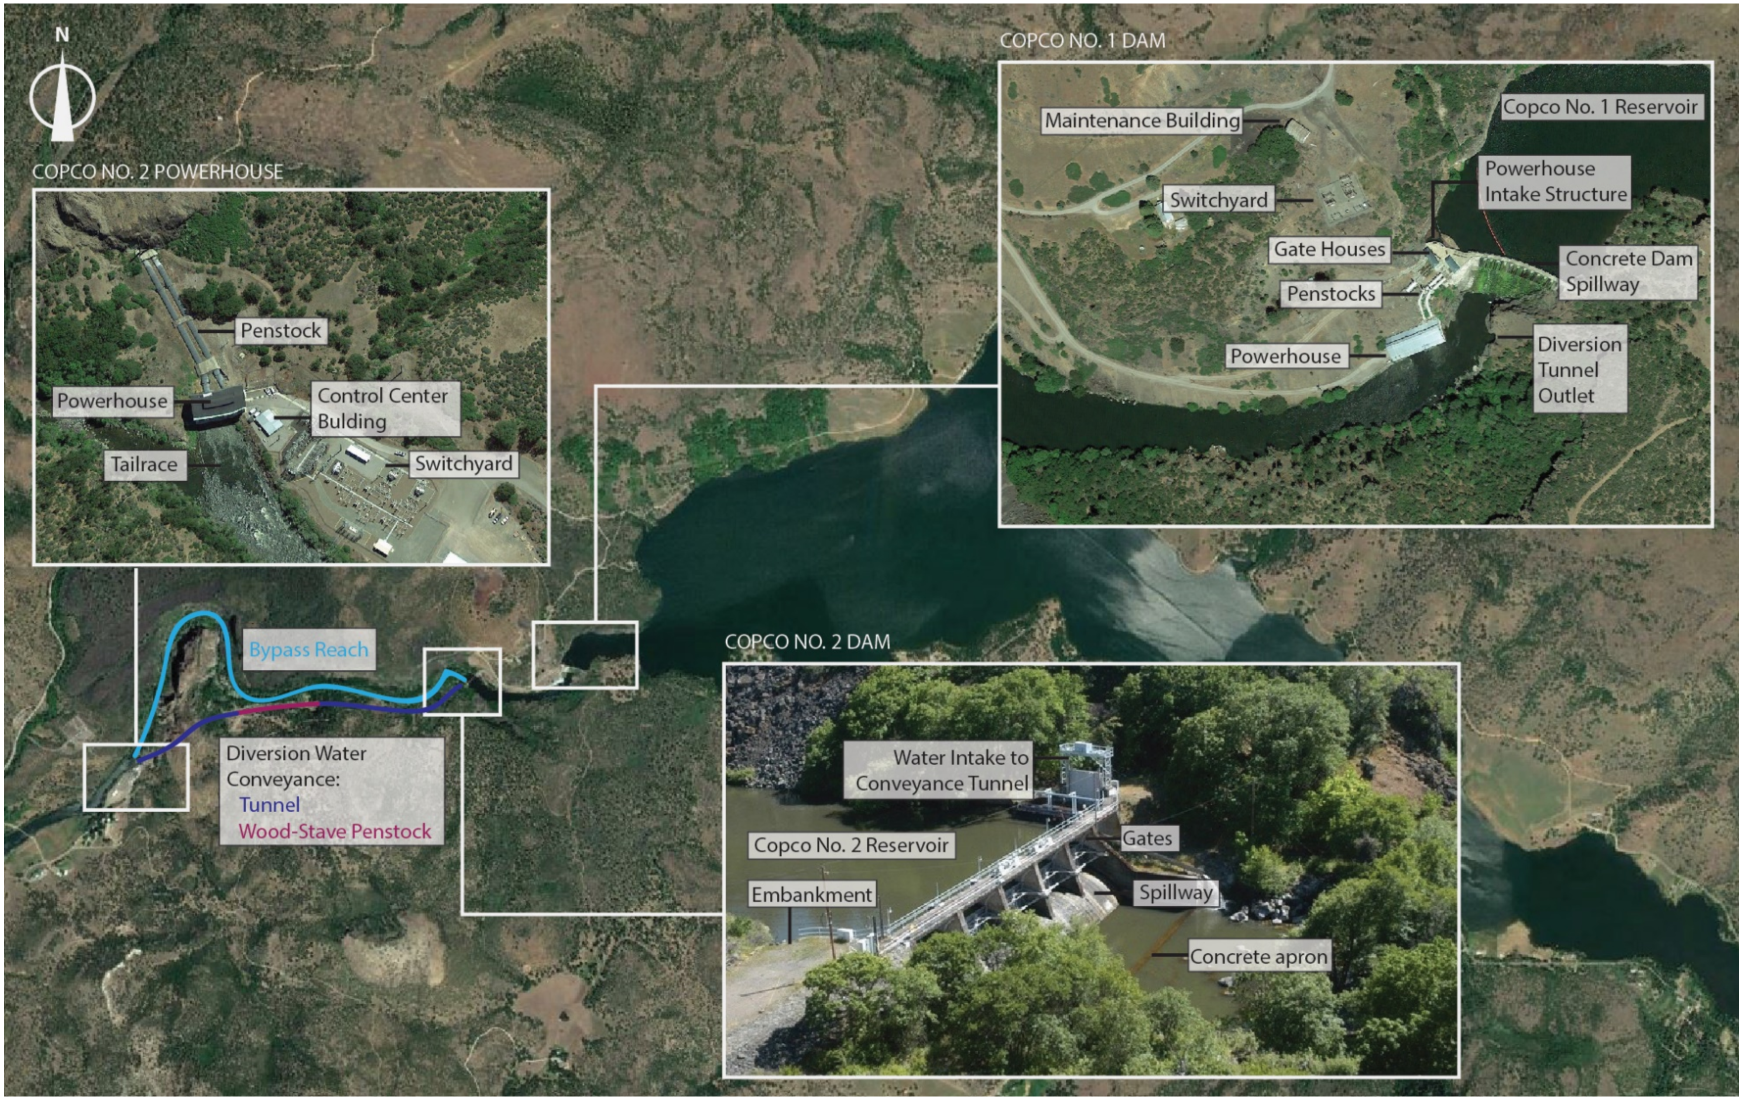

Figure 2.3-3. Copco No. 1 Dam and Copco No. 2 Dam and Associated Facilities.

2.3.3 Copco No. 2 Dam and Associated Facilities

The Copco No. 2 Dam and associated facilities (Figure 2.3-3) are located on the Klamath River between RM 201.5 and RM 201.8 in Siskiyou County, California. The Copco No. 2 Dam was completed in 1925. The dam and associated facilities consist of the following:

1. A 70-acre-feet reservoir (Copco No. 2 Reservoir);
2. A 32-foot tall concrete diversion dam (Copco No. 2 Dam) including a gated spillway, basin apron, end sill, and a remnant cofferdam upstream of the concrete dam below the normal water surface elevation of the reservoir;
3. An approximately 15,000-square foot earthen embankment section with a gunite cutoff wall along the river right sidewall;
4. A diversion water conveyance system consisting of 3,610 feet of concrete-lined, 16-foot diameter conveyance tunnel, 1,330 feet of a 16-foot diameter wooden-stave penstock, an underground surge tank, a 405.5-foot long, 16-foot diameter steel penstock, and a 410.6-foot long, 16-foot diameter steel penstock;
5. A 7,000-square foot, 27-MW Copco No. 2 Powerhouse;
6. A 1,900-square foot control center building;
7. A 4,500-square foot maintenance building;
8. A 650-square foot oil and gas storage building; and
9. The nearby mostly vacant historical Copco Village, with a total structure area of 32,200 square feet, consisting of a cookhouse, bunkhouse, storage building, bungalow, three modular houses, four old style ranch houses, and a schoolhouse/community center.

Copco No. 2 Dam is located approximately 0.25 miles downstream of Copco No. 1 Dam and has no associated recreation facilities. Water diversions for hydropower generation at Copco No. 2 Dam create a 1.5-mile-long Bypass Reach in the Klamath River between the Copco No. 2 Dam and the Copco No 2. Powerhouse (Figure 2.3-3).

2.3.4 Iron Gate Dam and Associated Facilities

The Iron Gate Dam and associated facilities (Figure 2.3-4) are located on the Klamath River between RM 193.1 and RM 200.0 in Siskiyou County, California. The Iron Gate Dam was completed in 1965. The dam and associated facilities consist of the following:

1. An approximately 50,900-acre-feet reservoir (Iron Gate Reservoir);
2. A 189-foot tall earthen embankment dam with a clay core on a basalt rock foundation and cutoff walls (Iron Gate Dam);
3. A 45-foot tall, free-standing, reinforced concrete penstock intake structure, its adjoining footbridge, and a 12-foot diameter, welded steel penstock with concrete supports;
4. The Iron Gate Fish Hatchery, which raises steelhead, coho salmon, and Chinook salmon. The hatchery includes a warehouse, a hatchery building, four fish-rearing ponds, a fish ladder, a visitor center, and four employee residences;
5. A fish trapping and holding facility including a fish ladder, holding tanks, and a processing facility at the downstream base of Iron Gate Dam;

6. A cold-water supply to Iron Gate Hatchery including an aerator, one 30-inch pipe, one 18-inch pipe, and two 24-inch pipes located below Iron Gate Dam and Powerhouse;
7. An ungated side-channel spillway capable of discharging 26,200 cfs;
8. A reinforced concrete diversion tunnel capable of diverting 2,700 cfs from the reservoir to the Klamath River and a footbridge to the gate control building;
9. A 9,000-square foot 18 MW powerhouse (excluding adjoining fish facilities);
10. 6.5 miles of 69-kV transmission lines;
11. Additional ancillary facilities, such as communication buildings, restrooms, and two residences; and
12. Recreation facilities, including the developed sites at Fall Creek, Jenny Creek, Wanaka Springs, Camp Creek, Juniper Point, Mirror Cove, Overlook Point, and Long Gulch, four small dispersed shoreline recreation sites (Iron Gate 1, 2, 3, and Long Gulch Bluff), and the recreation facilities associated with the Iron Gate Fish Hatchery. The recreation sites have a combined total of 57 picnic tables, 16 toilets, 6 boat launches, 7 docks, 1 RV dump station, and parking for approximately 200 vehicles with Camp Creek having the most facilities of all the sites. Additionally, some sites also have informal or developed campsites, a storage building, a well house, or timber shelters.

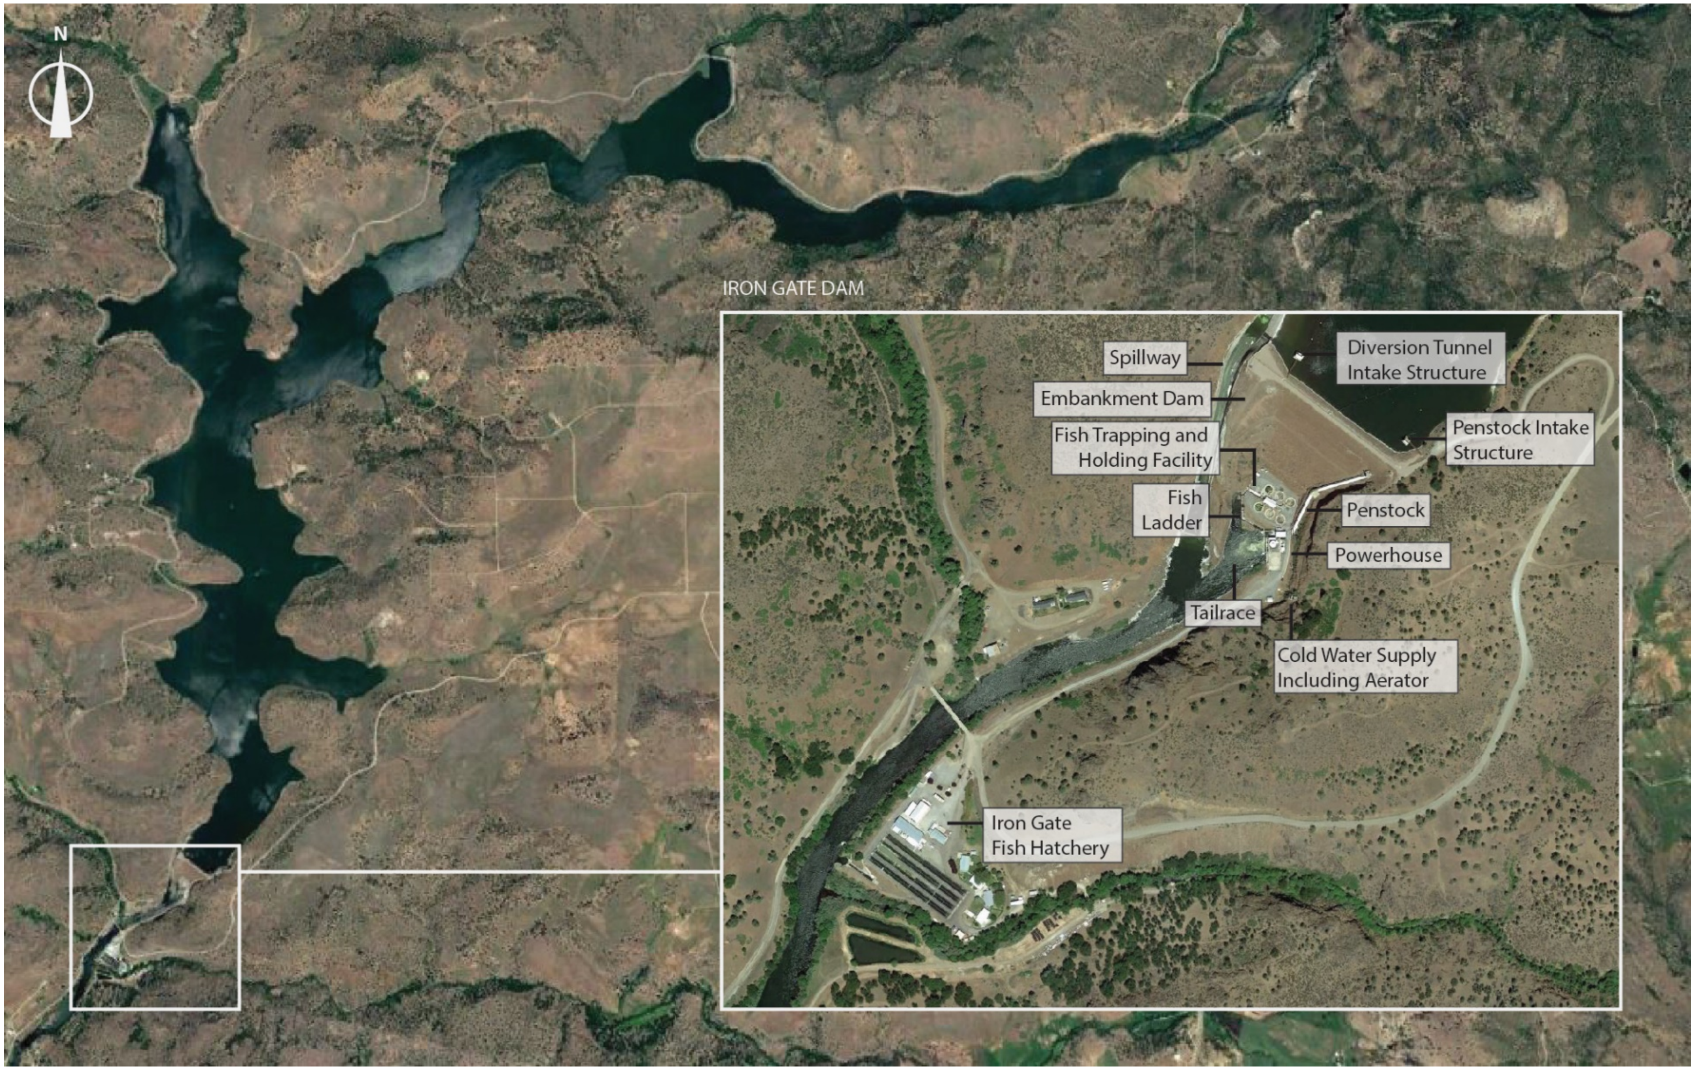

Figure 2.3-4. Iron Gate Dam and Associated Facilities.

2.4 Surrounding Land Ownership and Land Use

Land ownership within and proximal to the Project Boundary in California includes Bureau of Land Management (BLM), USDA Forest Service, State of California, PacifiCorp, and other privately-owned land (Figure 2.5-1). Further discussion of land ownership is presented in Section 3.14.2.1 *Land Ownership.*

Major Siskiyou General Plan zoning classifications surrounding the Proposed Project are Open Space – Natural Resources, Forest Resources, Agriculture – Grazing, Rural Vacant, and Rural Residential, with most of the land uses devoted to grazing and open space and conservation (Figure 2.5-2). The closest urban areas to the Proposed Project are the City of Yreka, California, and Klamath Falls, Oregon. A small amount of local land use is devoted to hydroelectric operations and recreation sites, although these activities are not specified by specific land use categories in Figure 2.5-2. There are also small residential communities and individual residences adjacent to portions of Iron Gate and Copco No. 1 reservoirs (e.g., Copco Village), and downstream.

2.5 Surrounding Land Cover

The primary land cover types within and surrounding the Proposed Project in California are Grassland/Herbaceous, Shrub/Scrub, and Evergreen Forest, along with smaller amounts of Deciduous Forest, Mixed Forest, Pasture/Hay, and Cultivated Crops (Figure 2.5-3). Developed land is generally limited to areas near existing roadways.

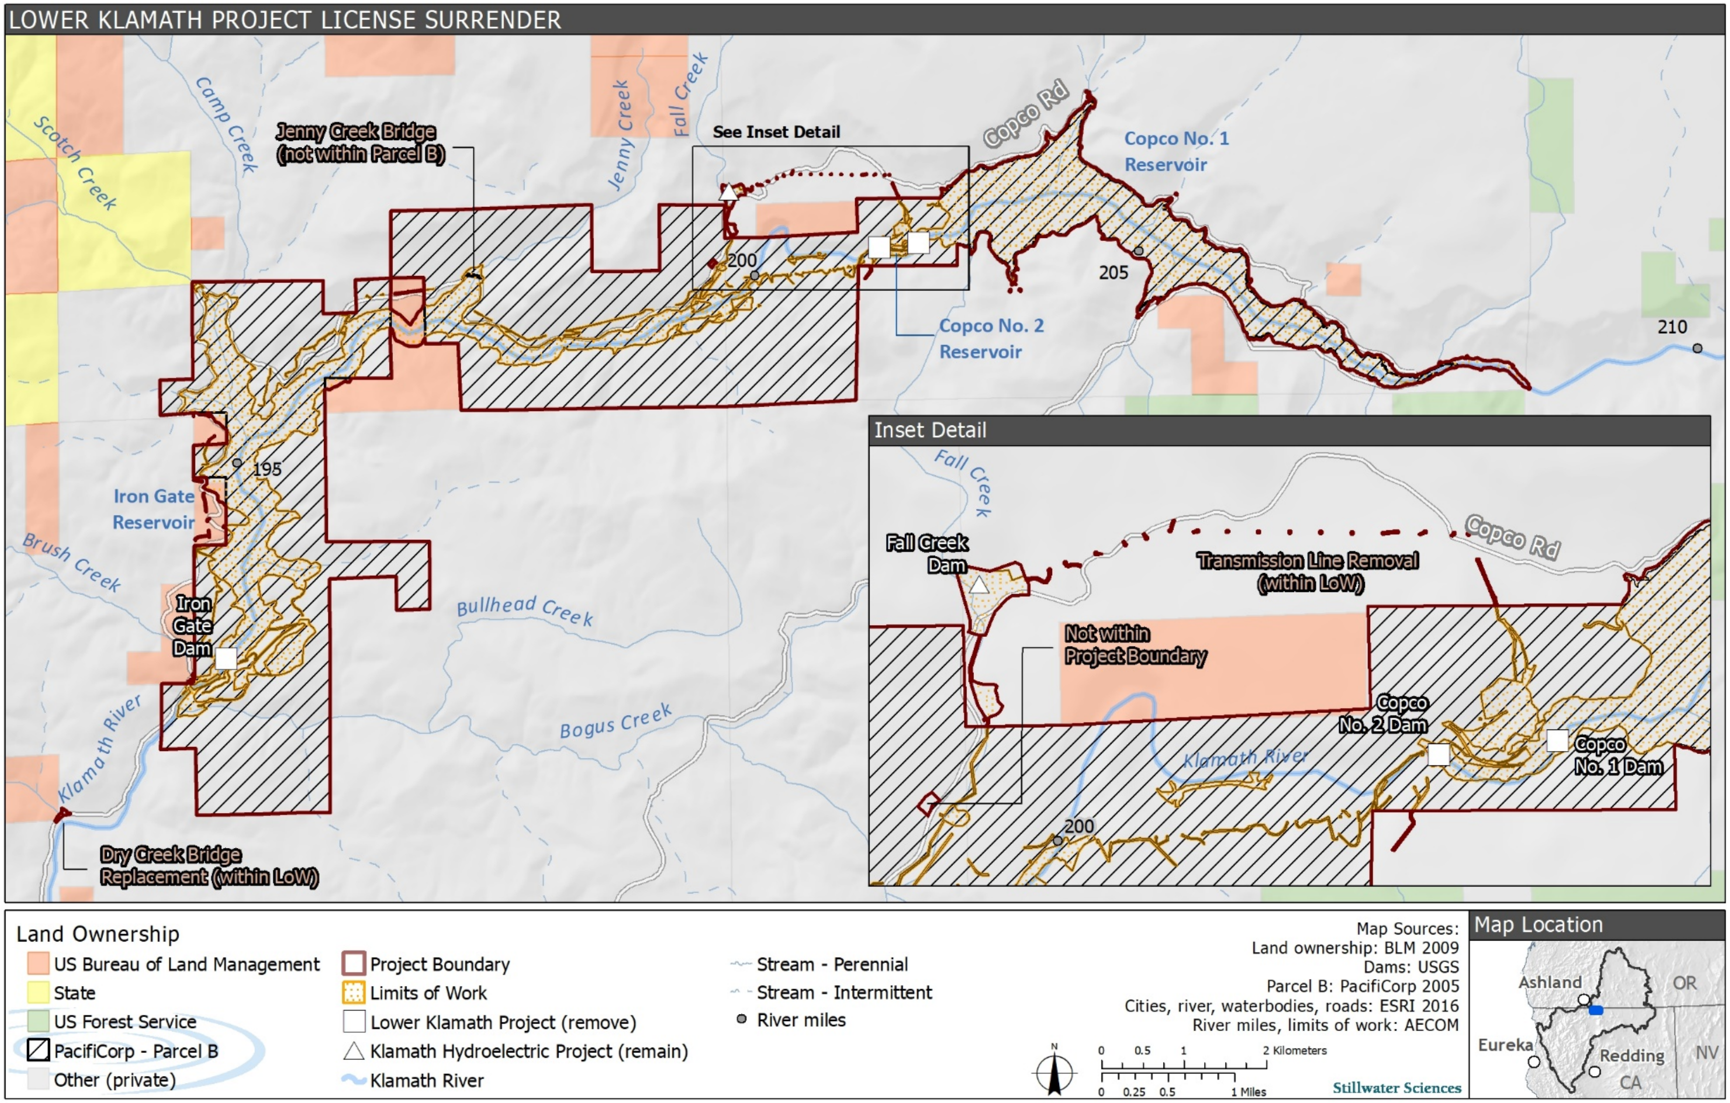

Figure 2.5-1. Surrounding Land Ownership.

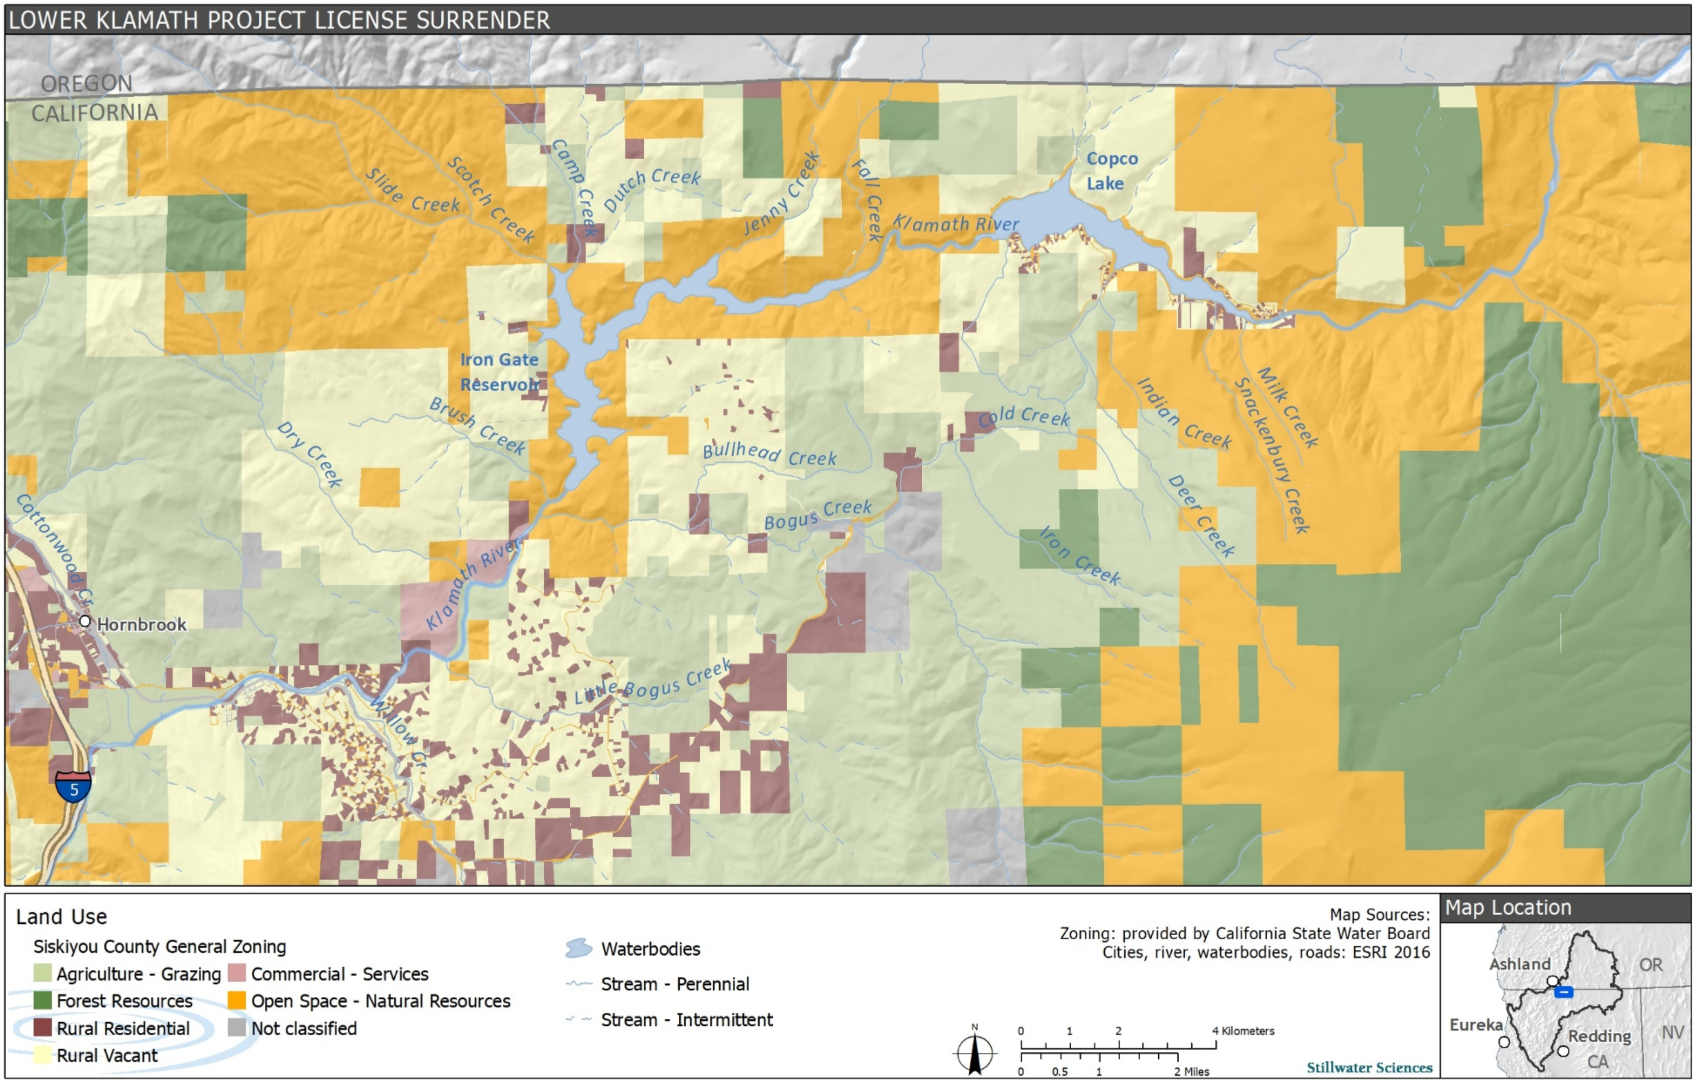

Figure 2.5-2. Surrounding Siskiyou General Plan Zoning Classifications.

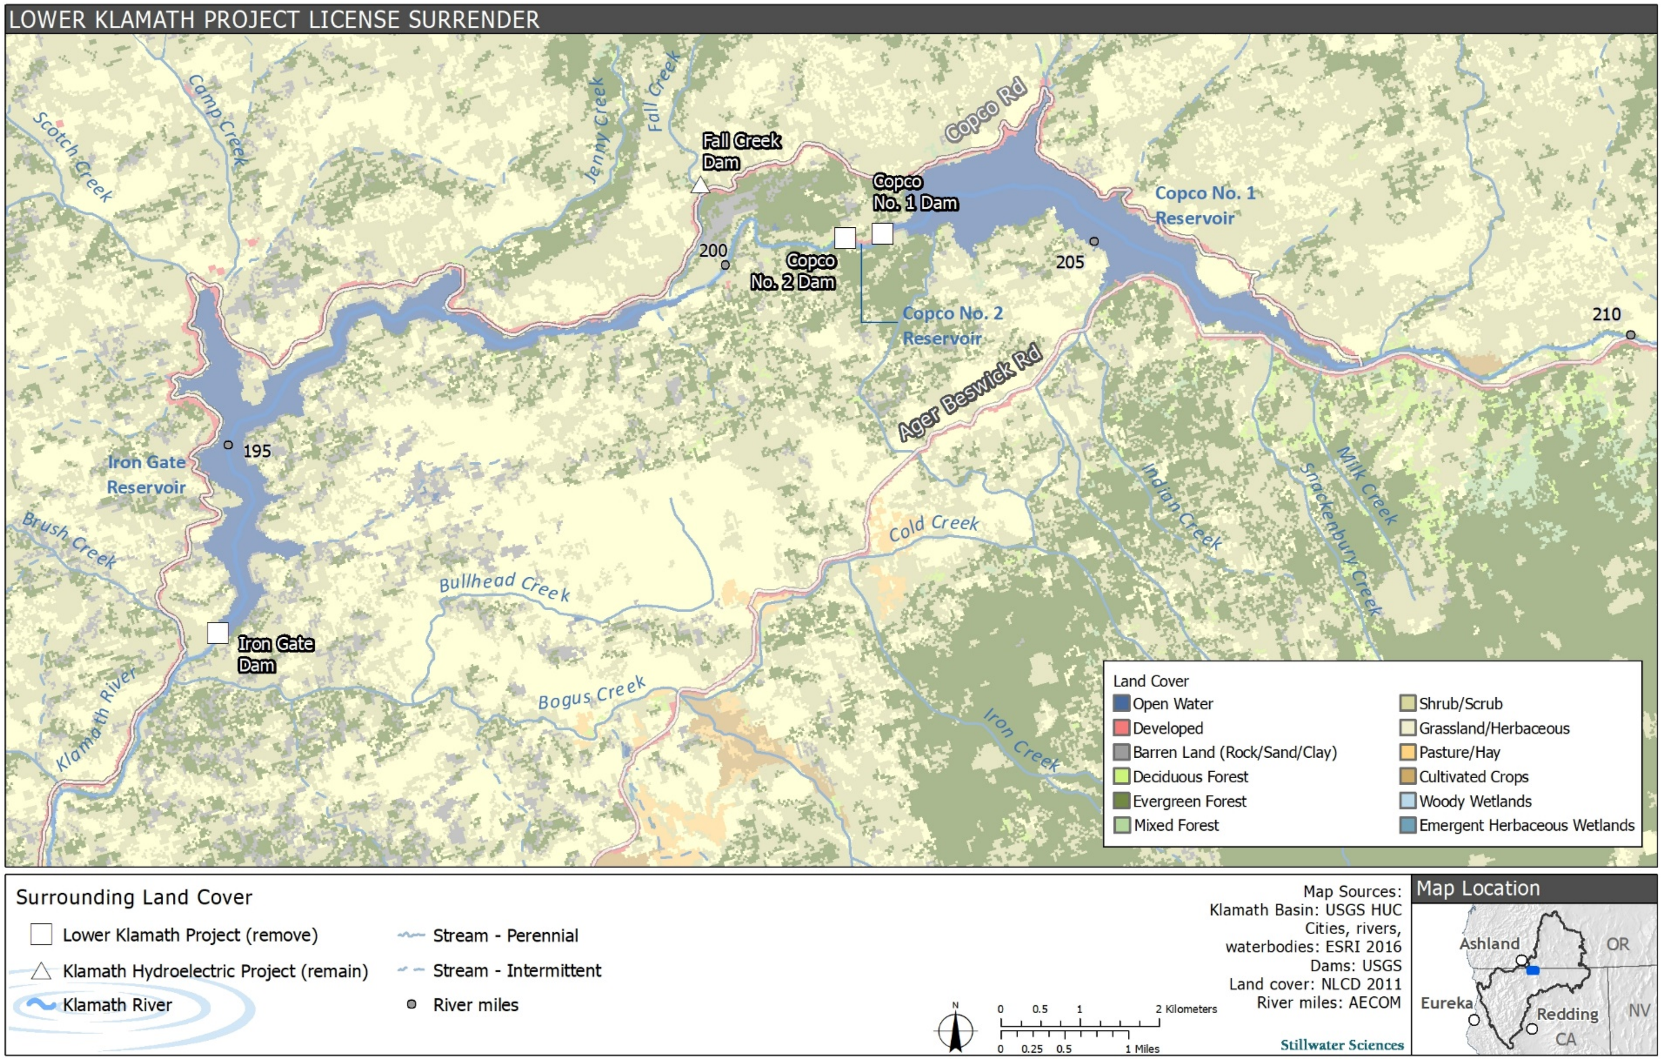

Figure 2.5-3. Surrounding Land Cover.

2.6 Project Background

2.6.1 Water Conflicts in the Klamath River Basin

Water-related disputes, including competing uses for water, water quality concerns, and impacted fisheries (commercial, tribal, and recreational) are difficult issues in the Klamath Basin. Below are some highlights of major water-related milestones and issues in the Klamath Basin over approximately the last few decades:

1957	Klamath River Basin Compact between the states of Oregon and California, ratified by the states and consented to by Act of Congress including integrated and comprehensive development of water use for equitable distribution between the two states and the Federal Government, with uses identified for domestic, irrigation, protection and enhancement of fish, wildlife and recreational resources, industrial and hydroelectric power production, and for navigation and flood prevention.
1975	Comprehensive basin plan adopted for the Klamath River in California including multiple beneficial use designations such as cold freshwater habitat, aquatic organism migration, spawning, reproduction, and/or early development for protected fish, water contact recreation, agricultural supply, and hydropower generation.
1996	Klamath River from the California/Oregon state line to Iron Gate Dam and from the confluence with the Scott River to the Klamath River Estuary added to the Clean Water Act Section 303(d) list for nutrients and temperature. Klamath River from its confluence with the Trinity River to the Klamath River Estuary added to the Clean Water Act Section 303(d) list for sediment. Klamath River from Iron Gate Dam to its confluence with the Scott River added to the Clean Water Act Section 303(d) list for organic enrichment/low dissolved oxygen.
1997	Coho salmon listed as Federally threatened under the Endangered Species Act (ESA).
1998	Lost River and shortnose sucker listed as endangered under the ESA.
1998	Klamath River from the California/Oregon state line to Iron Gate Dam and from the confluence with the Scott River to the Klamath River Estuary added to the Clean Water Act Section 303(d) list for organic enrichment/low dissolved oxygen. Klamath River from Iron Gate Dam to its confluence with the Scott River added to Clean Water Act Section 303(d) list for nutrients and temperature.
2001	(Spring) For the first time ever at a Federal reclamation (USBR) project, water deliveries from Upper Klamath Lake to Klamath Irrigation Project irrigators (and wildlife refuges) in California and Oregon did not occur in order to comply with requirements to protect ESA-listed fish (Lost River and shortnose suckers in the Upper Klamath Lake and coho salmon in the Lower Klamath River) during a severe drought (Braunworth et al. 2002).
2002	(Late summer/fall) Major fish die-off in in the Lower Klamath River of more than 33,000 adult salmon (primarily fall-run Chinook salmon) and steelhead during a disease outbreak (CDFG 2004).
2002	Coho salmon listed as threatened under the California ESA (CESA).

2003	Native American cultural use adopted as a beneficial use of the Klamath River from the Seiad Valley Hydrologic Subarea downstream to the Klamath Glen Hydrologic Subarea.
2004	First documented toxic bloom of the blue-green algae (cyanobacteria) *Microcystis aeruginosa* in Copco No. 1 Reservoir (Kann and Corum 2006).
2005	Public health warnings to avoid contact with water in Copco No. 1 and Iron Gate reservoirs due to toxic algae blooms began being posted annually.
2006	Low abundance of Klamath Basin Chinook salmon lead to severe restrictions on commercial and recreational harvest along 700 miles of the California and Oregon coast, as well as major reductions in Klamath River recreational and tribal fisheries. Broad commercial and recreational restrictions on the coast because of Klamath Basin Chinook returns were repeated in 2008, 2009, 2010, 2016, and 2017, including complete closure of commercial and recreational fisheries.
2006	Copco No. 1, Copco No. 2, and Iron Gate reservoirs identified by the USEPA for inclusion on the Clean Water Act Section 303(d) list for blue-green algae (cyanobacteria)-produced microcystin toxin as an additional cause of water quality impairment.
2010	Water deliveries from Upper Klamath Lake to Klamath Irrigation Project irrigators (and wildlife refuges) in California and Oregon significantly reduced in order to comply with requirements to protect ESA-listed suckers and provide flow augmentation for ESA-listed coho downstream of Iron Gate Dam, given dry hydrologic conditions.
2010	The Klamath Tribes limited their harvest of suckers to ceremonial use for the 25th consecutive year and experienced their 92nd year without access to salmon.
2010	Siskiyou County Advisory Election Vote on November 2, 2010 (Measure G). The Siskiyou County ballot asked, “Should the Klamath River Dams (Iron Gate, Copco 1, and Copco 2) and associated hydroelectric facilities be removed – Yes or No?” 78.84 percent of voters expressing an opinion voted “no” to dam removal, while 21.86 percent voted “yes”.
2010	Copco No. 1 Reservoir identified by the USEPA for inclusion on the California Section 303(d) List for mercury as an additional cause of water quality impairment.
2010	Klamath River from the California/Oregon state line to its confluence with the Trinity River added to the Clean Water Act Section 303(d) list for blue-green algae (cyanobacteria)-produced microcystin toxin. Iron Gate Reservoir added to the Clean Water Act Section 303(d) list for mercury.
2010	North Coast Regional Board established: (1) Site specific water quality objectives for the Klamath River; (2) an Action Plan for the Klamath River Total Maximum Daily Loads (TMDLs) addressing temperature, dissolved oxygen, nutrient, and microcystin impairments in the Klamath River; and (3) an Implementation Plan for the Klamath and Lost River Basins.
2010	USEPA approved TMDLs for the Klamath River in California.
2011	Improved abundance forecasts for Klamath River fall-run Chinook allowed for the first substantial ocean salmon fisheries off of California and Oregon to occur since 2007.
2013	NMFS and USFWS 2013 Joint Biological Opinion for the Klamath Irrigation Project, including increased minimum daily flow targets for Iron Gate Dam

	in spring and early summer months, clarifications to operations criteria for meeting requirements for minimum flows and high flows, and an adaptive management approach for minimizing fish disease.
2012–2014	In 2012, an estimated 10,000 to 15,000 migrating birds died in the Klamath Basin National Wildlife Refuge due to less water available to create wetland habitat, crowding of waterfowl during migration periods, and lethal disease outbreaks. In 2013, an estimated 9,000 migrating birds died and in 2014 an estimated 20,000 migrating birds died for the same reasons.
2012	Yurok harvest timing restrictions (Klamath River Technical Team 2013).
2013	Yurok harvest timing restrictions (Klamath River Technical Team 2014).
2016	No Yurok Tribe commercial fishery due to low returns of fall-run Chinook salmon.
2017	U.S. District Court of the Northern District of California ordered the USBR to release flushing flows from Iron Gate Dam to mitigate the effects of a parasite called *Ceratanova shasta* on outmigrating juvenile salmon and continue to implement flushing flows in future years based on specific triggers or until formal federal consultation is completed.
2017	Estimated 12,000 fall-run Chinook salmon were projected to return the Klamath River making it the smallest run on record resulting in closures of the fall-run Chinook recreational fishery and restrictions on the spring-run chinook fishery in the Klamath and Trinity rivers since record.
2017	No Yurok Tribe commercial fishery due to low returns of fall-run Chinook salmon.
2017	Karuk Tribe suspended ceremonial Chinook salmon harvest due to projected low chinook returns.

The role of the Lower Klamath Project dams in the various water quality and resource impacts listed above is part of this EIR, particularly in the description of the environmental setting for the various resource areas. As with the impacts of other facilities and actions on the Klamath River and outside the basin, the role of the dams is debated, with different stakeholders interpreting information in differing ways (see, for example, "*Fish, Farms, and the Clash of Cultures in the Klamath Basin" (*Doremus and Tarlok 2003).

2.6.2 Relationship with Klamath Hydroelectric Project

PacifiCorp currently owns and operates the Lower Klamath Project (FERC Project No. 14803) as part of the Klamath Hydroelectric Project (Klamath Hydroelectric Project) (FERC Project No. 2082). FERC exercises broad authority over most hydroelectric developments under the Federal Power Act. Among other authorities, FERC must approve and set conditions for the construction, operation, transfer of ownership and decommissioning of these hydroelectric facilities. FERC issued the original license for the Klamath Hydroelectric Project in 1956, for a term of 50 years. On March 1, 2006, the original FERC license expired. Since then, PacifiCorp has continued to operate the Klamath Hydroelectric Project (including the Lower Klamath Project complex) under annual licenses issued by FERC while PacifiCorp pursued relicensing. On June 16, 2016, at PacifiCorp's request, FERC issued an order placing the Klamath Hydroelectric Project relicensing process in abeyance.

On September 23, 2016, PacifiCorp and the KRRC filed a joint license transfer application with FERC, which seeks to transfer the J.C. Boyle, Copco No. 2, Copco No. 1, and Iron Gate dams and associated facilities to the KRRC. Concurrent with the license transfer application, the KRRC filed a license surrender application with FERC to decommission the Lower Klamath Project. The Lower Klamath Project license transfer and surrender processes are subject to FERC's approval.

2.6.3 Klamath Settlement Agreements

During the FERC relicensing process for PacifiCorp's Klamath Hydroelectric Project, a number of parties, with a range of interests including but not limited to PacifiCorp; state and federal agencies[9]; tribal governments; agriculture communities; fishery and conservation groups; local governments; and special interest groups executed several settlement agreements intended to resolve some of the problems in the Basin:

- Klamath Hydroelectric Settlement Agreement (KHSA), February 18, 2010, (later amended April 6, 2016)[10]
- Klamath Basin Restoration Agreement (KBRA), February 18, 2010
- Upper Klamath Basin Comprehensive Agreement (UKBCA), April 18, 2014
- Klamath Power and Facilities Agreement (KPFA), April 6, 2016

Among other things, the settlement agreements:

- Provided a decision-making framework and process for removal of J.C. Boyle, Copco No. 2, Copco No. 1, and Iron Gate dams and associated facilities;
- Addressed water supply and allocation issues; and
- Set forth water quality improvement and land restoration measures for the Upper Klamath Basin.

The water supply, restoration, and water quality issues all hinged on removal of the four mainstem Klamath River dams. Federal legislation was to provide much of the funding for the restoration and water supply portions of the agreements.

As originally executed, the KHSA proposed federal legislation that would have withdrawn the Klamath Hydroelectric Project from FERC's relicensing process. Instead of following the process set forth in the Federal Power Act, the original KHSA terms sought legislation to grant the Secretary of the Interior the authority to make a "Secretarial Determination" whether removing the J.C. Boyle, Copco No. 2, Copco No. 1, and Iron Gate dams and associated facilities was in the public interest and would advance salmon restoration. The agreement anticipated that the governor of each state would then be able to concur or not with the Secretarial Determination.

Federal legislation to enact the settlement agreements did not pass, and on December 31, 2015, the KBRA terminated, and on December 28, 2017 the UKBCA terminated. On April 6, 2016, some of the parties to the KHSA and KBRA executed the Klamath Power and Facilities Agreement to address the disposition of specific Oregon facilities on the Klamath River, and to commit to continue negotiations regarding certain issues addressed in the KBRA.

[9] The State Water Board is not a signatory to any of the settlement agreements.
[10] PacifiCorp is a signatory solely to the KHSA.

On April 6, 2016, the KHSA was amended to remove the need for Congressional authorization, and instead contemplate dam removal through the FERC license surrender process. The KHSA set forth the process for the signatories to form a "dam removal entity"—now the KRRC—as a non-profit organization that will, upon approval by FERC, receive ownership of the Lower Klamath Project facilities and undertake the necessary steps to remove the facilities. Pursuant to the KHSA, KRRC and PacifiCorp have initiated the FERC process, and the KRRC is now the applicant for the Proposed Project analyzed in this EIR.

2.6.4 Prior/Related Environmental Reviews

In November 2007, FERC released a final Environmental Impact Statement (EIS) under the National Environmental Policy Act (NEPA) for the Klamath Hydroelectric Project. The 2007 FERC EIS for the Klamath Hydroelectric Project examines the probable effects of a range of alternatives, including continued operations of the Lower Klamath Project dam complexes with or without fish passage improvements, and removal of some or all of the four dams and associated facilities that compromise the Lower Klamath Project. The 2007 FERC EIS is available online at: https://www.ferc.gov/industries/hydropower/enviro/eis/2007/11-16-07.asp

In accordance with the original KHSA, the 2012 KHSA EIS/EIR was prepared to support Klamath Hydroelectric Project dam removal and to inform the Secretarial Determination. On September 22, 2011, the United States Department of Interior (DOI) and the former California Department of Fish and Game, now California Department of Fish and Wildlife (CDFW) released the Draft 2012 KHSA EIS/EIR to analyze removal of four Klamath Hydroelectric Project dams for public comment. The agencies circulated the Final 2012 KHSA EIS/EIR, but DOI never entered a Record of Decision and CDFW never certified the document.

Similar to FERC's 2007 EIS, the 2012 KHSA EIS/EIR evaluated a range of project alternatives, including continued operation of the dams and associated facilities, with and without fish passage improvements, as well as removal of some or all of the dams that make up the Lower Klamath Project. The 2012 KHSA EIS/EIR is available online at: https://klamathrestoration.gov/Draft-EISEIR/download-draft-eis-eir.

In 2016, USBR developed the Klamath Facilities Removal EIS/EIR Supplemental Information Report (SIR) to summarize new information relevant to facilities removal of J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams (USBR 2016).

The 2012 KHSA EIS/EIR, FERC's 2007 NEPA document, and USBR's 2016 SIR provide a great deal of information regarding the existing Klamath Hydroelectric Project, the various alternatives for the future of the hydroelectric facilities, and the potential impacts of and mitigation measures for these alternatives. After careful consideration and review of past environmental documents prepared for the Klamath Hydroelectric Project, the State Water Board determined it should develop a separate EIR, rather than adopting one of the existing reviews, for the following reasons:

- The State Water Board's EIR will represent its independent judgement and analysis of the KRRC's Proposed Project.

- The KRRC's Proposed Project is different enough from the project considered in the previous environmental documents that further analysis was needed. It was clearer to address these changes as part of a comprehensive project than as supplements to existing evaluations.
- Since development of the previous environmental documents, new scientific information has been published about the Klamath River that warrants consideration. Again, it was clearer to address this new information in a manner integrated with prior information, rather than as a supplement to existing evaluations.
- The KBRA expired. The KBRA was evaluated in the 2012 KHSA EIR/EIS as a connected action to the then dam removal proposal. The KBRA is not part of the KRRC's Proposed Project.
- The State Water Board received multiple comments during the scoping phase that requested it perform additional environmental review of the Proposed Project.

2.7 Proposed Project

To meet the stated project objectives (Section 2.1), KRRC proposes to remove the Iron Gate, Copco No. 1, Copco No. 2, and J.C. Boyle dams and associated facilities. The Detailed Plan (USBR 2012a) and the Definite Plan (AECOM et al. 2018) constitute the applicant's Proposed Project. The Detailed Plan is available online at the following links:

https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/krrc_detail_1.pdf

https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/krrc_detail_2.pdf

The Definite Plan is presented in Appendix B of this EIR. To the extent that there is conflicting information in the Definite Plan relative to the Detailed Plan, the KRRC has indicated that information in the Definite Plan supersedes the information in the Detailed Plan.

A summary overview of the Proposed Project is presented in this section of the EIR, including an overall project schedule (Table 2.7-1), information regarding dam and powerhouse deconstruction activities (Section 2.7.1), and the proposed approach to reservoir drawdown (Section 2.7.2).

The Proposed Project would result in large sediment releases as water and sediment stored behind the Lower Klamath Project dams are released during, and to a lesser extent, following decommissioning activities. The Lower Klamath Project schedule proposes to minimize flood risks and downstream impacts due to the release of impounded reservoir sediments, as described in Section 2.7.3. For sediment deposits that remain in the reservoir footprint, the KRRC has proposed a set of reservoir restoration activities (Section 2.7.4), as well as restoration activities for upland areas (Section 2.7.5).

As part of the Lower Klamath Project, the KRRC proposes modifying fish hatchery facilities downstream of Iron Gate Dam on the Klamath River and upstream of Iron Gate

Dam on Fall Creek, and continuing operation of the hatcheries for eight years following dam removal, consistent with the Amended KHSA Section 7.6.6. Further discussion of hatchery operations is presented in Section 2.7.6 of this EIR. The Proposed Project also includes relocating the City of Yreka's water supply line for its Fall Creek diversions, which is described in Section 2.7.7 of this EIR. Environmental, safety, and quality of life measures associated with the Proposed Project are described in Section 2.7.8. The estimated Lower Klamath Project workforce is presented in Section 2.7.1.5 *Estimated Deconstruction Workforce and Work Shifts,* and land disposition and transfer associated with the Proposed Project is discussed in Section 2.7.10. Where greater detail regarding the Proposed Project is important to the analysis of specific environmental impacts, the additional description is presented in the relevant environmental impact section(s) of this EIR.

Table 2.7-1 provides the proposed schedule for facilities drawdown and removal along with associated Proposed Project activities before and after removal. Drawdown timing for J.C. Boyle, Copco No. 1, and Iron Gate reservoirs was selected to minimize impacts to salmonids and other aquatic species. Based on the distribution and life-history timing of aquatic species in the Klamath Basin, only a portion of fish populations are likely to be present in the mainstem Klamath River during the periods of greatest sediment transport between January and March (Figure 2.7-1). Most species are in tributaries which would be unaffected by the Proposed Project or are further downstream during this time where river conditions would be less influenced by sediment transport by the Proposed Project due to dilution by tributary inflows. Additionally, the timing of drawdown coincides with periods of naturally high suspended sediment in the Klamath River, to which aquatic species have adapted through avoidance and tolerance.

Table 2.7-1. Proposed Lower Klamath Project Schedule.

Dark grey shading indicates planned activities. Stippled shading represents planning for activities still under development.

[1] Definite Plan Section 8.6 Construction Schedule does not explicitly list these tasks. Timing for these tasks provided in KRRC (2018).
[2] While the specific timeline is not proposed, Iron Gate Hatchery and Fall Creek Hatchery must be operational prior to reservoir drawdown.
[3] Definite Plan - Section 8.6 Construction Schedule does not explicitly list all of the proposed road access improvement items, however they would occur before, during, and after dam removal, as needed.
[4] Proposed pipeline relocation would have to occur before Iron Gate Dam removal. The KRRC proposes that the outage associated with the final connections would preferably occur during the winter to avoid disruption to Yreka's water supply.
[5] Scheduled from November 3 to March 8.
[6] Scheduled from September 30 to December 7.
[7] Scheduled from June 18 to July 30.
[8] Copco No. 2 Dam drawdown will occur on one day (May 1, 2021)
[9] Scheduled from January 1 to March 2.
[10] Scheduled from January 4 to June 7.
[11] Scheduled for one week from June 1 to June 7.
[12] Refers to movement of additional sediment in the reservoir footprints to provide tributary connectivity and create wetlands, floodplain and off-channel habitat features. Also includes placement of large woody debris (LWD) features.

This page left blank intentionally.

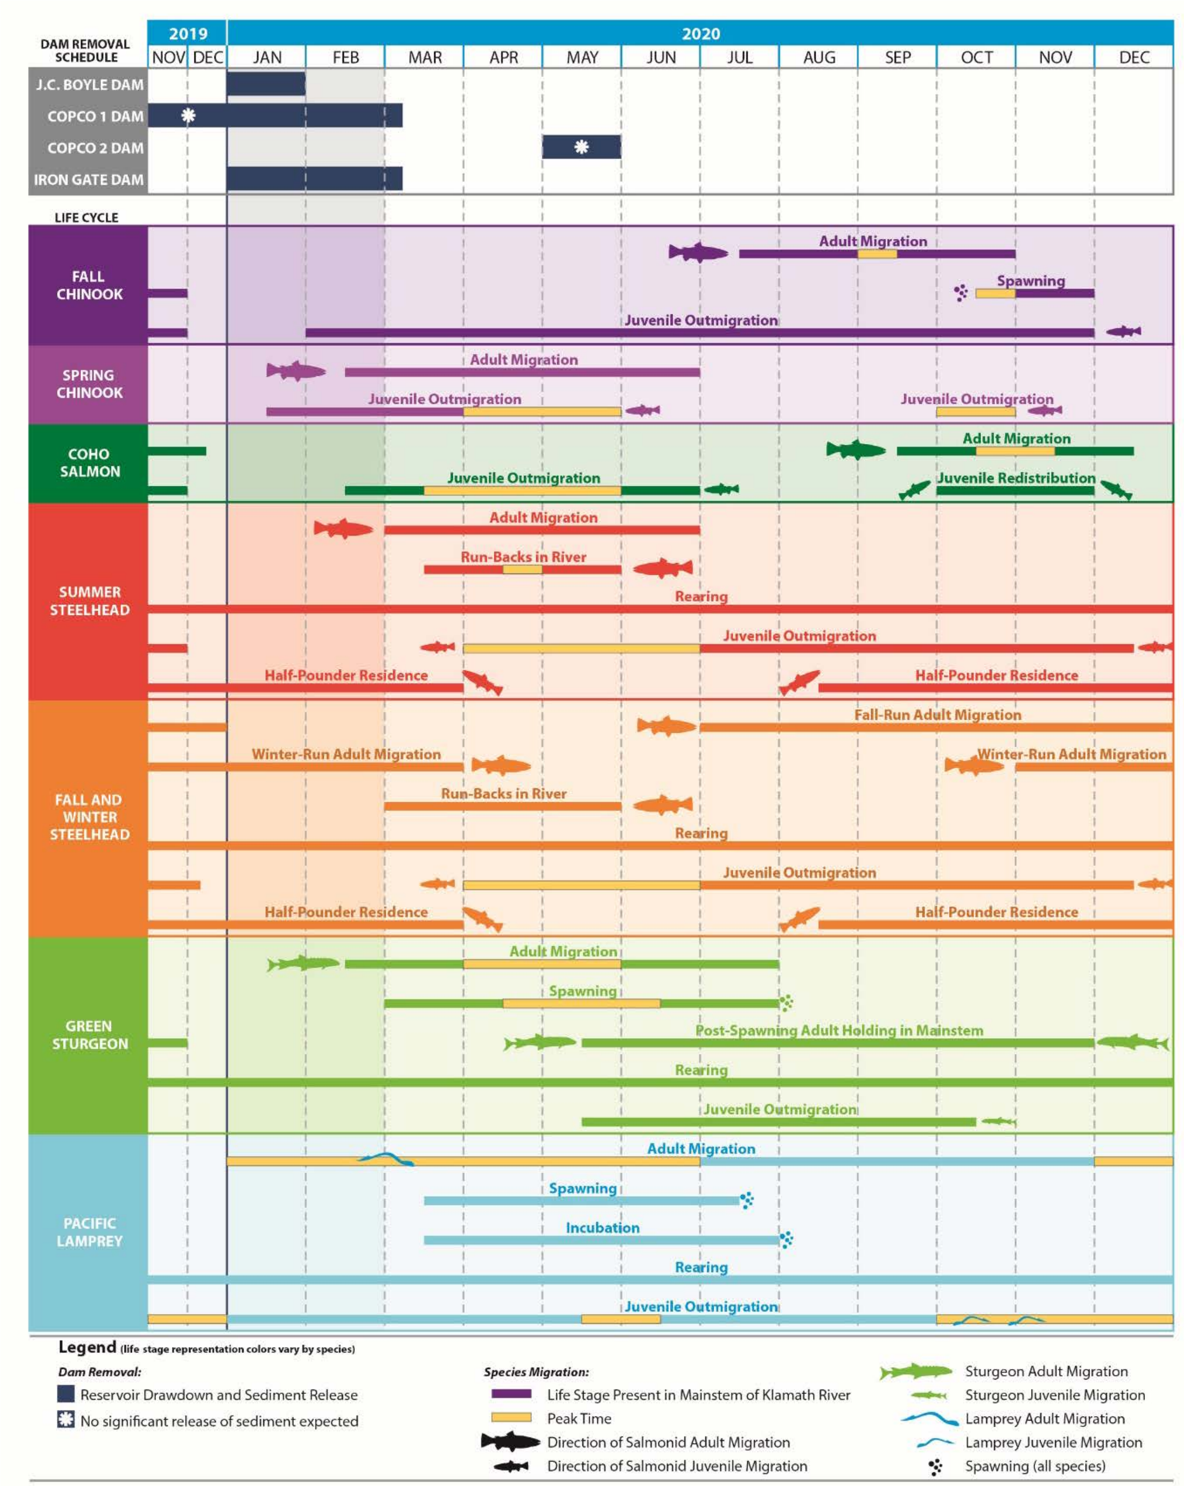

Figure 2.7-1. Distribution and Life-History Timing of Aquatic Species in the Klamath Basin. Source: CDM Smith.

2.7.1 Dam and Powerhouse Deconstruction

2.7.1.1 J.C. Boyle Dam and Powerhouse

The KRRC proposes removal of the J.C. Boyle dam, spillway and gates, powerhouse, powerhouse equipment, and concrete fish ladder. The applicant further proposes removal of ancillary facilities, such as the canal and pipeline that convey water to the powerhouse. The complete removal of the embankment section and concrete cutoff wall to the bedrock foundation are proposed to ensure long-term stability of the site and to prevent the development of a potential fish barrier in the future. In order to access the dam for deconstruction, the KRRC would perform a controlled reservoir drawdown using the spillway gates, conveyance pipeline and canal, and diversion conduit. J.C. Boyle Dam and Powerhouse features to be removed and removal plans are detailed in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*.

2.7.1.2 Copco No. 1 Dam and Powerhouse

Deconstruction Activities

Features to be removed for Copco No. 1 Dam and Powerhouse are summarized in Table 2.7-2. An overview of the facilities and removal plans is found below. Additional details are presented in Appendix B: *Definite Plan*.

The Detailed Plan (USBR 2012a) included sequential notching of Copco No. 1 Dam as part of reservoir drawdown and dam deconstruction, where the notching option would have included making releases through a combination of modifications to the existing diversion tunnel to restore operation through three existing 6-foot-diameter pipes in the diversion tunnel intake structure, in addition to a series of 13 notches sequentially excavated in the left abutment of the dam. Successful reservoir drawdown using the notching option would be highly dependent on successful dam demolition and notching during January and February, with the following identified constructability and schedule risks: safety of construction workers operating on narrow, steep access roads during winter months with wet and icy conditions; weather delays that are likely to be worse in the wettest years when reservoir drawdown would rely on notching more than in dry years; and incomplete reservoir drawdown during wet years if notching is not complete. Due to these risks, KRRC is no longer proposing notching as the preferred plan for demolition of this dam (Appendix B: *Definite Plan*).

Instead, as a necessary first step for removal of Copco No. 1 Dam, the KRRC's Proposed Project would install a new, larger (14- by 16-foot) roller gate on the downstream end of the existing diversion tunnel, to be used as the primary mechanism for reservoir drawdown. Modifications to the diversion tunnel would begin by June of the year prior to reservoir drawdown (Table 2.7-1). The KRRC then proposes the complete removal of the concrete gravity arch dam between the left abutment rock contact and the concrete powerhouse intake structure on the right abutment (Figure 2.7-2, 1 of 4) to ensure long-term stability of the site. So that river bed sediment mobilization through natural channel processes does not expose the concrete foundation of the dam and create a fish passage barrier or prevent bedload movement in the active bed layer, removal of Copco No. 1 Dam would occur to 20 feet below the pre-dam streambed at the dam, or to the approximate elevation of 2,463.5 feet (Appendix B: *Definite Plan*).

The KRRC's Proposed Project indicates dam demolition would occur over approximately four months using blasting, hydraulic excavators, conventional or diamond-wire sawcutting, and drilling to remove the dam in sections from the top of the dam to 20 feet below the streambed level at the dam. After May 15 of dam removal year 2 (Table 2.7-1), conventional drilling and blasting methods would remove the dam in horizontal sections (lifts) with each section estimated to be approximately 12 feet high. Drilling would likely require the most time during the demolition and control the overall rate of dam removal so drill crews would work two 10-hour shifts, 5 days per week. Blasting is estimated to occur an average of between three and six shots per day for up to 16 weeks. Concrete rubble from the dam removal would be dropped to the base of the dam to form a temporary access road between the dam base, the powerhouse, and the powerhouse intake structure, then hauled by truck to the disposal site on the right abutment. The temporary access road would be removed once it is no longer necessary.

Table 2.7-2. Copco No. 1 Dam and Powerhouse Decommissioning and Removal Proposal.

Feature[1]	KRRC Proposal
Concrete Dam	Remove to elevation 2,463.5 feet, which is 20 feet below original river channel bottom
Spillway Gates and Operators, Deck, Piers	Remove
Penstocks	Remove
Powerhouse Intake Structure	Remove
Gate Houses on Right Abutment	Remove
Diversion Control Structure	Remove[2]
Tunnel Portals[3]	Retain the tunnel, plug the tunnel portals with reinforced concrete
Powerhouse (including mechanical and electrical equipment)	Remove
Powerhouse Hazardous Materials (transformers, batteries, insulation)	Remove
Four 69-kv Transmission Lines (3.03 miles total) (including poles and transformers)	Remove
Switchyard	Remove
Warehouse and Residence[4]	Remove

[1] Feature as presented in Appendix B: *Definite Plan – Table 5.3-1*.
[2] The existing diversion control structure includes gate hoists, stems, and wire ropes, which would be demolished along with unstable concrete as part of modifying the diversion structure prior to reservoir drawdown. Proposed features to modify the diversion control structure (i.e., new downstream tunnel gate and portal, new upstream blind flanges) would be removed as part of reservoir drawdown and dam deconstruction.
[3] Refers to the Diversion Tunnel shown in Figure 2.7-2.
[4] Refers to the Maintenance Building and the North and South Residences shown in Figure 2.7-2.

The spillway components would be removed as the reservoir is drawn down to below the spillway crest (to be completed by January 1 of dam removal year 2). Once the reservoir is drawn down to an approximate elevation of 2,590 feet, a barge-mounted crane would be used to remove spillway gates and operators, the spillway bridge deck, and the spillway gate piers in the dry. The barge-mounted crane would then be removed from the site.

The KRRC proposes that the powerhouse removal would occur as the reservoir is drawn down through the new large gate structure at the downstream end of the diversion tunnel. Gate houses and penstocks would be demolished, and mechanical and electrical equipment would be removed from the powerhouse. The above grade portion of the powerhouse would be demolished and prepared for use as a part of a temporary construction access road between the dam base, the powerhouse, and the powerhouse intake structure. The KRRC proposes to construct and maintain temporary cofferdams in the river channel and to use sump pumps as required to enable dewatered conditions during the removal of the remaining powerhouse portions, the diversion control structure, and concrete in the powerhouse intake structure on the right abutment. The cofferdams would be supported using re-purposed on-site concrete rubble from Copco No. 1 Dam, plus as-needed source material from an existing borrow site located on the hillslope above Copco No. 1 village, where the borrow site was used during dam construction. Sump pumps and cofferdams would be removed from the river channel when they are no longer needed.

The KRRC proposes to plug the upstream diversion tunnel intake, then demolish the new diversion gate structure and plug the downstream portal of the diversion tunnel with concrete.

Site demobilization would occur after the dam site, staging areas, and concrete disposal site are restored, including topsoil and seed placement, where required as explained in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* and the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*).

Construction Access and Road Improvements

An overview of construction access roads required for removal of Copco No.1 Dam and Powerhouse, and associated work, are shown in Figure 2.7-2. Existing conditions of the highways, local roads, and structures to be used were observed in the field to identify deficiencies and determine if improvements are necessary for mobilization and/or hauling during construction and demolition activities. The Proposed Project in the KRRC's Definite Plan *(*Appendix B: *Definite Plan*) details the below road, bridge, and culvert improvements to facilitate access for dam removal vehicles and equipment, to ensure safety for public and project road users during dam deconstruction activities, and to return roads used by the Proposed Project related vehicles in an acceptable state, mitigating any potential reduction in function attributed to the dam removal work. For additional details, see Appendix B: *Definite Plan − Table 7.4.1, Sections 5.2.2, 5.3.2, 5.4.2* and *5.5.2*, and *Appendix K*.

Road and Bridge Improvements/Replacements

- Copco Road from I-5 to Ager Road—some pavement rehabilitation
- Copco Road from Ager Road to Lakeview Road—poor condition, some pavement rehabilitation
- Copco Road Bridge—potential erosion protection to abutments/ pier
- Dry Creek Bridge—to be replaced, strengthened, or provided with a temporary crossing
- Copco Road between Lakeview Road and Daggett Road—poor condition, some pavement rehabilitation
- Jenny Creek Bridge—to be replaced post-construction
- Copco Road from Daggett Road to Copco Access Road—some road surface rehabilitation during construction

- Fall Creek Bridge—to be replaced
- Copco Access Road—grading and clearing required
- Barge Access to Copco Lake—minor access improvements for barge/crane, boat ramp extension
- Ager Beswick Road—minor access improvements for barge/crane, boat ramp extension at Mallard Cove
- Daggett Road—some road surface rehabilitation during construction
- Daggett Road Bridge—to be replaced, strengthened or provided with a temporary crossing.
- Lakeview Road Between Copco Road and Disposal Site—some road surface rehabilitation during construction
- Lakeview Road Bridge—to be replaced, strengthened or provided with a temporary crossing.
- Powerhouse Access Road—some road surface rehabilitation during construction
- Upstream Left Abutment Access Road—to be re-established then reclaimed post-construction
- Access Road from Long Gulch Recreational Facility to Lakeview Road—some road surface rehabilitation during construction.
- Access Road from Overlook Point Recreational Facility to Copco Road—some road surface rehabilitation during construction.

Culvert Replacements

- Copco Road at Beaver Creek, East Fork Beaver Creek, Raymond Gulch, West Fork Unnamed Creek, Scotch Creek, 200 feet east of Scotch Creek, small cross-culverts between Brush Creek and Scotch Creek, Camp Creek
- Patricia Avenue at East and West Forks Unnamed Creek
- Deer Creek
- Indian Creek
- Daggett Road at Fall Creek

For Copco No. 1 specifically, three roads would have pavement or road surface rehabilitation as necessary during or post-construction, temporary traffic controls during road improvements, and construction signage; two bridges would be replaced; one road would be regraded and cleared; and two boat ramps would be extended. The delivery of off-road construction equipment, including cranes, large excavators, loaders, and large capacity dump trucks would be by special tractor-trailer vehicles operating under "wide load" restrictions and at appropriate speeds.

Staging Areas and Disposal Sites

Construction staging areas and a disposal site for removal of Copco No.1 Dam and Powerhouse are shown within the Limits of Work in Figure 2.7-2. The contractor would need to mobilize construction equipment to the site by approximately June of the year prior to drawdown to prepare the staging areas and disposal site and construct the diversion tunnel improvements.

The primary 2.3-acre staging area for the Copco No. 1 Dam complex would be located on the right abutment near the existing Copco No. 1 switchyard (Figure 2.7-2, tile 1 of 4). Two smaller staging areas are in the near vicinity (0.6 acre across the road and 0.5 acre near the penstocks) (Figure 2.7-2, tile 1 of 4).

A single 3.5-acre disposal site, located on the right abutment at the current location of a maintenance building and the vacant south residence (Figure 2.7-2, tile 1 of 4), would be used for concrete debris generated from the removal of the dam and powerhouse as detailed in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*. The disposal site would be graded as a hill (maximum fill height of about 55 feet) contoured to blend into the surrounding topography. Preparation of the disposal area would include clearing of vegetation, demolition of the two structures, removal of transmission lines, and stripping and stockpiling of excavated topsoil for later use. After placement of the concrete debris (without rail and rebar), the on-site disposal area would be covered with topsoil and the excavated embankment material from Copco No. 2 Dam (see Section 2.7.1.3 *Copco No. 2 Dam and Powerhouse*), graded, sloped for drainage, and hydroseeded. Compaction of materials placed in the disposal area other than by bulldozers spreading the materials and equipment travel would not be required.

Erosion monitoring would be completed on an annual basis for five years following placement to assess whether significant erosion and slope deterioration has occurred. If significant erosion occurs, the eroded area shall be repaired.

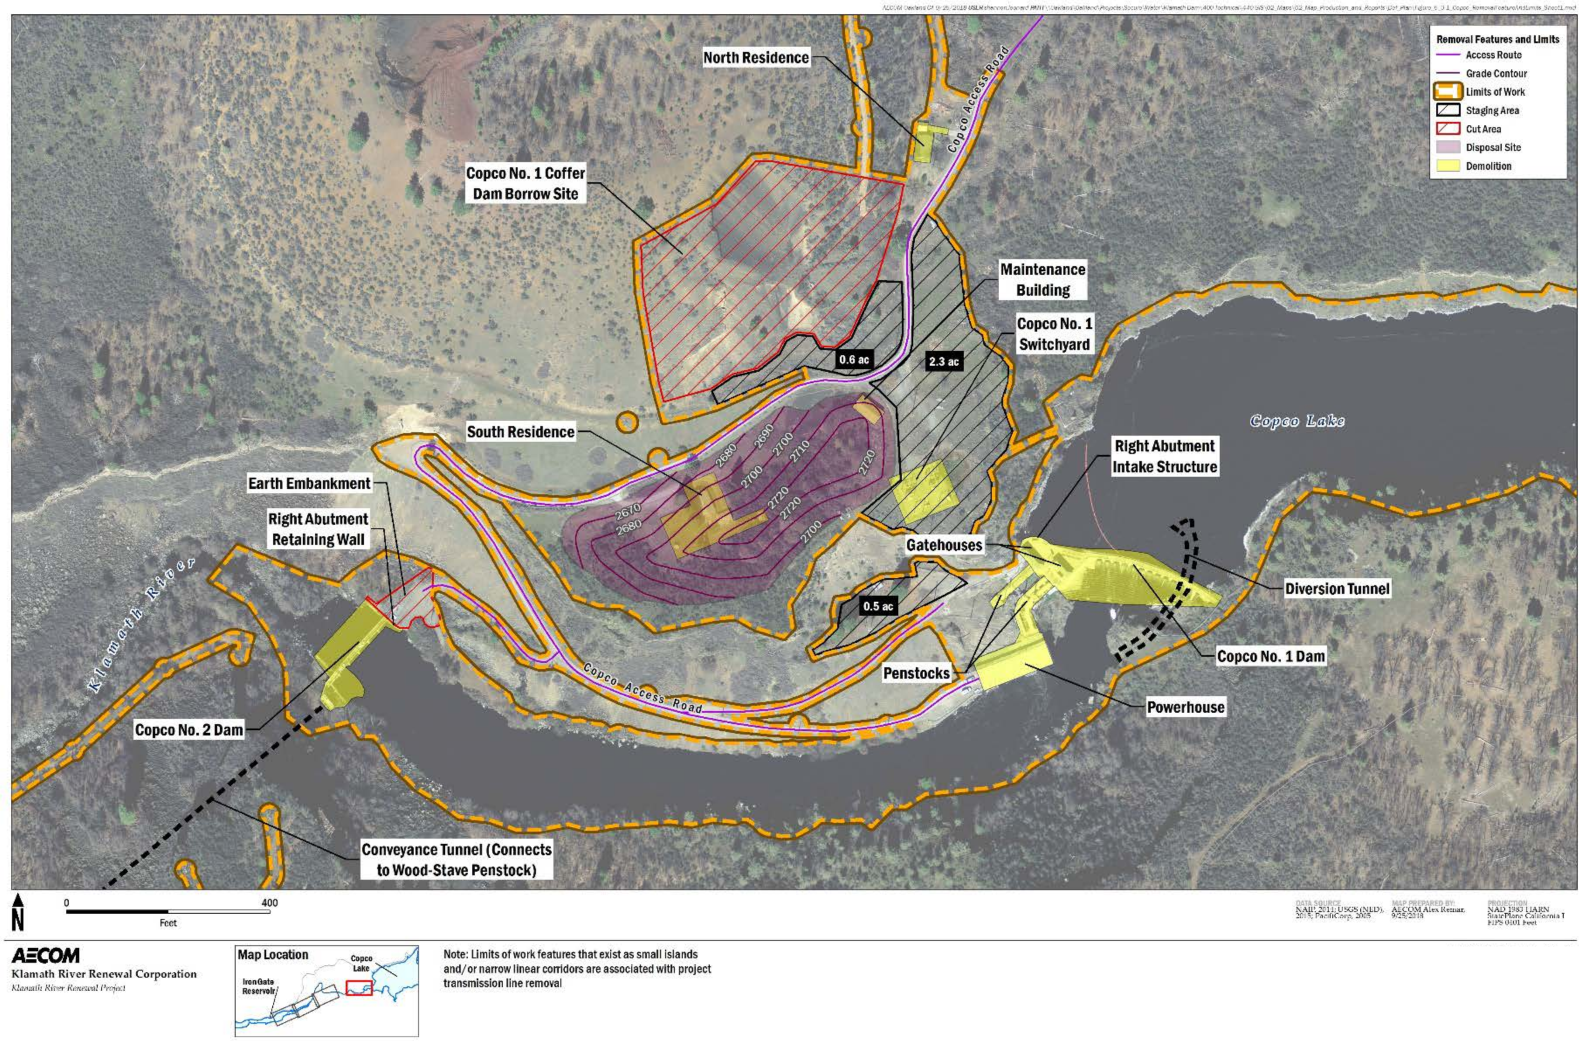

Figure 2.7-2. Copco No. 1 and Copco No. 2 Dam Removal Features and Limits of Work (1 of 4).

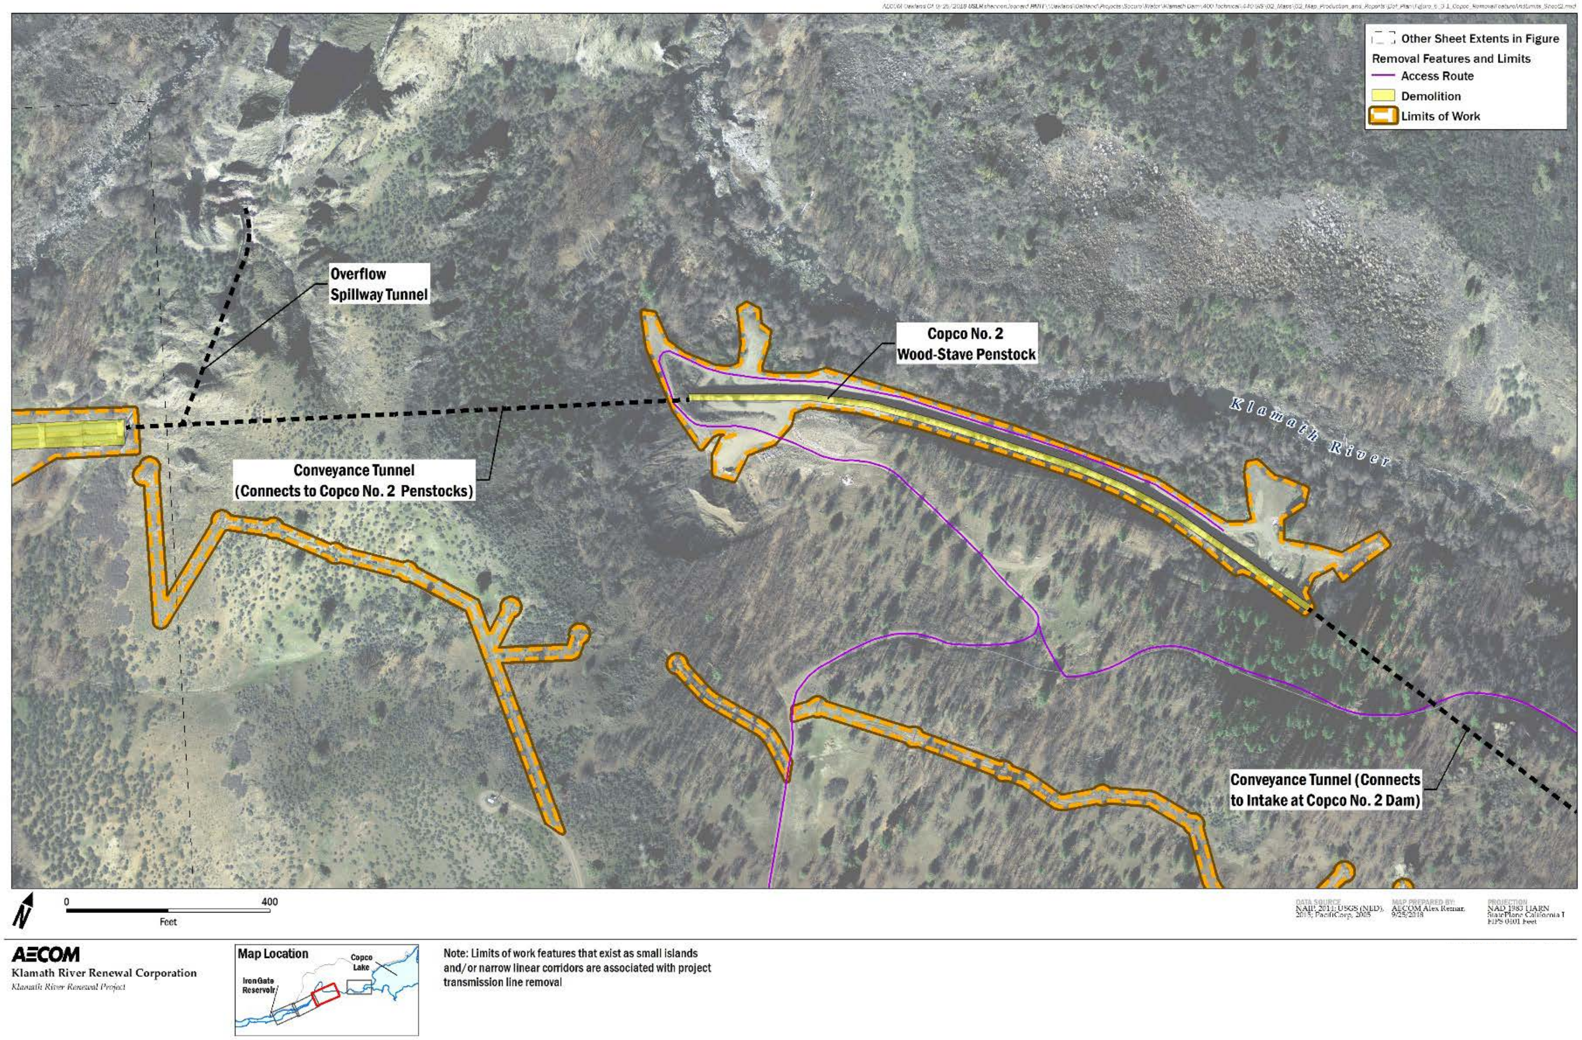

Figure 2.7-2. Copco No. 1 and Copco No. 2 Dam Removal Features and Limits (2 of 4).

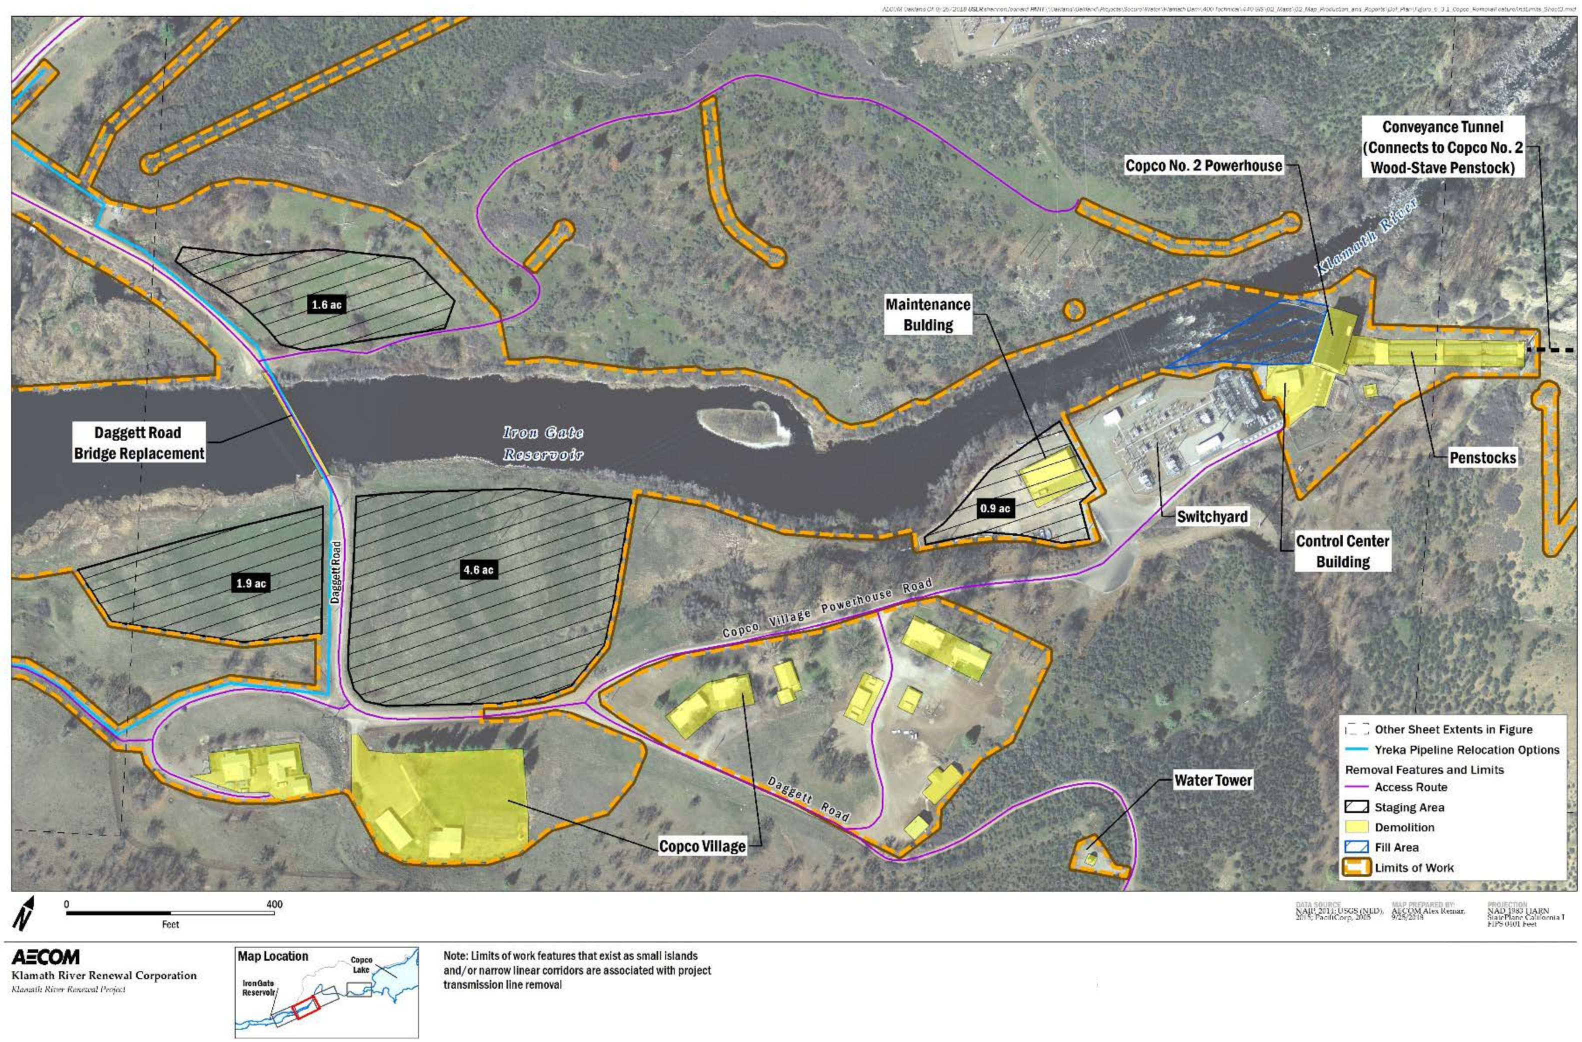

Figure 2.7-2. Copco No. 1 and Copco No. 2 Dam Removal Features and Limits of Work (3 of 4).

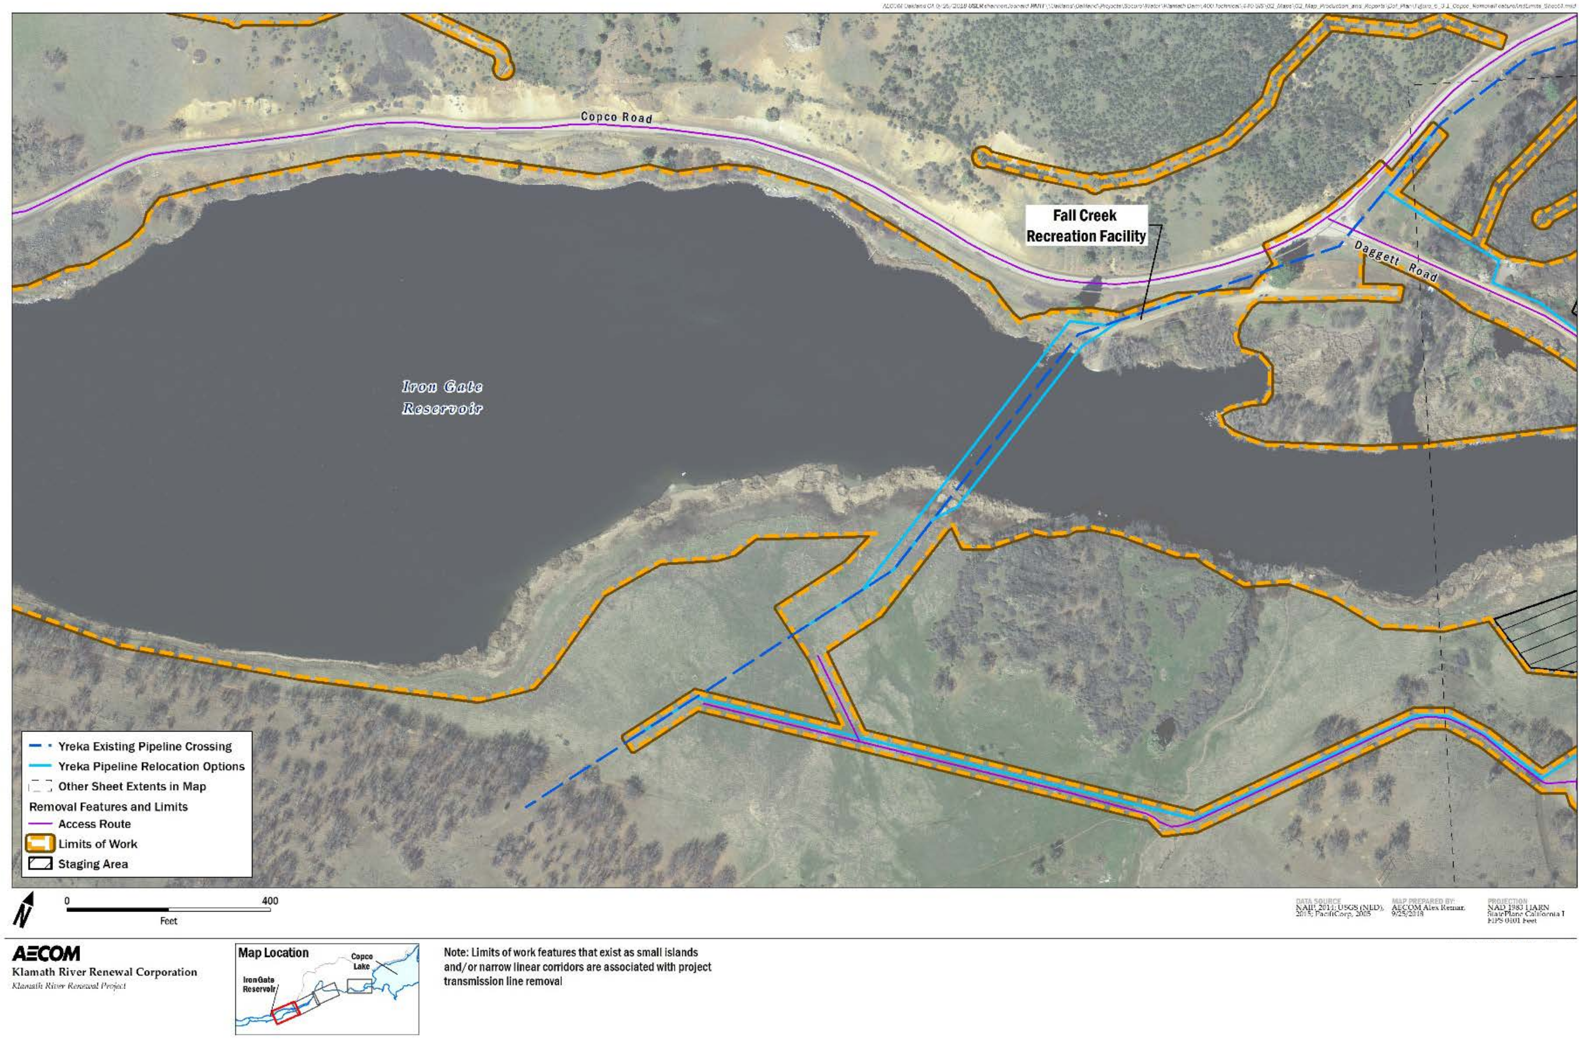

Figure 2.7-2. Copco No. 1 and Copco No. 2 Dam Removal Features and Limits of Work (4 of 4).

Imported Materials and Waste Disposal

The most likely import materials for supporting dam removal include gravel surfacing from a commercial quarry for temporary haul roads, sheetpile or H-piles for construction of cofferdams (in addition to the concrete rubble and borrow pit materials described above), topsoil, seed and mulch materials, and minor quantities of ready-mix concrete and reinforcing steel from local commercial sources for tunnel plugs. Additional imported materials would be necessary for culverts, pavement or road surface improvements, signage, and bridge replacements. Construction of the new gate structure for Copco No. 1 in dam removal year 1 would require importing mechanical equipment, additional reinforcing steel, and potentially ready-mix concrete for lining the diversion tunnel, if inspections determine it is necessary.

Estimated quantities of materials generated during removal of Copco No. 1 Dam and Powerhouse, numbers of truck trips, and approximate haul distances for waste disposal in miles per round trip (miles RT) are detailed in Table 2.7-3 based on the information itemized in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 7 Road Improvements)* and updated by KRRC based on further investigations since the release of the Definite Plan (S. Leonard, AECOM as KRRC Technical Representative, pers. comm., November 2018). Excavated concrete would be placed in the on-site disposal site described above. Rail and reinforcing steel would be separated from the concrete prior to placement in the disposal area and hauled to a local recycling facility. All mechanical and electrical equipment would be hauled to a suitable commercial landfill or salvage collection point (e.g., Yreka Transfer Station, Yreka, CA). The estimated haul distances for waste disposal not on-site assumed the Yreka Transfer Station in Yreka, CA. The Yreka Transfer Station is a Class III sanitary landfill with a remaining capacity of approximately 3,924,000 yd^3 (2010) that accepts construction, demolition, and mixed municipal waste and a medium volume transfer station accepting metals and mixed municipal recyclable materials.

Table 2.7-3. Estimated quantities of waste disposal for full removal of Copco No. 1 Dam.

Waste Material	In-Situ Quantity	Bulk Quantity[1]	Disposal Site[2]	Peak Daily Trips[3]	Total Trips[4]
Concrete	75,900 yd^3	104,00 yd^3	On-site	2 units/50 trips (unpaved road)	4,430 trips (2 miles RT)
Rebar	1,100 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	110 trips (62 miles RT)
Mech. and Elec.	1,100 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	140 trips (62 miles RT)
Building Waste	7 buildings; 7,500 ft^2	1,700 yd^3	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	90 trips (62 miles RT)
Power Lines	4.3 miles of 69-kV and smaller	--	Transfer station near Yreka, CA	--	5 trips (62 miles RT)
Wood Utility Poles	120 poles	--	Transfer station near Yreka, CA	--	8 trips (62 miles RT)

Source: S. Leonard, AECOM as KRRC Technical Representative, pers. comm., November 2018

1 Volumes increased 30 percent for concrete rubble from reinforced concrete and 40 percent for concrete rubble from mass concrete.

2 Currently, solid waste is transferred approximately 45 miles from the Yreka Transfer Facility to the Dry Creek Landfill facility near White City Oregon.

3 Peak daily trips for each site are based on the number of vehicles (units) shown, operating within one 8-hour shift.

4 Total trips of concrete assume off-highway articulated trucks with a nominal load capacity of 22 yd^3. Total trips for hauling rebar using truck tractor-trailers is based on 10 tons per trip. Total trips for hauling mechanical and electrical items using truck tractor-trailers is based on 8 tons per trip. Total trips for building waste using truck tractor-trailers is based on 10 yd^3 per trip. Mileage is reported in miles per round trip (miles RT).

Potential hazardous materials at Copco No. 1 Dam and Powerhouse include asbestos, batteries, bearing and hydraulic control system oils, treated wood, flammable gases, nonflammable gases, flammable and combustible liquids, mercury in older light switches, contaminated soils near painted exterior equipment, and coatings containing heavy metals in the powerhouse, on the exterior surfaces of the steel penstocks, air vents, and other painted materials. All hazardous materials would be handled and disposed of as hazardous waste at an approved hazardous waste facility in accordance with applicable federal and state regulations. Additional details and their disposal are provided in the KRRC's Hazardous Material Management Plan (Appendix B: *Definite Plan – Appendix O3*) and discussed in Section 3.21 *Hazards and Hazardous Materials* of this EIR.

2.7.1.3 Copco No. 2 Dam and Powerhouse

Deconstruction Activities

The KRRC's Proposed Project would remove the Copco No. 2 Dam, the unnamed reservoir associated with the Copco No. 2 Dam (hereinafter referred to as Copco No. 2 Reservoir), the Copco No. 2 Powerhouse, and their associated structures and equipment (Table 2.7-4). Additional details are presented in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*. The KRRC proposes to remove the Copco No. 2 dam, the associated structures, and drain the reservoir in dam removal year 2 by lowering the reservoir water surface elevation, constructing temporary cofferdams to dry out sections of the construction area, removing the structures in sections under dry conditions, and restoring the dam site after the structures are removed.

The KRRC proposes to begin preparing for deconstruction of Copco No. 2 Dam on about May 1 of dam removal year 2 by closing the caterpillar gate at the power penstock intake structure to stop releases to Copco No. 2 Powerhouse and cease power generation. Controlled releases would be made through the gated spillway during the low flow period to draw the reservoir down from reservoir water surface elevation 2,486.5 feet to reservoir water surface elevation 2,481.5 feet in one day using the two right-hand side spillway gates.

The KRRC's Proposed Project would begin physical deconstruction of Copco No. 2 Dam with the removal of equipment and the concrete pad from the dike crest to provide room for demolition equipment and for construction access as described in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*. A temporary cofferdam would be constructed within the river channel to isolate the two left-hand spillway bays and the power penstock intake structure (Figure 2.7-2, tile 1 of 4). The spillway gates, hoists, bridge deck, and concrete crest structure would be removed to elevation 2,457.5 feet in the dry. The spillway gates and hoists would be removed by a large crane for loading onto highway trucks and heavy-haul trailers. The reinforced concrete spillway bridge deck and piers could be removed in pieces by hydraulic excavators, or in sections by conventional or diamond-wire sawcutting. Removal of the remainder of the spillway concrete structure would likely be performed using conventional drilling and blasting methods as each portion is dewatered.

For the conveyance tunnel, trash racks, a caterpillar gate, and a concrete structure would be removed, and the tunnel would be plugged "in the dry" (i.e., dewatered conditions). The left river bank would be restored, the temporary cofferdam would be removed, and the reservoir water surface would be allowed to stabilize at approximately elevation 2,463.5 through the left-hand dam breach.

Subsequently, the KRRC proposes a second temporary cofferdam would be constructed within the river channel to isolate the three remaining spillway bays on the right-hand side as described in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*. The spillway gates, hoists, bridge deck, and concrete crest structure would be removed to elevation 2,457.5 feet in the dry. Removal methods for the right-hand side spillway section would be similar to the removal of the left-hand side spillway section with a large crane removing the spillway gates and hoists, hydraulic excavators or sawcutting removing the reinforced spillway bridge deck and piers in pieces, and conventional drilling and blasting for the remainder of the spillway concrete structure as each portion is dewatered. After removal of the right-hand side spillway section is completed, the earth embankment and temporary cofferdam would be removed.

Similar to cofferdams at Copco No. 1, the Copco No. 2 cofferdams would be constructed using concrete rubble from Copco No. 1 Dam, plus borrow material from the existing site located on the hillslope above Copco No. 1 village that was used during dam construction and could be reactivated for cofferdam source material.

Table 2.7-4. Copco No. 2 Dam and Powerhouse Removal Proposal.

Feature[1]	KRRC Proposal
Concrete Dam	Remove
Spillway Gates, Structure	Remove
Power Penstock Intake Structure and Gate	Remove
Tunnel Portals[2]	Retain the tunnel, plug the tunnel portals with reinforced concrete
Embankment Section and Right Sidewall	Remove
Basin Apron and End Sill	Remove
Remnant Cofferdam Upstream of Dam	Remove
Wood-stave Penstock	Remove
Concrete Pipe Cradles	Remove
Steel Penstock, Supports, Anchors	Remove
Powerhouse (including mechanical and electrical equipment)	Remove
Powerhouse Hazardous Materials (transformers, batteries, insulation)	Remove
Powerhouse Control Center Building, Maintenance Building, Oil and Gas Storage Building	Remove
69-kV Transmission Line, 0.14 mile	Remove
Switchyard	Retain – the switchyard is not part of the Proposed Project
Tailrace Channel	Backfill
Copco Village (including former cookhouse/bunkhouse, garage/storage building, bungalow with garage, 3 modular houses, 4 ranch-style houses, and school house/community center)	Remove

[1] Feature as presented in Appendix B: *Definite Plan – Table 5.4-1*.
[2] Refers to Conveyance Tunnel and Overflow Spillway Tunnel shown in Figure 2.7-2.

The KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* proposes that removal of the wooden-stave penstock and Copco No. 2 Powerhouse (Figure 2-7.2, tiles 2 of 4 and 3 of 4) would occur following closure of the caterpillar gate and shutdown of the powerhouse on or near May 1 of dam removal year 2. The wooden-stave penstock would be plugged with reinforced concrete at the tunnel portal at each end of the penstock. A third cofferdam would be constructed in the Copco No. 2 Powerhouse tailrace channel for removal of the powerhouse in the dry and during the low flow period. Sump pumps would be used to dewater the area and would be removed when they are no longer needed. The cofferdam would remain in place within the tailrace channel and would be backfilled to restore the left river bank. KRRC proposes to source cofferdam material from two areas near the powerhouse: (a) the wide bench/terrace where the maintenance shop to be demolished is located and/or (b) the toe of the hillslope nearest the powerhouse.

Site demobilization would occur after the dam site, staging areas, and concrete disposal site are restored, including topsoil and seed placement, where required as explained in the KRRC's Definite Plan (Appendix B: *Definite Plan – Section 5 Dam Removal Approach*) and the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*).

Construction Access and Road Improvements

The KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* details several road improvements to facilitate access for dam removal vehicles and equipment, to ensure road safety for the public during dam deconstruction activities. The KRRC proposes to return roads used for the Proposed Project to an acceptable state, including mitigating any potential reduction in function attributed to the dam removal work. The majority of the construction access roads and associated improvements that would be required for removal of Copco No. 2 Dam and Powerhouse would be the same as for the Copco No. 1 Dam and Powerhouse (Figure 2.7-2). In addition to the road improvements, the removal of Copco No. 2 Powerhouse and the wooden-stave penstock specifically would require one bridge replacement, road surface maintenance as necessary during or post-construction, temporary traffic controls during road improvements, and construction signage for one road. The construction access roads for the removal of Copco No. 2 Powerhouse and the wooden-stave penstock are shown within the Limits of Work on Figure 2.7-2, tiles 2 of 4 and 3 of 4. The delivery of off-road construction equipment, including cranes, large excavators, loaders, and large capacity dump trucks would be by special tractor-trailer vehicles operating under "wide load" restrictions and at appropriate speeds.

Staging Areas and Disposal Sites

The KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* proposes the staging areas and disposal sites for removal of Copco No. 2 Dam and Powerhouse would be the same as for Copco No. 1 Dam and Powerhouse. The staging areas and disposal sites for removal of Copco No. 2 Powerhouse and the wooden-stave penstock are shown within the Limits of Work on Figure 2.7-2, tiles 2 of 4 and 3 of 4. Equipment staging areas for removal of the wooden-stave penstock and the powerhouse would be as shown in Figure 2.7-2, tile 3 of 4. Concrete rubble generated from removal of Copco No. 2 Dam would be permanently buried (without rail and rebar) in the disposal site described for Copco No. 1 Dam. After placement of the concrete debris, earth materials generated from removal of Copco No. 2 Dam would be used as cover over the concrete rubble at the disposal site. The disposal site would then be graded, sloped for drainage, and hydroseeded as detailed in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*.

Erosion monitoring would be completed on an annual basis for 5 years following placement to assess whether significant erosion and slope deterioration has occurred. If significant erosion occurs, the eroded area shall be repaired.

Imported Materials and Waste Disposal

Imported materials and waste disposal for removal of Copco No. 2 Dam and Powerhouse would be the same as for Copco No. 1 Dam and Powerhouse (Section 2.7.1.2 *Copco No. 1 Dam and Powerhouse*). In Table 2.7-5 below are the estimated quantities of materials generated during removal of Copco No. 2 Dam and Powerhouse, numbers of truck trips, and approximate haul distances for waste disposal in miles per round trip (miles RT) based on the information itemized in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* and updated by KRRC based on further investigations since the release of the Definite Plan (S. Leonard, AECOM as KRRC Technical Representative, pers. comm., November 2018).

Table 2.7-5. Estimated quantities of waste disposal for full removal of Copco No. 2 Dam.

Waste Material	In-Situ Quantity	Bulk Quantity[1]	Disposal Site[2]	Peak Daily Trips[3]	Total Trips[4]
Earth	1,800 yd^3	2,100 yd^3	On-site	2 units/50 trips (unpaved road)	100 trips (2 miles RT)
Concrete at Dam	6,600 yd^3	8,500 yd^3	On-site	2 units/50 trips (unpaved road)	390 trips (2 miles RT)
Concrete at Powerhouse	6,300 yd^3	8,100 yd^3	Tailrace area	Dispose at site (no hauling)	0
Rebar at Dam	300 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	30 trips (62 miles RT)
Rebar at Powerhouse	100 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	10 trips (56 miles RT)
Mech. and Elec. at Dam	300 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	40 trips (62 miles RT)
Mech. and Elec. at Powerhouse	2,600 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	320 trips (56 miles RT)
Building Waste	14 buildings 43,000 ft^2	9,500 yd^3	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	480 trips (56 miles RT)
Treated Wood (Wood-Stave Penstock)	700 tons	--	Landfill near Anderson, CA	1 units/2 trips (Interstate 5)	70 trips (280 miles RT)
Power Lines	6.7 miles of 69-kV and smaller	--	Transfer station near Yreka, CA	--	7 trips (62 miles RT)
Wood Utility Poles	100 poles	--	Transfer station near Yreka, CA	--	7 trips (62 miles RT)

Source: S. Leonard, AECOM as KRRC Technical Representative, pers. comm., November 2018

1 Volumes increased 30 percent for concrete rubble from reinforced concrete and 20 percent for loose earth materials.

2 Currently, solid waste is transferred approximately 45 miles from the Yreka Transfer Facility to the Dry Creek Landfill facility near White City Oregon.

3 Peak daily trips for each site are based on the number of vehicles (units) shown, operating within one 8-hour shift.

4 Total trips of earthfill or concrete assume off-highway articulated trucks with a nominal load capacity of 22 yd^3. Total trips for hauling rebar using truck tractor-trailers is based on 10 tons per trip. Total trips for hauling mechanical and electrical items using truck tractor-trailers is based on 8 tons per trip. Total trips for building waste using truck tractor-trailers is based on 10 yd^3 per trip. Mileage is reported in miles per round trip (miles RT).

Potential hazardous materials at Copco No. 2 Dam and Powerhouse include creosote-treated wooden-stave (redwood) penstock, treated wood, asbestos, batteries, bearing and hydraulic control system oils, flammable and nonflammable gases, flammable and combustible liquids, mercury in older light switches, contaminated soils near painted exterior equipment, coatings containing heavy metals in the powerhouse, on the exterior surfaces of the steel penstocks, air vents, and other painted materials, a fueling facility containing above-ground gasoline (1,000 gallon) and diesel (500 gallon) tanks, and underground septic systems used for seven residences near the powerhouse. All hazardous materials would be handled and disposed of as hazardous waste at an approved hazardous waste facility in accordance with applicable federal and state regulations. Additional details are provided in the KRRC's Hazardous Material Management Plan (Appendix B: *Definite Plan – Appendix O3*) and discussed in Section 3.21 *Hazards and Hazardous Materials* of this EIR.

2.7.1.4 Iron Gate Dam and Powerhouse

Deconstruction Activities

The KRRC's Proposed Project would remove the Iron Gate Dam, the Iron Gate Powerhouse, and associated structures and equipment as described in the KRRC's Definite Plan (Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*. The KRRC proposes removal between June 1 and September 30 of dam removal year 2 by lowering the reservoir water surface elevation, removing the fish facilities near the base of the dam, excavating the dam, removing the Iron Gate Dam associated structures and their equipment summarized in Table 2.7-6, and restoring the dam site after construction activities are completed. Modifications to Iron Gate Hatchery, including removal of the fish trapping and holding facilities located on random fill downstream of the dam, would be completed prior to drawdown activities so that Iron Gate Hatchery operations would continue during reservoir drawdown.

Features to be removed or retained for Iron Gate Dam and Powerhouse are summarized in Table 2.7-6 and are discussed briefly below. Additional details are presented in the KRRC's Definite Plan (Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*.

Table 2.7-6. Iron Gate Dam and Powerhouse Removal and Decommissioning Proposal.

Feature[1]	KRRC Proposal
Embankment Dam, Cutoff Walls	Remove
Penstock Intake Structure and Footbridge	Remove
Penstock	Remove
Water Supply Pipes and Aerator	Remove
Spillway Structure	Retain and bury to extent practicable
Powerhouse (including mechanical and electrical equipment)	Remove
Powerhouse Hazardous Materials (transformers, batteries, insulation)	Remove
Powerhouse Tailrace Area	Backfill
Fish Trapping and Holding Facilities on Dam (fish ladder and trapping and holding facilities)	Remove
Iron Gate Fish Hatchery	Fish ladder and holding tanks at the toe of the dam would be removed, as would the cold-water supply for the hatchery; these facilities would be relocated such that the hatchery remains operational for eight years after the removal of Iron Gate Dam (see also Section 2.7.6)
Switchyard	Remove
69-kV Transmission Line, 0.5 mi	Remove
Diversion Tunnel Intake Structure and Footbridge	Remove
Diversion Tunnel and Portals	Retain the tunnel, plug the tunnel portals with reinforced concrete

Feature[1]	KRRC Proposal
Diversion Tunnel Control Tower, Hoist, and Gate	Remove above finished-grade portion and retain below finished-grade portion
Additional Ancillary Facilities (e.g., Communication Buildings, Restrooms and Two Residences)[3]	Remove

[1] Feature as presented in Appendix B: *Definite Plan – Table 5.5-1*.
[2] Features to be partially removed would involve long-term maintenance costs, including the preservation of any exposed items with coatings containing heavy metals.
[3] These facilities are discernible in Figure 2.7-4 although they not itemized in Appendix B: *Definite Plan – Table 5.5-1.*

The KRRC proposes to remove Iron Gate Dam and its associated facilities following spring runoff of dam removal year 2 (approximately June 1). The embankment dam crest would be retained at a level needed for flood protection, with a minimum flood release capacity of approximately 7,000 cfs in July (reservoir water surface elevation 2,242.3 feet) and 3,000 cfs in August and September (reservoir water surface elevation 2,194.3 feet), in order to accommodate the passage of at least a 1 percent probable flood for that time of year. Excavation of the embankment section at Iron Gate Dam would not begin before June 1 of dam removal year 2, and it would be complete by September 30 to minimize the risk of flood overtopping. During excavation, rockfill would be temporarily stockpiled for placement on the downstream slope of a temporary cofferdam. Throughout excavation, access would be provided to the gate control house at the base of the intake tower for flow control.

The fish hatchery facilities near the downstream toe of embankment, including the fish ladder and the holding tanks, would be removed once the area is dry. The water supply features for the fish hatchery facilities would be removed as well. Note: modifications to Iron Gate Hatchery would be completed prior to drawdown activities so that Iron Gate Hatchery operations would continue during reservoir drawdown.

A cofferdam would be constructed in the tailrace channel to facilitate removal of the Iron Gate Powerhouse. The cofferdam would be comprised of remaining portions of the Iron Gate Dam embankment (i.e., the dam embankment would be excavated height wise and widthwise until only the cofferdam remains). Sump pumps would be used to dewater the area and then would be removed following construction activities. The Iron Gate cofferdam would be breached prior to the J.C. Boyle cofferdam-breach so that the sediment released by the upstream breach is not trapped at the Iron Gate cofferdam and subsequently released in a larger, combined event. Breaching of the Iron Gate cofferdam would occur by notching below the reservoir level (expected to be below reservoir water surface elevation 2,186.3 feet). The maximum breach outflow from the cofferdam at Iron Gate Dam is estimated to be approximately 5,000 cfs. Following the cofferdam breach, any remaining embankment materials would be removed from the river channel while the river channel is wet, during the low flow period. The diversion tunnel intake structure and topple gate control tower would be removed and the tunnel and shaft portals would be plugged with reinforced concrete. The cofferdam materials would then be removed.

As explained in the KRRC's Definite Plan (Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* and the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*), site demobilization would occur after restoration of the dam site, right abutment disposal site, staging areas and concrete disposal site. This restoration would include topsoil and seed placement where appropriate.

Construction Access and Road Improvements

An overview of construction access roads required for removal of Iron Gate Dam and Powerhouse, and associated work, are shown in Figure 2.7-4. Existing conditions of the highways, local roads, and structures to be used were observed in the field to identify deficiencies and determine if improvements are necessary for mobilization and/or hauling during construction and demolition activities. The KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* details several road improvements to facilitate access for dam removal vehicles and equipment and to ensure public safety during dam deconstruction activities. The KRRC proposes to return roads used for the project to an acceptable state, including mitigating any potential reduction in function attributed to the dam removal work.

The road improvements identified for the removal of Copco No. 1 are also required for access to Iron Gate Dam (see Section 2.7.1.2 *Copco No. 1 Dam and Powerhouse – Construction Access and Road Improvements*). In addition, the Iron Gate Dam removal would require surface maintenance of two roads during or post-construction, temporary traffic controls during road improvements, and construction signage at one bridge. The delivery of off-road construction equipment, including cranes, large excavators, loaders, and large capacity dump trucks would be performed by special tractor-trailer vehicles operating under "wide load" restrictions and would travel at appropriate speeds.

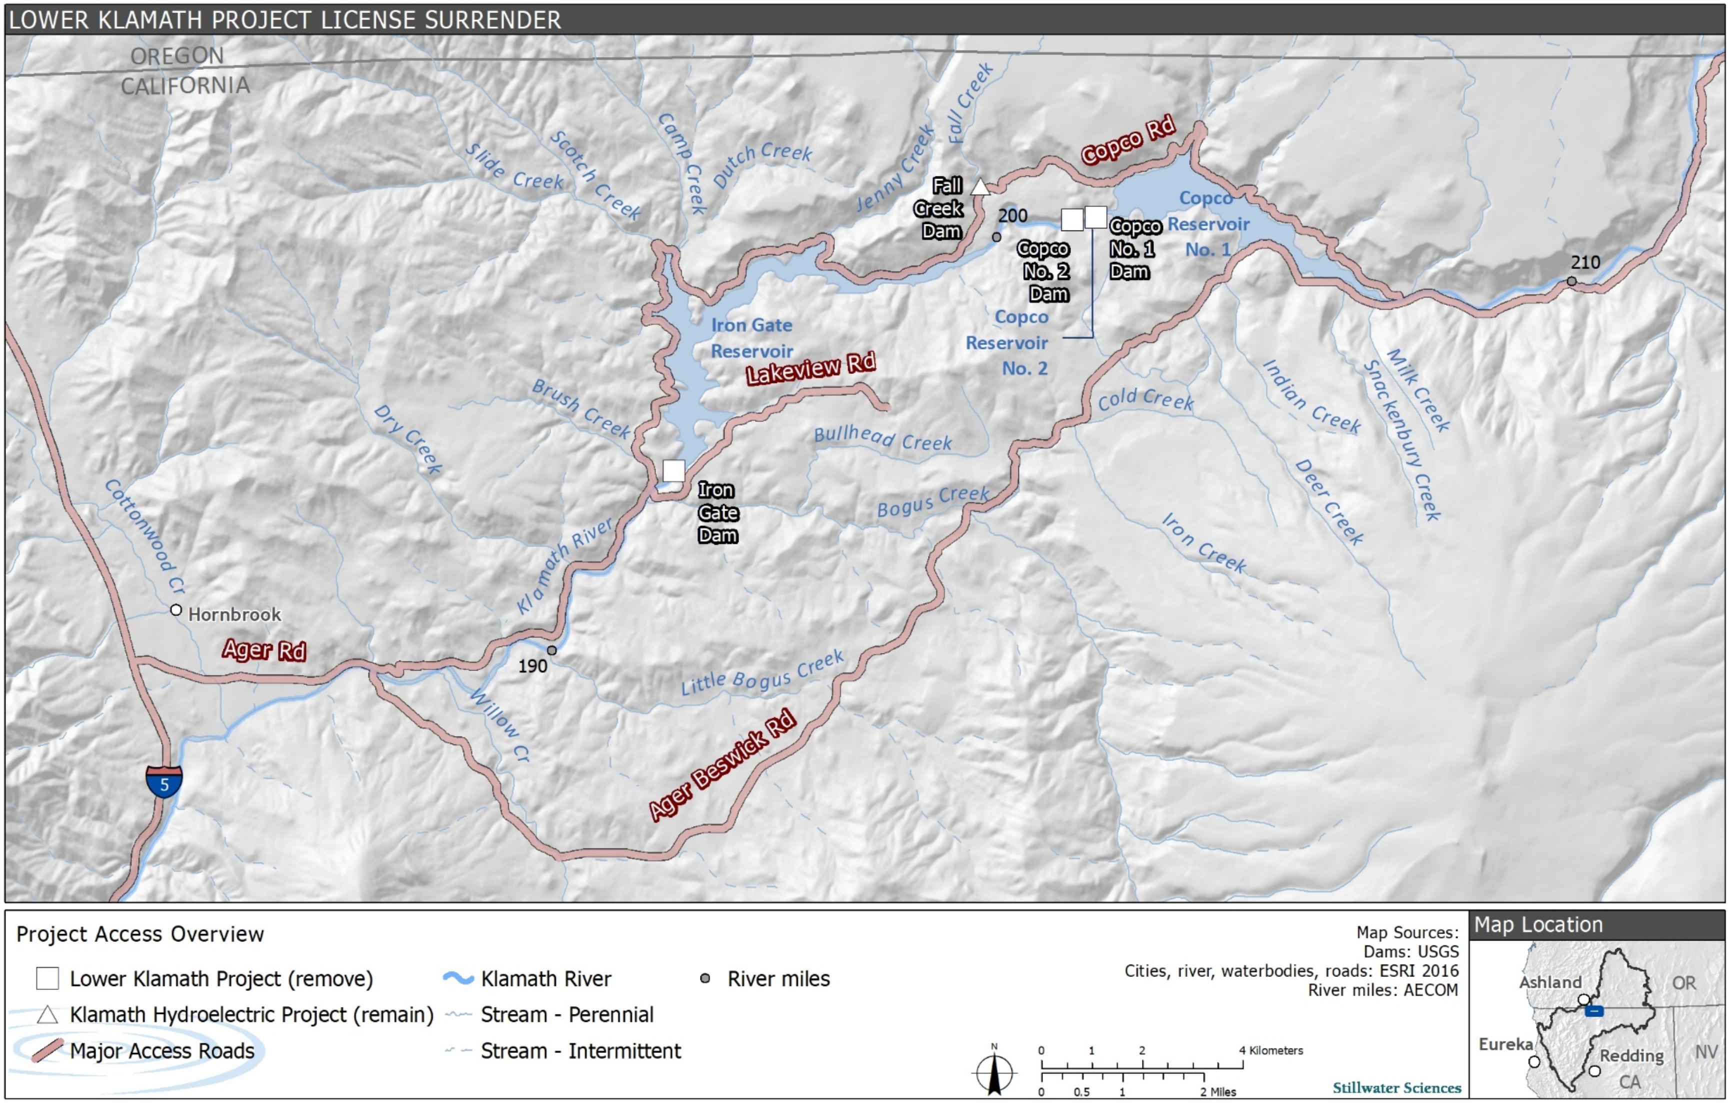

Figure 2.7-3. Lower Klamath Project Access Overview.

Staging Areas and Disposal Sites

The KRRC's Proposed Project construction staging areas and a disposal site for removal of Iron Gate Dam and Powerhouse are shown within the Limits of Work in Figure 2.7-4 and detailed further in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*. Equipment or material staging areas at the Iron Gate Dam site include 7.7 acres above the left abutment of the dam, 1.4 acres southwest of the disposal site, and 1.4 acres northeast of the disposal site (Figure 2.7-4, tiles 1 of 2, 2 of 2). A 1.9-acre area near the right abutment downstream of the dam (currently occupied by two PacifiCorp residences and outbuildings) could be used for construction offices. The staging areas would be prepared by clearing vegetation and minor grading, and would be restored by minor grading, decompaction, and hydroseeding consistent with the upland planting zones in the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*). Staging of mechanical and electrical debris would likely occur at the downstream toe of the dam in the parking area and the area of the fish collection facilities (Figure 2.7-4, tile 1 of 2).

The KRRC proposes that most of the earth materials and all of the concrete rubble generated from removal of the Iron Gate facilities would be permanently buried on-site in a disposal area covering approximately 36 acres located on PacifiCorp property approximately 1 mile south of the dam (Figure 2.7-4, tile 1 of 2). The disposed material would be placed to a maximum fill height of about 50 feet and graded to conform to the existing topography. Concrete rubble would be covered by a minimum of 3 feet of earth materials. Final grading of the disposal site would include relatively flat slopes (8H:1V to 5H:1V) to reduce the potential for erosion. Preparation of the disposal site would require clearing of vegetation and stripping and stockpiling of topsoil for later use during restoration of the disposal site. After final grading for drainage and aesthetics, the disposal site would be covered with topsoil and hydroseeded. Erosion monitoring would be completed on an annual basis for five years following placement to assess whether significant erosion and slope deterioration has occurred. If significant erosion occurs, the eroded area shall be repaired to the satisfaction of the appropriate regulatory agency. Additional details for the KRRC's Proposed Project disposal sites for Iron Gate Dam are provided in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)*.

Earth materials excavated from the dam would be placed in the existing concrete-lined side-channel spillway, chute, and flip-bucket terminal structure (located on the right abutment of the dam) to the extent practicable for restoration. Finished grades of the backfill would be no steeper than approximately 4H:1V. Following backfilling, the uphill portion of the spillway excavation would still be visible. After final grading for drainage and aesthetics, the disposal site would be covered with topsoil and hydroseeded. Compaction other than by equipment travel would not be necessary.

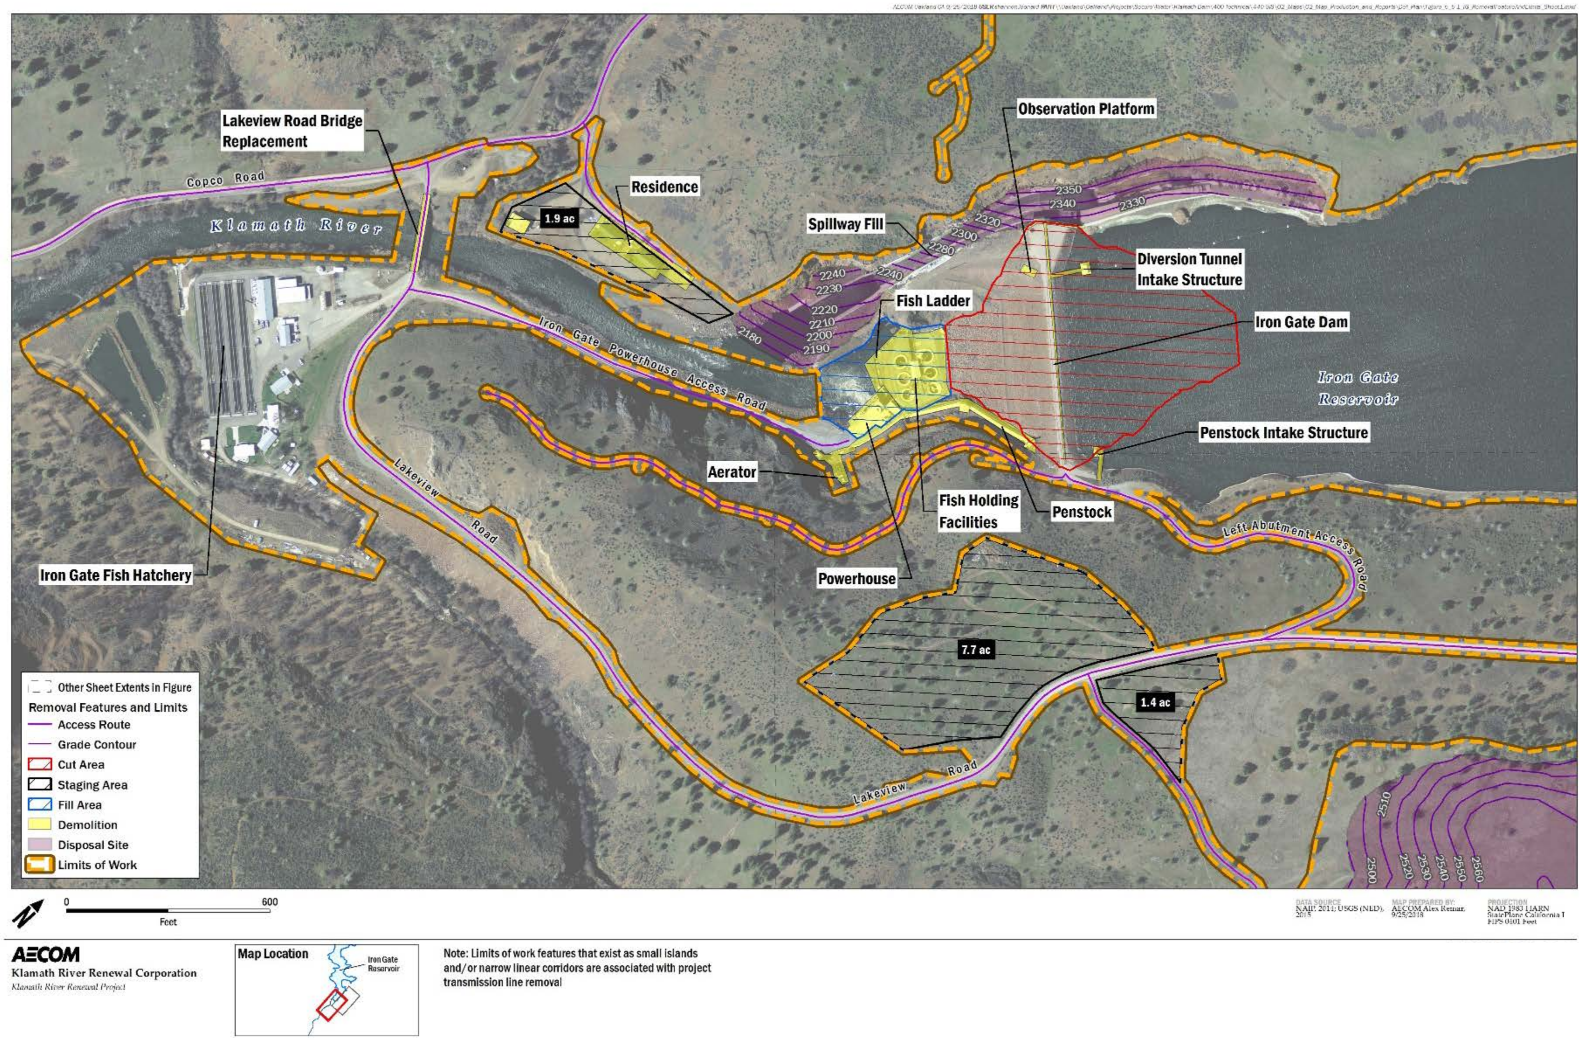

Figure 2.7-4. Iron Gate Dam Removal Features and Limits of Work (1 of 2).

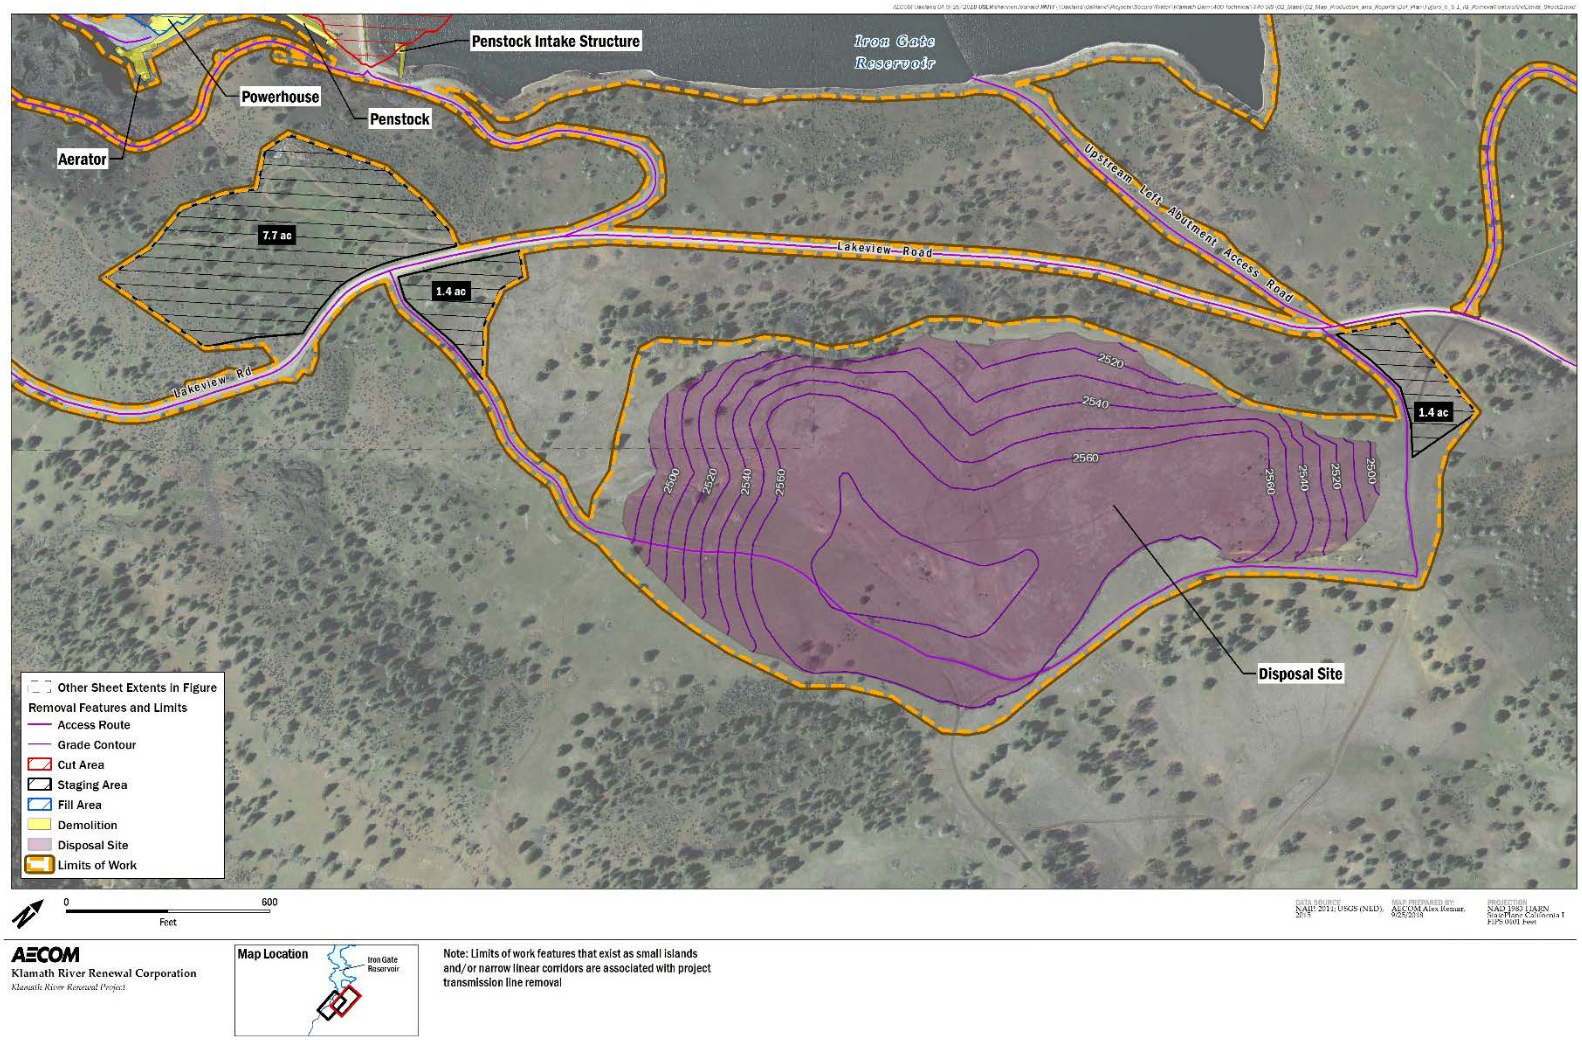

Figure 2.7-4. Iron Gate Dam Removal Features and Limits of Work (2 of 2).

Imported Materials and Waste Disposal

KRRC proposes to import some materials to support dam removal. Those materials include gravel surfacing from a commercial quarry for temporary haul roads, topsoil, seed and mulch materials, and minor quantities of ready-mix concrete and reinforcing steel from local commercial sources for tunnel plugs. Additional imported materials would be necessary for road surface improvements, signage, and the bridge replacement. The KRRC's Proposed Project modification of the diversion tunnel and installation of a new gate in the existing gate structure would require importing mechanical equipment, as well as additional reinforcing steel and potentially ready-mix concrete for lining the diversion tunnel if inspections determine it is necessary.

Estimated quantities of materials generated during removal of Iron Gate Dam and Powerhouse, numbers of truck trips, and approximate haul distances for waste disposal in miles per round trip (miles RT) are detailed in the KRRC's Definite Plan *(*Appendix B: *Definite Plan – Section 5 Dam Removal Approach)* and updated information on waste disposal details has been provided by KRRC based on further investigations since the Definite Plan was released (S. Leonard, AECOM as KRRC Technical Representative, pers. comm., November 2018). Please see Table 2-7.7 for a summary of the updated information on waste disposal. Excavated earth would be disposed on-site at either the spillway fill area or the main disposal site. Excavated concrete would be placed in the on-site disposal site. Rail and reinforcing steel would be separated from the concrete prior to placement in the disposal area and hauled to a local recycling facility. All mechanical and electrical equipment would be hauled to a suitable commercial landfill or salvage collection point (e.g., Yreka Transfer Station, Yreka, CA).

Table 2.7-7. Estimated quantities of waste disposal for full removal of Iron Gate Dam.

Waste Material	In-Situ Quantity	Bulk Quantity[1]	Disposal Site[2]	Peak Daily Trips[3]	Total Trips[4]
Earth	155,000 yd^3	170,000 yd^3	On-site spillway fill area	12 units/ 800 trips (unpaved road)	8,640 trips (0.5 miles RT)
Earth	912,000 yd^3	1,087,000 yd^3	On-site	12 units/ 800 trips (unpaved road)	48,640 trips (2 miles RT)
Concrete	15,800 yd^3	20,700 yd^3	On-site	2 units/ 50 trips (Copco Road)	950 trips (2 miles RT)
Rebar	1,000 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	100 trips (54 miles RT)
Mech. and Elec.	1,200 tons	--	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	150 trips (54 miles RT)
Building Waste	8 buildings; 10,400 ft^2	2,300 yd^3	Transfer station near Yreka, CA	1 units/5 trips (Copco Road)	120 trips (54 miles RT)
Power lines	0.5 miles of 69-kV	--	Transfer station near Yreka, CA	--	1 trip (54 miles RT)

Waste Material	In-Situ Quantity	Bulk Quantity[1]	Disposal Site[2]	Peak Daily Trips[3]	Total Trips[4]
Wood Utility Poles	30 poles	--	Transfer station near Yreka, CA	--	2 trips (54 miles RT)

Source: S. Leonard, AECOM as KRRC Technical Representative, pers. comm., November 2018

[1] Volumes increased 30 percent for concrete rubble and 20 percent for loose earth materials.

[2] Currently, solid waste is transferred approximately 45 miles from the Yreka Transfer Facility to the Dry Creek Landfill facility near White City Oregon.

[3] Peak daily trips for each site are based on the number of vehicles (units) shown, operating within one 8-hour shift.

[4] Total trips of earthfill or concrete assume off-highway articulated trucks with a nominal load capacity of 22 yd^3. Total trips for hauling rebar using truck tractor-trailers is based on 10 tons per trip. Total trips for hauling mechanical and electrical items using truck tractor-trailers is based on 8 tons per trip. Total trips for building waste using truck tractor-trailers is based on 10 yd^3 per trip. Mileage is reported in miles per round trip (miles RT).

Potential hazardous materials at Iron Gate Dam and Powerhouse include asbestos, batteries, bearing and hydraulic control system oils, treated wood, flammable and nonflammable gases, flammable and combustible liquids, mercury in older light switches, contaminated soils near painted exterior equipment, coatings containing heavy metals in the powerhouse, on the exterior surfaces of the steel penstocks, air vents, and other painted materials, and underground septic systems in use for the restroom and two residences near the dam. All hazardous materials would be handled and disposed of as hazardous waste at an approved hazardous waste facility in accordance with applicable federal and state regulations. Additional details and their disposal are provided in the KRRC's Hazardous Material Management Plan (Appendix B: *Definite Plan – Appendix O3*) and disposal is discussed in Section 3.21 *Hazards and Hazardous Materials* of this EIR.

2.7.1.5 Estimated Deconstruction Workforce and Work Shifts

The size of the deconstruction workforce at each site would vary, and the peak times for construction would be staggered. Table 2.7-8 presents a summary of the projected workforce needed for the Proposed Project.

Table 2.7-8. Workforce Projections for Dam Removal for the Proposed Project.

Dam	Estimated Average Deconstruction Workforce	Duration	Estimated Peak Workforce	Peak Period
J.C. Boyle*	30 people	9 months	45 people	Jun−Sep dam removal year 2
Copco No. 1	35 people	12 months	55 people	Apr–Nov dam removal year 2
Copco No. 2	30 people	6 months	40 people	Apr−Sept dam removal year 2
Iron Gate	40 people	10 months	80 people	Jun−Sep dam removal year 2

* J.C. Boyle Dam is included in this table as some of the traffic flow may use roads in California (e.g., I-5 to OR 66)

Source: Appendix B: *Definite Plan – Section 5*

The Proposed Project includes two shifts of workers to deconstruct each of the three California dams (Copco No. 1, Copco No. 2, and Iron Gate). At each dam the first work shift would be 6 a.m. to 4 p.m. and the second work shift would be 6 p.m. to 4 a.m. This would allow for 2-hour breaks between shifts for refueling and maintenance. Blasting would occur at each dam (see Sections 2.7.1.2 through 2.7.14) and would be restricted to the period from 8 a.m. to 6 p.m. (S. Leonard, AECOM as KRRC Technical Representative, pers. comm., September 2018).

2.7.2 Reservoir Drawdown

The KRRC proposes that drawdown of J.C. Boyle, Copco No. 1 (Copco Lake), and Iron Gate reservoirs would take place between November 1 of dam removal year 1 and March 15 of dam removal year 2, as detailed in the KRRC's Reservoir Drawdown and Diversion Plan (Appendix B: *Definite Plan*). Copco No. 1 Reservoir drawdown would occur from November 1 of dam removal year 1 to March 15 of dam removal year 2, while the drawdown of J.C. Boyle and Iron Gate reservoirs would occur from January 1 to March 15 of dam removal year 2. Drawdown of Copco No. 2 Reservoir would not be necessary until after Copco No. 1 Dam has been breached to final grade in May of dam removal year 2 because it will not impound a significant volume of water or sediment.

KRRC proposes to begin drawdown of Copco No. 1 Reservoir beginning on November 1 of dam removal year 1. Copco No. 1 is the largest Lower Klamath Project reservoir. The drawdown is expected to be completed by March 15 of dam removal year 2, at which point the Klamath River would most likely re-occupy its historical active channel (Figures 2.7-5 and 2.7-6). The proposed drawdown period is integral to the project in that it would provide for power generation revenues for the period specified in the KHSA and it would undertake reservoir drawdown at a period when winter flows and levels of suspended sediment are naturally high in river and only a portion of fish populations are likely to be present in the mainstem Klamath River immediately downstream of the Hydroelectric Reach (Figure 2.7-1). Most fish are in tributaries or further downstream during the period when mainstem concentrations of suspended sediments due to dam removal would be the highest, and in general many native aquatic species are adapted to naturally high levels of suspended sediment during the winter through avoidance and tolerance behaviors. Additional proposed measures to reduce sediment-related impacts to salmonids during and following Proposed Project drawdown activities are discussed in Section 2.7.8.1 *Aquatic Resource Measures*.

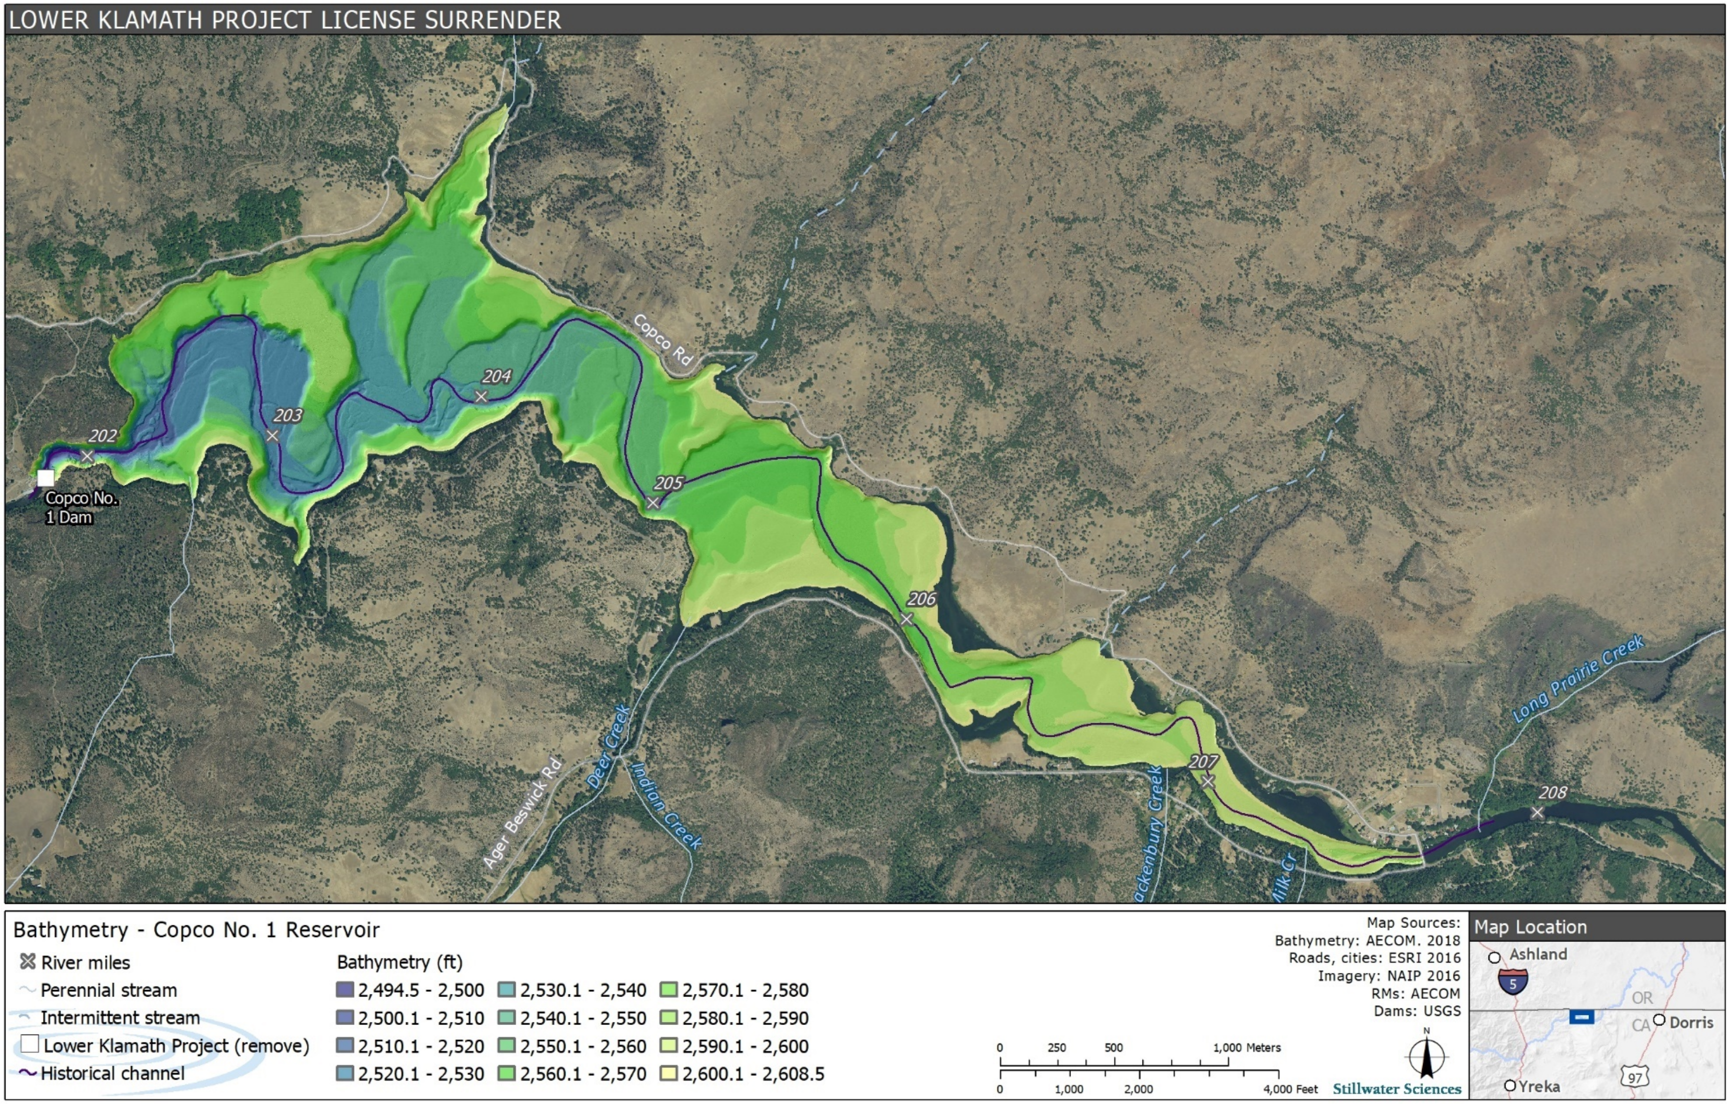

Figure 2.7-5. Copco No. 1 Reservoir Bathymetry.

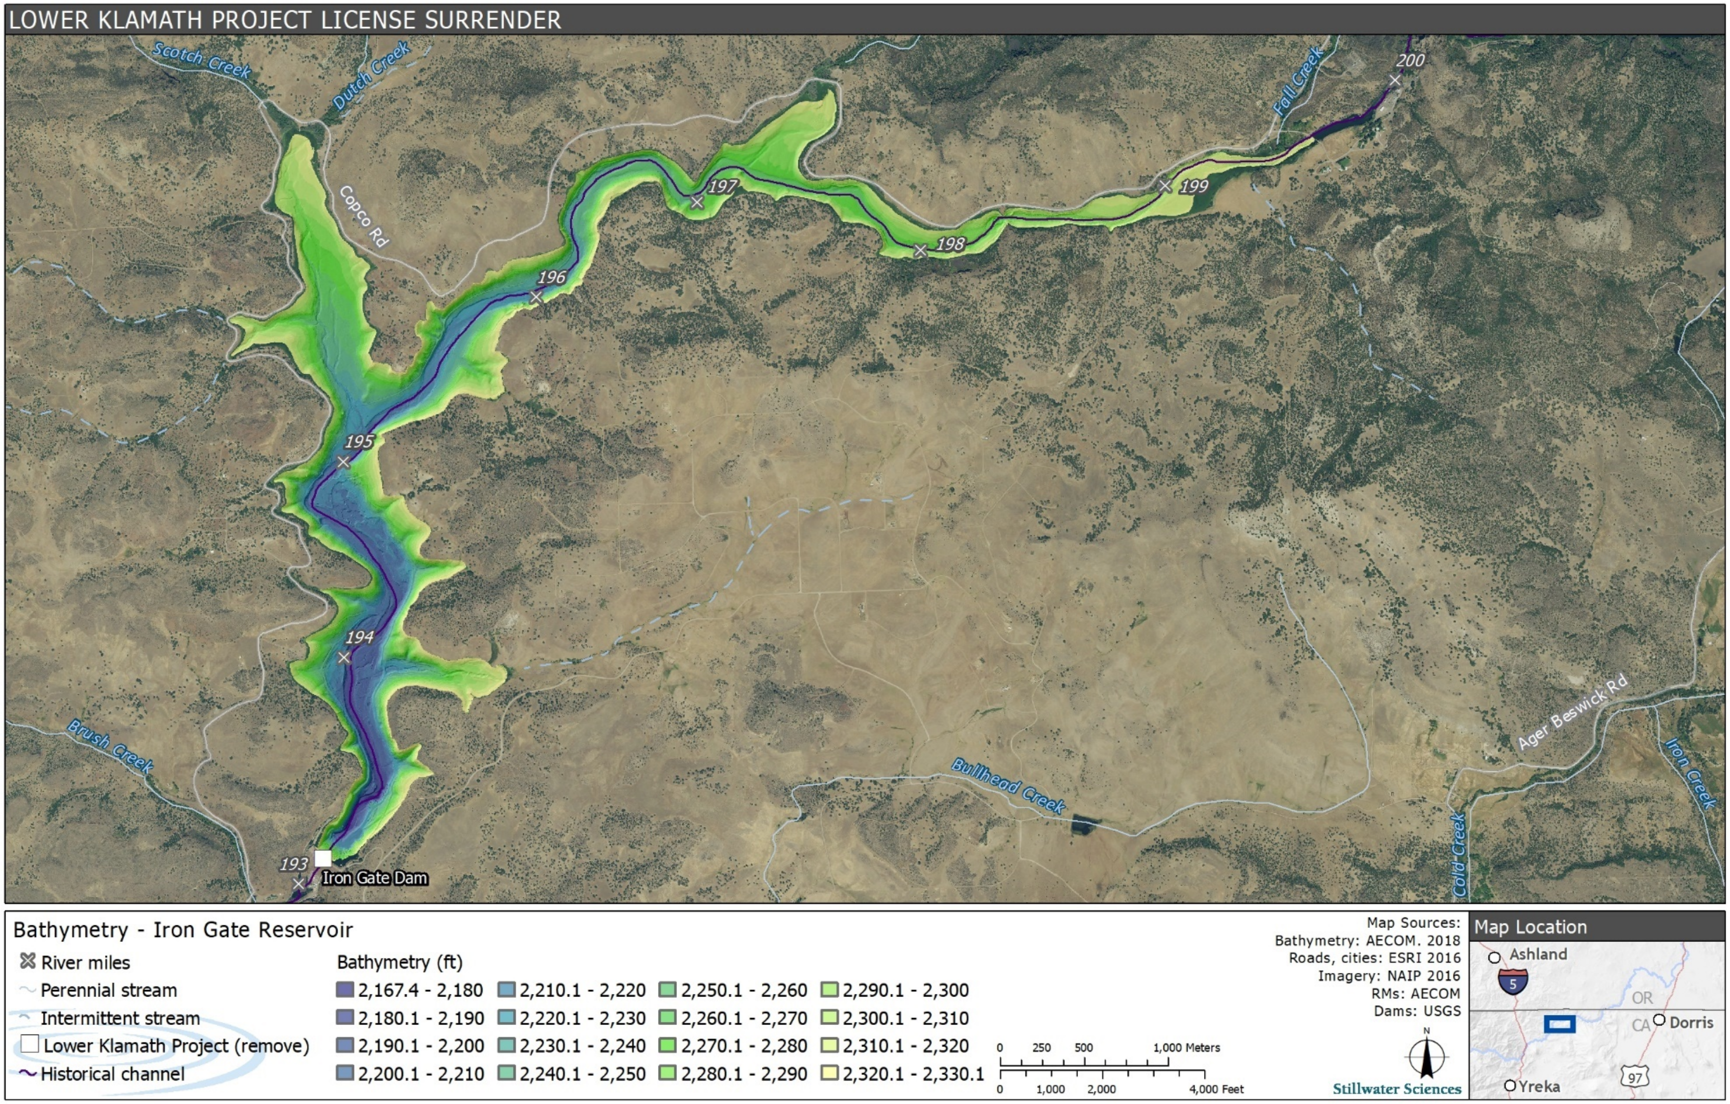

Figure 2.7-6. Iron Gate Reservoir Bathymetry.

For J.C. Boyle and Iron Gate Dams, power generation would end on January 1 of dam removal year 2. Power generation at Copco No. 1 Dam would end after the reservoir reaches the minimum operating level at reservoir surface elevation 2,604.5 feet, in November of dam removal year 1. To offset lost revenue from shutting down Copco No. 1 Powerhouse prior to January 1 of dam removal year 2, power generation at Copco No. 2 Dam could continue for up to four months after January 1 of dam removal year 2 (or until May 1 of dam removal year 2), if Copco No. 2 power generating equipment proves capable of operating under sediment-laden flow conditions. This EIR assumes continued production at Copco No. 2, as the need to halt production is speculative. If the Copco No. 2 Powerhouse is not capable of operating under sediment-laden conditions, then drawdown of this reservoir would still use the penstock. Reservoir drawdown below the minimum operating level would commence at each dam once power generation has ceased.

For all reservoirs, the minimum drawdown rate would be 2 feet per day and the maximum drawdown rate would be 5 feet per day, until drained. Although the new gates at Copco No. 1 and Iron Gate dams would be able to accommodate higher drawdown rates, the maximum drawdown rate of 5 feet per day is proposed by KRRC as a conservative value based upon slope stability analyses conducted for each of the Lower Klamath Project reservoirs.

According to the KRRC's Reservoir Drawdown and Diversion Plan (Appendix B: *Definite Plan*), the drawdown of Copco No. 1 and Iron Gate reservoirs would be managed through automated gate control systems with operator oversight, where inputs to determine the amount of gate opening at each reservoir would include continuous measurement of reservoir levels by remote sensor. The gate control system would incrementally open (or close) the gate to increase (or decrease) flow through the diversion tunnel (14-foot by 16-foot) to maintain the reservoir drawdown at an approximately constant rate. This will allow the project to maintain embankment and reservoir rim stability even as reservoir inflows vary. For example, flows may vary due to storms or changes in upstream reservoir releases.

Once the Copco No. 1 and Iron Gate reservoirs have been fully drawn down, the gates would remain in the fully open position to limit reservoir refilling during storm events. Any storm inflows large enough to cause partial refilling of the reservoir would pass through the spillway, unless spillway outflows reach a pre-determined level (13,000 cfs for Copco No. 1 and 15,000 cfs for Iron Gate). If these levels are reached the gates would be closed until the flow drops below this level to avoid high water levels that would impact the Copco No. 2 Powerhouse (which could still be operating until May 1).

During dam removal, the drawdown of Iron Gate Reservoir would need to maintain enough capacity to pass a 1 percent probable flood for that time of the year to reduce the potential for flow to overtop the dam embankment. The following minimum flood release capacities by month would be maintained during drawdown of Iron Gate Reservoir:

- June—approximately 7,700 cfs
- July—approximately 7,000 cfs
- August/September—approximately 3,000 cfs

Drawdown of J.C. Boyle Reservoir would be initially controlled by the capacity of the opened spillway, followed by the capacity of the opened power intake. Once the reservoir stabilizes with spillway and intake fully open, the diversion culverts would be opened, and drawdown would only be controlled by the capacity of the diversion culverts, which is approximately 6,000 cfs at the spillway elevation. For storm flows that refill the reservoir before deconstruction, higher discharge rates would be experienced over the spillway. Drawdown of J.C. Boyle Reservoir would maintain a minimum flood release capacity of 3,500 cfs, in order to accommodate the passage of at least a 1 percent probable flood for September and prevent flood overtopping of the dam embankment during dam removal.

The resulting range of release flows due to drawdown of the three larger reservoirs is provided in Table 2-7.8. Release flows would add water to the otherwise existing flows in the river (i.e., Keno Reservoir releases and tributary inflows). The percent increase in the Klamath River caused by the minimum average and maximum average release flows compared to the 2-year and 10-year peak flows in the Klamath River at individual locations for each reservoir are also detailed in Table 2-7.8. The 2-year and 10-year peak flows are calculated from the available USGS flow gage data in the Klamath River below J.C. Boyle Dam for J.C. Boyle Reservoir, in the Klamath River downstream of Fall Creek at the upstream end of Copco No. 1 Reservoir, and in the Klamath River downstream of Iron Gate Dam for Iron Gate Reservoir. Details for the release flow modeling and the associated assumptions are provided in Section 3.6.5.1 *Flood Hydrology* of this EIR.

Table 2.7-9. Range of Release Flows from Reservoirs due to Drawdown.

Reservoir	Reservoir Depth[1] (feet)	Reservoir Volume[2] (acre-feet)	Minimum Average Release Flow (cfs)[3]	Minimum Average as Percent of 2-Year Peak Flow in Klamath River[4]	Minimum Average as Percent of 10-Year Peak Flow in Klamath River[5]	Maximum Average Release Flow (cfs)[6]	Maximum Average as Percent of 2-Year Peak Flow in Klamath River[4]	Maximum Average as Percent of 10-Year Peak Flow in Klamath River[5]
J.C. Boyle	41.5	2,267	19	0.4	0.2	138	3	1
Copco No. 1	111.5	33,724	288	5	3	762	13	7
Iron Gate	155	50,941	435	7	3	828	14	6

1 Reservoir depth is the difference between the initial water surface elevation (normal operating level at J.C. Boyle or spillway elevation at Copco No. 1 and Iron Gate) and invert elevation of the reservoir diversion structure.

2 Reservoir volume based on a 2003 bathymetric survey (Eilers and Gubala 2003).

3 Minimum assumes 59 days to drain reservoir.

4 2-Year peak flow (4,736 cfs for J.C. Boyle, 5,974 cfs for Copco, and 5,942 cfs for Iron Gate) based on flood frequency results in the Klamath River below J.C. Boyle Dam for J.C. Boyle, in the Klamath River downstream of Fall Creek at the upstream end of Copco No. 1 Reservoir for the Copco No. 1, and in the Klamath River below Iron Gate Dam for Iron Gate. Period of record 1932–2017 for J.C. Boyle, 1932–2017 for Copco No. 1, and 1961–2016 for Iron Gate (AECOM et al. 2017).

5 10-Year peak flow (9,438 cfs for J.C. Boyle; 11,340 cfs for Copco; and 14,912 cfs for Iron Gate) based on flood frequency results in the Klamath River below J.C. Boyle Dam for J.C. Boyle, in the Klamath River downstream of Fall Creek at the upstream end of Copco No. 1 Reservoir for the Copco No. 1, and in the Klamath River below Iron Gate Dam for Iron Gate. Period of record 1932–2017 for J.C. Boyle, 1932–2017 for Copco No. 1, and 1961–2016 for Iron Gate (AECOM et al. 2017).

6 Maximum assumes continuous 5 feet per day drawdown.

For J.C. Boyle Reservoir, the increase in flow to the Klamath River due to drawdown is expected to range from less than 1 percent to approximately 3 percent of the 2-year peak flow in the Klamath River below J.C. Boyle Dam. For Copco No. 1 Reservoir, the increase is expected to be between 5 percent and 13 percent of the 2-year peak flow in the Klamath River downstream of Fall Creek near the upstream end of Copco No. 1 Reservoir. The increase in flow from Iron Gate Reservoir is expected to be between 7 percent to 14 percent of the 2-year peak flow in the Klamath River below Iron Gate Dam. The maximum additional discharge in the Klamath River during drawdown of all the Lower Klamath Project reservoirs combined would be approximately 6,000 cfs. The minimum drawdown rate (and minimum average release flows) would likely occur during large storm events, such that the increase in flow to the river due to dam removal would be a small percentage of the 2-year peak flow (i.e., less than 1 to 7 percent) and an even smaller percentage of the 10-year peak flow (i.e., less than 1 to 3 percent) (Table 2.7-8). During dry periods, the reservoirs could be drawn down more quickly, resulting in a larger percent increase in Klamath River flows due to drawdown releases compared to the 2-year peak flow (i.e., 3 to 14 percent) or the 10-year peak flow (i.e., 1 to 7 percent). In comparison to the magnitude of the 2-year and 10-year peak flows, the incremental increase in flow due to reservoir drawdown would be minimal.

2.7.3 Reservoir Sediment Deposits and Erosion During Drawdown

J.C. Boyle, Copco No. 1, and Iron Gate reservoirs contain a significant amount of highly erodible sediment with approximately 1/3 to 2/3 of this sediment anticipated to be transported downstream with the water during drawdown. Over 80 percent of the reservoir sediments are fine sediment (organics, silts, and clays), which are expected to remain suspended in the Klamath River flow as it moves downstream and out into the Pacific Ocean. Coarse sediment (i.e., sand and larger) transport would occur more slowly depending on the hydrologic conditions with deposition of coarser sediment from dam removal expected to primarily occur between the reservoirs and the confluence of the Klamath River and the Shasta River. Sediment transport from dam removal would not be expected to have a significant effect on the streambed downstream of Shasta River (USBR 2012b).

Sediment in the Lower Klamath Project reservoirs is primarily composed of silt-sized particles of organic material from dead algae, silt, and clay (fine sediment) with lesser amounts of cobble and gravel (coarse sediment) (USBR 2012a). The distribution of sediment deposits varies within each of the reservoirs. In J.C. Boyle Reservoir, sediment primarily resides in the area nearest the dam, with measured sediment thicknesses ranging from 0 feet in the middle and upper portions of the reservoir to over 20 feet near the dam. Figure 2.7-7 presents the estimated average sediment thickness throughout the reservoir based on measurements. Both Copco No. 1 and Iron Gate reservoirs have generally even distributions of sediment with thicknesses increasing towards the dams. Figures 2.7-8 and Figure 2.7-9 show the estimated average sediment thickness based on position in the reservoir. The measured thickness of Copco No. 1 Reservoir sediment ranges from approximately 1.2 feet to approximately 10 feet. The maximum deposition within the thalweg (original river channel) of Iron Gate Reservoir is around 5 feet, with a measured deposition thickness of nearly 10 feet in the Jenny Creek arm of the reservoir, while the minimum measured sediment thickness is approximately 0.3 feet near the upstream end of the reservoir.

No detailed measurements (bathymetry or sediment sampling results) are available for the smaller (approximately 73 acre-feet) Copco No. 2 Reservoir. Sediment sampling was attempted in Copco No. 2, but no samples were collected due to the absence of accumulated sediment deposits (USBR 2011b). This condition likely results from the presence of the larger, upstream Copco No. 1 Dam that was completed seven years prior to Copco No. 2 Dam, cutting off upstream sediment supply to the Copco No. 2 Reservoir. Although there appears to be a lack of historical sediment deposits in Copco No. 2 reservoir under current conditions, during drawdown of the two upstream reservoirs J.C. Boyle and Copco No. 1, a large volume of sediments would be transported into Copco No. 2 Reservoir. Estimates of the particle trapping efficiency of Copco No. 2 Reservoir can be made over a range of grain sizes using known relations between reservoir geometry, the range of expected flows during drawdown, and assumptions regarding mixing conditions (Nazaroff and Alvarez-Cohen 2001). Given an expected flow range of 1,000 cfs to 13,000 cfs within Copco No. 2 Reservoir during drawdown operations, estimated settling velocities suggest that no particle trapping would occur in this reservoir for particles smaller than 0.2 millimeters (fine sand) and 1.0 millimeters (coarse sand). While coarser substrates may be trapped in Copco No. 2 Reservoir between 1,000 cfs to 13,000 cfs, because the intake of the diversion tunnel to the power house is located on the floor of Copco No. 2 Reservoir, regular scour along the thalweg would occur, limiting any potential sediment deposits to calm areas along the channel margins and areas nearest the dam face.

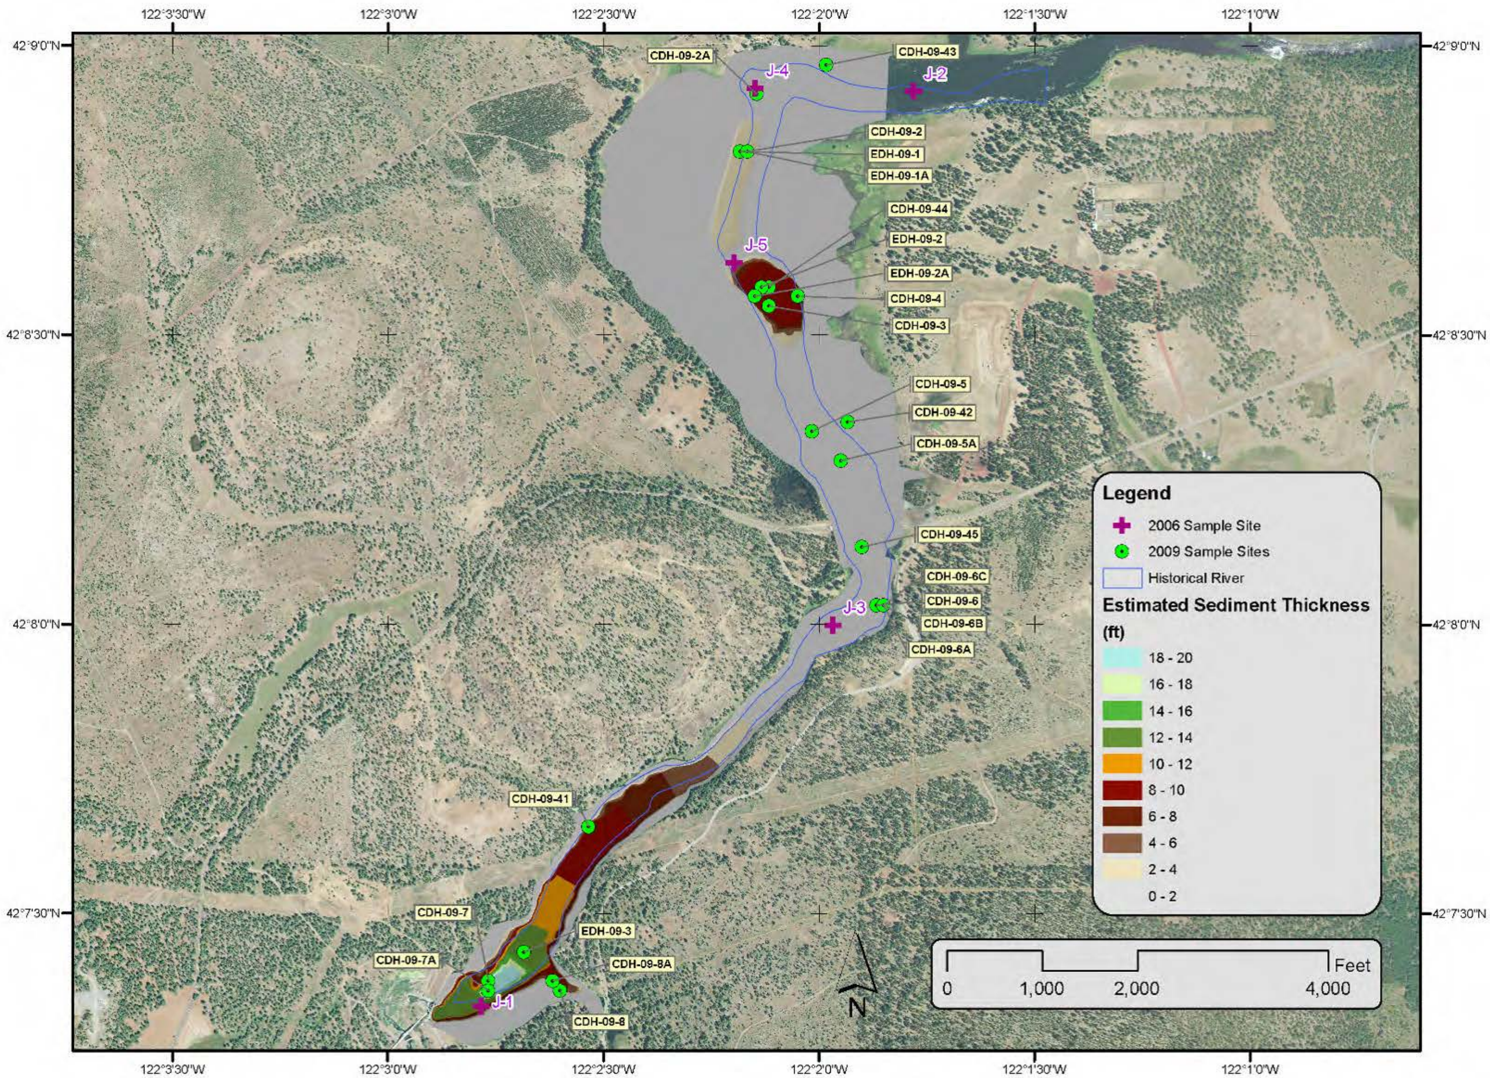

Figure 2.7-7. J.C. Boyle Reservoir Estimated Average Sediment Thickness and Sample Site Locations.

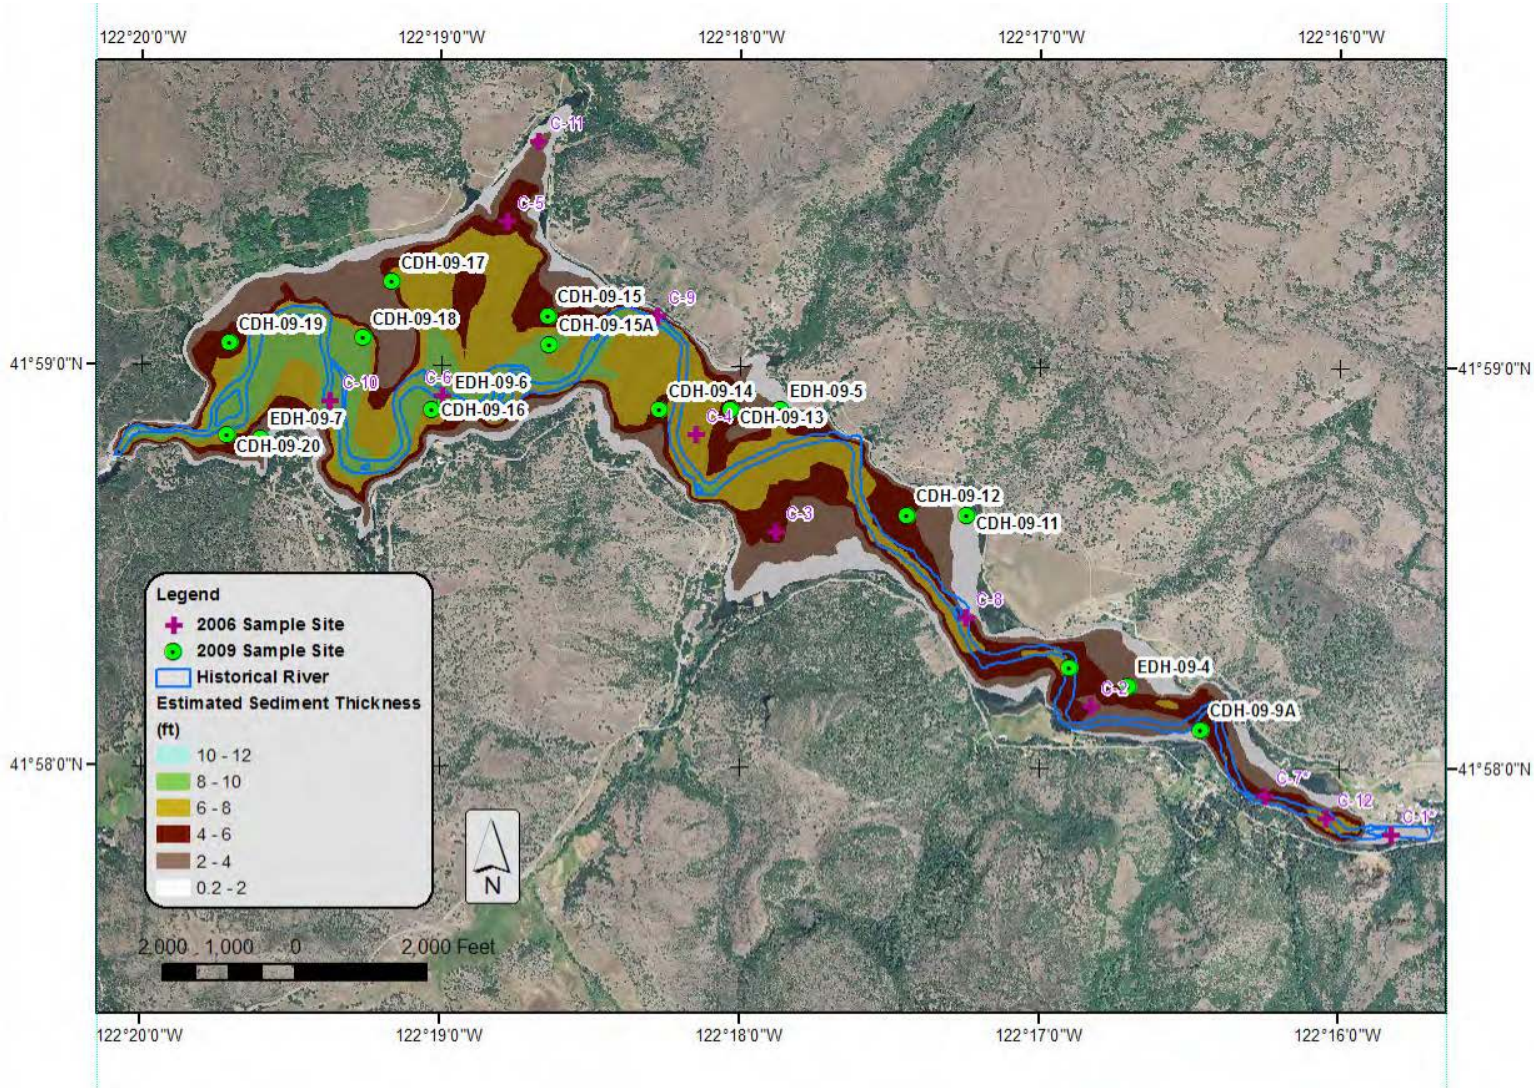

Figure 2.7-8. Copco Reservoir Estimated Average Sediment Thickness and Sample Site Locations.

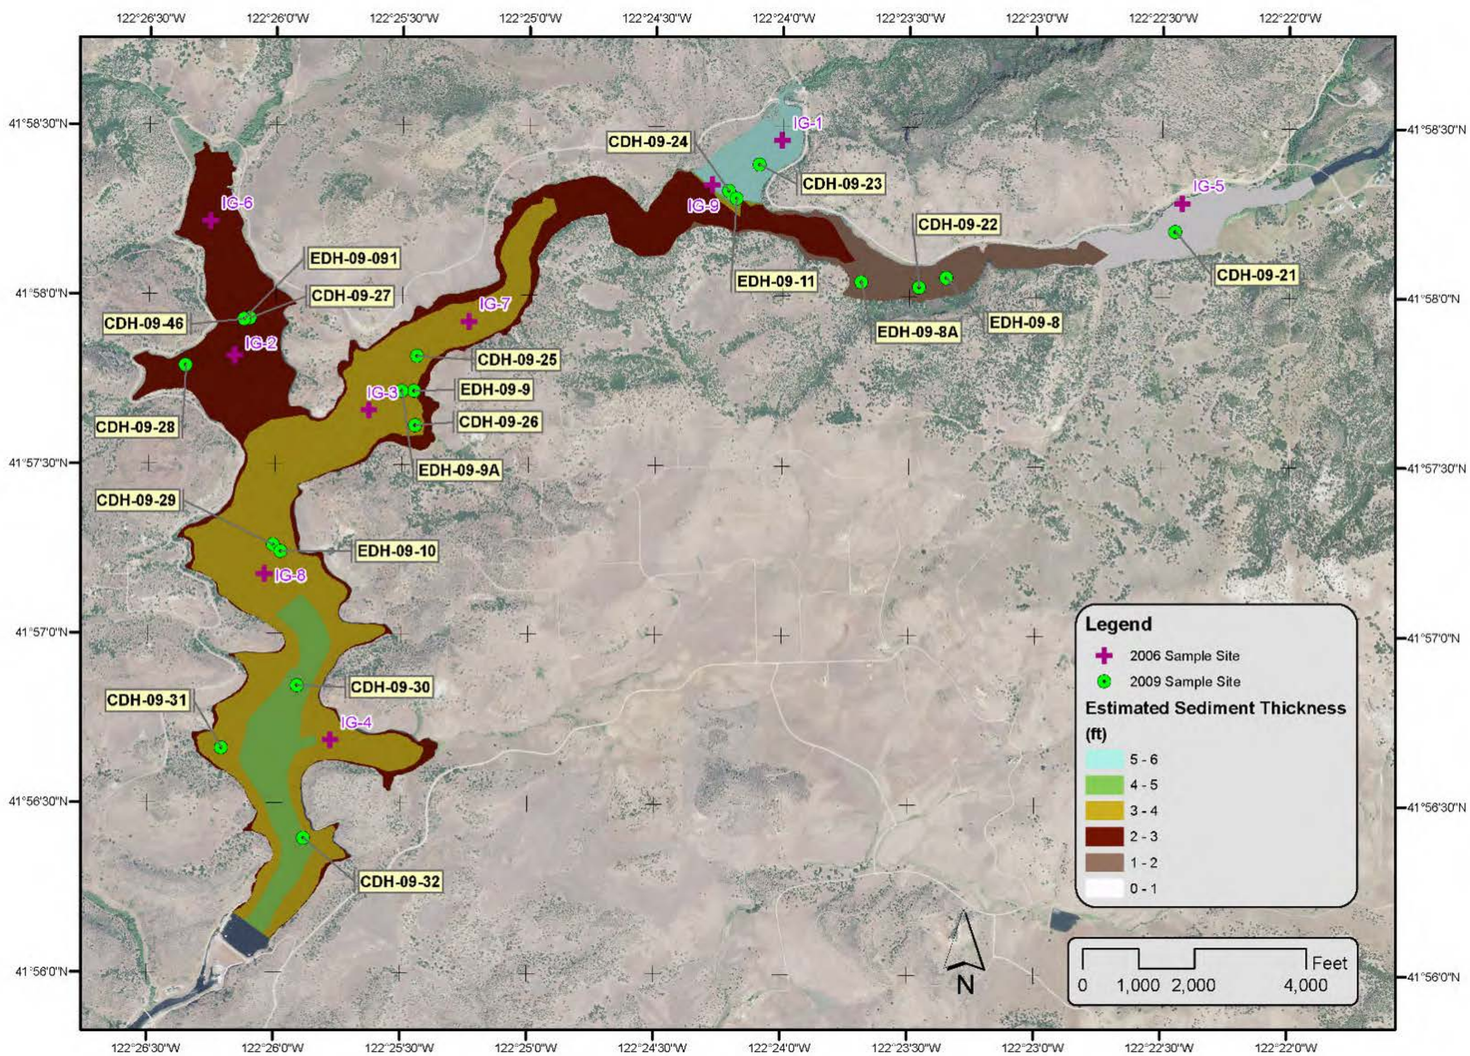

Figure 2.7-9. Iron Gate Reservoir Estimated Average Sediment Thickness and Sample Site Locations.

The current volume and weight of sediment for each reservoir is presented in Table 2.7-9. The uncertainty in the sediment volume estimates is due to interpolation between the 28 to 31 drill holes in each reservoir (USBR 2012a). While the uncertainty in the sediment volume estimate is noticeable, the analysis of sediment erosion potential for the reservoirs is not sensitive to the degree of uncertainty in the volume estimates. Whether the actual reservoir sediment volumes are on the higher end or the lower end of the uncertainty estimate, the dam removal approach and the significance of potential impacts due to sediment transport during reservoir drawdown would remain the same. Sediments as they are deposited in the reservoirs are generally presented in terms of volume, since the sediment volume was measured by the sediment cores taken in each reservoir. However, sediments are typically discussed in terms of mass once they are transported from the reservoir footprints, since the sediment mass would remain constant.

Based on estimated annual sediment deposition rates, an approximately 15.13 million cubic yards (4.16 million tons [dry weight][11]) of sediment would be present behind the dams by 2020[12] (USBR 2012b) (Table 2.7-10). Because the trapped sediments consist primarily of organic material (e.g., dead algae), silts, and clays, they would be easily eroded and flushed out of the reservoirs into the Klamath River, and would continue to be suspended in the river downstream to the Pacific Ocean. Two-dimensional sediment transport modeling of Copco No. 1 Reservoir during drawdown indicates sediments are mobilized from across the reservoir footprint, but the sediments in the historical Klamath River channel would be most likely to erode (USBR 2012b). Coarser reservoir sediment is primarily sand with negligible amounts of larger sediment sizes (i.e., gravel or cobble) which would be transported more slowly depending on the hydrologic conditions. Coarser sediment from dam removal would be expected to primarily deposit between the reservoirs and the confluence of the Klamath River and the Shasta River with an insignificant effect on the streambed downstream of the Shasta River (USBR 2012b).

During drawdown, erosion and transport of sediments deposited within the Copco No. 1 and Iron Gate reservoir footprints would be supported by using barge-mounted pressure sprayers to jet water onto newly exposed reservoir-deposited sediments as the water level decreases, a process called sediment jetting. Sediment jetting would increase the erosion of reservoir-deposited sediments on the historical floodplain areas, especially the historical two-year floodplain, during drawdown and in order to reduce the potential for reservoir sediment erosion outside of the reservoir drawdown period. Additionally, removal of reservoir-deposited sediments with sediment jetting would promote riparian bank and floodplain connectivity by increasing river inundation on the historical floodplain during high flow events and is intended to reduce manual excavation and grading of sediments from proposed restoration sites after drawdown completes. Sediment jetting would be focused in the six areas where restoration actions are proposed within the Copco No. 1 Reservoir footprint (Figure 2.7-11) and the three areas

[11] Ton, dry weight is defined as equal to 2,000 pounds.

[12] Since submitting the original application, KRRC has revised its projection for the year of primary drawdown to be 2021, rather than 2020. Between 2020 and 2021, the sediment volume present behind the dams is expected to increase by approximately 81,300 cubic yards in Copco No. 1 Reservoir and approximately 100,000 cubic yards in Iron Gate Reservoir based on estimates of annual sedimentation rates for each reservoir (USBR 2012b). The expected increase in sediment volume between 2020 and 2021 is an order of magnitude less than the range of the 2020 total sediment volume estimates, so model results using the 2020 sediment volumes would still be applicable to the Proposed Project.

where restoration actions are proposed within the Iron Gate Reservoir footprint (Figure 2.7-12).

While the anticipated amount of sediment to be eroded varies somewhat by reservoir, during reservoir drawdown approximately 36 to 57 percent of the total 2020 volume across J.C. Boyle, Copco No. 1, and Iron Gate reservoirs, or an estimated 5.4 to 8.6 million yd^3 (1.2 to 2.3 million tons [dry weight]) of reservoir sediment, would be eroded and flushed downstream during the drawdown period (Table 2.7-11). Large quantities of sediment would remain in place after dam removal in each of the former reservoir beds, primarily on areas above the active channel. The remaining sediments would consolidate (dry out and decrease in thickness). Studies of the existing sediments in J.C. Boyle Reservoir show an anticipated change in sediment depth of up to 61 percent of original depth (USBR 2012a). A higher degree of shrinkage of the sediment layers is expected for Copco No. 1 and Iron Gate reservoirs due to the increased organic matter content in the sediment deposits of these two downstream reservoirs.

The range in estimated erosion volume in each reservoir is primarily dependent upon whether the prevailing hydrology during reservoir drawdown corresponds to a dry hydrologic year or a wet hydrologic year. The majority of the sediment erosion would occur during the reservoir drawdown process and would be a combination of direct erosion of the sediment by moving water, slumping of the fine sediment along the reservoir sides toward the river, and sediment jetting of some areas of reservoir-deposited sediments during drawdown. In a dry hydrologic year, reservoir pool levels can be drawn down steadily and relatively quickly, resulting in a shorter period of interaction between the flow and sediment deposits, and thus less overall sediment erosion. In a wet hydrologic year, the reservoir pool may experience cycles of drawdown followed by periods of refilling during high flow events, resulting in longer period of interaction between the flow and the sediment deposits, and thus more overall sediment erosion.

The rate of reservoir drawdown would also affect the amount of erosion of the sediment deposit. A faster drawdown rate would reduce the time of interaction between the flow and reservoir sediment deposits, thus reducing the overall amount of sediment erosion, whereas a slower drawdown rate would increase the time of interaction between the flow and reservoir sediment deposits, thus increasing the overall amount of sediment erosion. It is expected that increasing the previously modeled maximum drawdown rate of 2.25 to 3 feet per day (USBR 2012b) to the Proposed Project maximum drawdown rate of 5 feet per day (Appendix B: *Definite Plan – Appendix P*) would slightly decrease the total amount of sediment erosion that occurs during drawdown. The previously modeled maximum drawdown rate would result in 36 to 57 percent of erosion of the sediment deposit from the reservoirs (Table 2.7-11) and increasing the drawdown rate to 5 feet per day would most likely result in an amount of erosion toward the lower end of the estimated range or slightly lower. However, the Proposed Project also includes sediment jetting in some locations in Copco No. 1 and Iron Gate reservoirs, which would tend to push the percent of eroded sediment to the higher end of the range (see discussion in Potential Impact 3.2-3 Although no measurements (bathymetry or sediment grain size) are available for Copco No. 2 reservoir (USBR 2011b), continuous operation of the outlet tunnel located on the reservoir bottom suggests little if any accumulation of sediments arriving from upstream would occur during drawdown operations.

Reservoir sediment field sampling and laboratory testing in 2012 (USBR 2012b) and 2018 (Appendix B: *Definite Plan – Appendix H*) indicates that sediments remaining in the reservoir footprint would strengthen as they dry out, but wetting and drying cycles of unvegetated reservoir sediment would cause the sediment to produce erodible fine particles and aggregates. There is the potential for unvegetated sediments to cause short-term elevated suspended sediment concentrations during fall rain events if not stabilized with vegetation, especially from Iron Gate Reservoir where the highest levels of fine sediment and particles were produced in response to the laboratory wetting and drying cycles. These results are consistent with suspended sediment modeling results (USBR 2012b) indicating that SSCs can periodically increase under storm conditions. Tests of sediment from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs showed that vegetation reduces the production of erodible fine particles during wetting and drying cycles in the Copco No. 1 reservoir sediments.

Additionally, the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) details restoration activities planned for the reservoir areas during reservoir drawdown including seeding (via ground equipment, barge, or aerial application) and native plantings to further anchor remaining sediments. As the system returns to riverine conditions within the reservoir footprints, erosion and sediment transport rates are anticipated to return to natural background rates for this portion of the watershed (USBR 2012b).

Table 2.7-10. Stored Sediment in the Klamath Hydroelectric Project, Fall 2009.

Reservoir	Total Sediment Volume[1] (yd^3)		Total Sediment Mass[2,3,4] (tons, dry weight)	Fine Sediment Mass[2,4,5] (tons, dry weight)	Sand Sediment Mass[2,4,6] (tons, dry weight)	Percent Fine Sediment by Mass[8]	Percent Sand Sediment by Mass[8]
J.C. Boyle	990,000	+/- 300,000	290,000	190,000	100,000	66 percent	34 percent
Copco No. 1[7]	7,440,000	+/- 1,500,000	1,880,000	1,630,000	260,000	86 percent	14 percent
Iron Gate[7]	4,710,000	+/- 1,300,000	1,430,000	1,210,000	230,000	84 percent	16 percent
Total[7]	13,150,000	+/- 2,000,000	3,600,000	3,020,000[6]	590,000	84 percent	16 percent
Total Copco No. 1 and Iron Gate[7]	**12,150,000**	**+/- 2,000,000**	**3,320,000**	**2,830,000[6]**	**490,000**	**85 percent**	**15 percent**

Source: Modified from USBR 2012a, as noted in the below footnotes.

1 Uncertainty resulted from interpolation between drill holes and is calculated as a volume with a +/- amount shown in the table (USBR 2012a).

2 Amount of sediment with a diameter greater than 2 millimeters is negligible (< 0.5 percent) for all the reservoirs and within the uncertainty of the sediment estimates.

3 Average dry densities vary between reservoirs and within the reservoir depending upon compaction and grain size distribution. The dry unit weight varies between 44.4 and 16.3 lb/ft^3 (USBR 2012a).

4 Ton, dry weight is defined as equal to 2000 pounds.

5 Fine sediment is sediment with a diameter less than 0.063 millimeters.

6 Sand sediment is sediment with a diameter between 0.063 and 2 millimeters.

7 Amounts of sediment (volumes and masses) from individual reservoirs may not equal the total amounts indicated because all volumes and masses taken from USBR (2012a) were rounded to the nearest 10,000 yd^3 (volume) or 10,000 tons, dry weight (mass). Copco No. 2 Reservoir does not retain measurable amounts of sediment and therefore is not included in the estimates of total stored sediment.

8 Percent sediments are calculated from the masses listed in the table and rounded so the percent fine sediment and the percent sand sediment sum to 100 percent.

Table 2.7-11. Estimated Amount of Sediment in the Lower Klamath Project Reservoirs in 2020.

Reservoir	Estimated 2020 Total[1]			
	Total Sediment Volume (yd^3)	Total Sediment Mass[2,3] (tons, dry weight)	Fine Sediment Mass[3,4] (tons, dry weight)	Sand Sediment Mass[3,5] (tons, dry weight)
J.C. Boyle	1,190,000	340,000	220,000	120,000
Copco No. 1	8,250,000	2,090,000	1,800,000	290,000
Iron Gate	5,690,000	1,730,000	1,460,000	280,000
Total[6]	**15,130,000**	**4,160,000**	**3,480,000**	**680,000[4]**
Total Copco No. 1 and Iron Gate[6]	**13,940,000**	**3,820,000**	**3,260,000**	**560,000[4]**

Source: Modified from USBR 2012a, as noted in the below footnotes.

1 Between 2020 and 2021 (i.e., dam removal year 2 when drawdown would primarily occur), the sediment volume present behind the dams would increase by approximately 81,300 cubic yards in Copco No. 1 Reservoir and approximately 100,000 cubic yards in Iron Gate Reservoir based on estimates of annual sedimentation rates for each reservoir (USBR 2012b). The increase in sediment volume between 2020 and 2021 be an order of magnitude less than the uncertainty of the 2020 total sediment volume estimates, so model results using the 2020 sediment volumes would still be applicable to the Proposed Project.

2 Amount of sediment with a diameter greater than 2 millimeters is negligible (< 0.5 percent) for all the reservoirs and within the uncertainty of the sediment estimates.

3 Ton, dry weight is defined as equal to 2000 pounds.

4 Fine sediment is sediment with a diameter less than 0.063 millimeters.

5 Sand sediment is sediment with a diameter between 0.063 and 2 millimeters.

6 Amounts of sediment (volumes and masses) from individual reservoirs may not equal the total amounts indicated because all volumes and masses taken from USBR (2012a) were rounded to the nearest 10,000 yd^3 (volume) or 10,000 tons, dry weight (mass). Copco No. 2 Reservoir does not retain measurable amounts of sediment and therefore is not included in the estimates of total stored sediment.

Table 2.7-12. Estimated Amount of Sediment Anticipated to Erode with Dam Removal.

Reservoir[1]	Percent Erosion[2]		Fine Sediment Mass[3,4,5] Erosion		Sand Sediment Mass[3,4,6] Erosion	
	Minimum Erosion (percent)	Maximum Erosion (percent)	Minimum (tons, dry weight)	Maximum (tons, dry weight)	Minimum (tons, dry weight)	Maximum (tons, dry weight)
J.C. Boyle	27 percent	51 percent	60,000	110,000	30,000	60,000
Copco No. 1	45 percent	76 percent	820,000	1,370,000	130,000	220,000
Iron Gate	24 percent	32 percent	350,000	460,000	70,000	90,000
Total[4]	36 percent	57 percent	1,230,000	1,950,000	230,000	370,000
Total Copco No. 1 and Iron Gate[4]	36 percent	56 percent	1,170,000	1,830,000	200,000	300,000

Source: Modified from USBR 2012a, as noted in the below footnotes.

1 Amount of sediment with a diameter greater than 2 millimeters is negligible (< 0.5 percent) for all the reservoirs and within the uncertainty of the sediment estimates.

2 Erosion would primarily occur during the drawdown period. The erosion rates are based on hydrologic conditions recorded for the March to June flow volume at Keno gage on the Klamath River from water year 2001 (90 percent exceedance) and 1984 (10 percent exceedance). Additional erosion and sediment transport could occur in the following year that would be indistinguishable from the background sediment regime.

3 Ton, dry weight is defined as defined as equal to 2,000 pounds.

4 Estimated amount of sediment mass eroded with dam removal based on estimated sediment amount in the reservoirs in 2020. Amounts of sediment masses from individual reservoirs may not equal the total amounts indicated because masses taken from USBR (2012a) were rounded to the nearest 10,000 tons, dry weight (mass). Copco No. 2 Reservoir does not retain measurable amounts of sediment and therefore is not included in the estimates of sediment anticipated to erode with dam removal.

5 Fine sediment is sediment with a diameter less than 0.063 millimeters

6 Sand sediment is sediment with a diameter between 0.063 and 2 millimeters.

2.7.4 Restoration Within the Reservoir Footprint

The KRRC's Proposed Project includes establishing native vegetation within the reservoir footprints to stabilize newly exposed reservoir sediments and support a functioning ecosystem. Additional information on planned restoration efforts during and following dam removal can be found in the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*).

2.7.4.1 Revegetation Activities

The following sequence describes the activities that would be implemented in the former reservoir footprints to manage remaining sediment deposits and restore habitats. Pre-dam removal restoration activities (i.e., one to two years before drawdown) would occur on the upland areas outside of the reservoir footprints; accordingly, these activities are discussed below in Section 2.7.5 *Restoration of Upland Areas Outside of the Reservoir Footprint*. See additional detail in KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*).

1. *Pre-dam Removal* (pre-dam removal year 3, and dam removal year 1): collect and propagate seed and control invasive plants.

2. Reservoir drawdown (January to March, dam removal year 2): amend sediment as necessary and stabilize sediments and exposed areas with hydroseeding13. To stabilize remaining reservoir sediment, the newly exposed reservoir areas would be revegetated during and following reservoir drawdown with native species through pioneer hydroseeding (via ground equipment, barge, or aerial application). Acorns, shrub seedlings, and pole cuttings would be installed early, as feasible.
3. Post-drawdown first summer/fall (dry season immediately after drawdown during dam removal year 2): monitor and rectify any non-natural fish passage barriers in the Klamath River's mainstem and tributaries, conduct additional fall overseeding application (overseeding application would involve a ground-based broadcast seeder, to be applied over mowed or rolled vegetation that grows in from the pioneer seeding) where needed on exposed reservoir areas, manual removal/treatment of invasive exotic vegetation, and installation of riparian trees and shrubs. Irrigation would be installed in the Riparian Bank Zone to support survival of planted riparian species. Plants below this zone would obtain water from the river and irrigation runoff. For plants above the Riparian Bank Zone, seedlings would be provided water by planting the seedling in a 'cocoon' which is a donut shaped container that surrounds the seedling and is made out of biodegradable paper mâché. If initial restoration efforts are unsuccessful in the upland areas, a temporary irrigation system would be installed. Riparian pole cuttings and other wetland plants would be harvested from on-site areas that would no longer support riparian species
4. Post-removal (post-dam removal year 1): maintain vegetation, continue to remove and treat invasive exotic vegetation, install floodplain and off-channel habitat features such as large wood to enhance complexity and stabilize banks or bury brush, limbs and wood to roughen the floodplain to enhance establishment of vegetation and organic materials. Monitor and rectify any non-natural fish passage barriers in mainstem and tributaries.
5. Establishment period (post-dam removal years 2 through 5): continued monitoring and maintenance of vegetation, removal of invasive exotic vegetation, fish passage monitoring, and enhancement of habitat features as needed.
6. Long term (years 5 through 10 post-dam removal): continued monitoring and adaptive management, removal of invasive exotic vegetation, and fish passage monitoring.

KRRC proposes to restore the former reservoir footprints with native plant species, trees and shrubs. The natives would be planted in upland, riparian, and wetland zones. To facilitate the restoration of this area and growth of planted vegetation, about 34.5 miles of permanent cattle exclusion fencing would be installed around the reservoir areas (Appendix B: *Definite Plan – Appendix H*) prior to drawdown or shortly after the pioneer seeding. It is unknown if this fencing would remain following the transfer of Parcel B

[13] Although not currently anticipated by KRRC, the Proposed Project may also include hydroseeding from a barge on exposed reservoir terraces as the water recedes during reservoir drawdown. Hydroseeding from a barge would be accomplished by placing a ground rig on one barge with another boat used to ferry materials from shore. A moveable pier or other engineered method of accessing the supply boat as the water level recedes would also be needed. If it occurs, barge hydroseeding would occur in the higher elevation portion of the reservoir shoreline, until the reservoir levels become too low to operate (i.e., March of dam removal year 2).

lands. Cattle currently free-range around reservoirs, and the purpose of cattle exclusion fencing is to prevent cattle from grazing on newly restored vegetation. The fencing would be wildlife-friendly and allow for the movement of deer, turtles, etc., while preventing access of cattle. Herbivore deterrent (e.g., screens, fencing, chemical deterrents) would be placed around planted riparian vegetation.

Proposed native seed mixes and plants along with information on the goals and objectives associated with the restoration activities are provided in KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*). The management techniques for invasive exotic vegetation (IEV) may include manual weed extraction, solarization (covering of ground areas with black visqueen), tilling, and use of herbicides. See additional detail in KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H).* In order to effectively eradicate IEV in the Limits of Work to the extent feasible and prevent the spread of IEV into restoration areas, KRRC would begin active control of IEV several years before drawdown and would continue until the required performance criteria are met. The KRRC began IEV surveys in fall 2017, between the existing water line and the boundary of the Limits of Work, to obtain information on the exact location of each invasive species and information on the diversity of invasive species. The results would be the basis for the IEV removal plan which would be initiated prior to drawdown.

The Proposed Project Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) incorporates monitoring and metrics to evaluate success of minimizing invasive exotic vegetation and enhancing native plant diversity and survival of planted trees and shrubs. Monitoring would continue for five years or until the performance criteria has been met. In the event the performance criteria are not being met, the cause would be evaluated, data collection and performance criteria metrics would be reassessed as necessary, and the KRRC would develop a plan to address problems and initiate further monitoring. The performance criteria are the following:

- Minimize invasive exotic vegetation—percent relative cover by medium and low priority IEV shall be less than the average at designated reference locations at Year 1—25 percent, Year 2—40 percent, Year 3—55 percent, Year 4—70 percent, Year 5—90 percent, and no high-priority invasive plants present in the Limits of Work;
- Enhance native plant diversity—percent diversity compared to reference sites in Year 1—60 percent, Year 2—65 percent, Year 3—70 percent, Year 4—75 percent, and Year 5—80 percent; and
- Survival of planted trees and shrubs—percent survival in Year 1—90 percent, Year 2—85 percent, Year 3—80 percent, Year 4—75 percent, and Year 5—70 percent.

2.7.4.2 Reservoir Restoration Features

Proposed restoration activities for the reservoir footprints are supporting reservoir-deposited sediment evacuation; enhancing tributary connectivity to the Klamath River; incorporating floodplain features such as wetlands, swales, and side channels; enhancing floodplain roughness to stabilize vegetation; and stabilizing banks and enhancing channel complexity, often with the use of large wood (Figure 2.7-10).

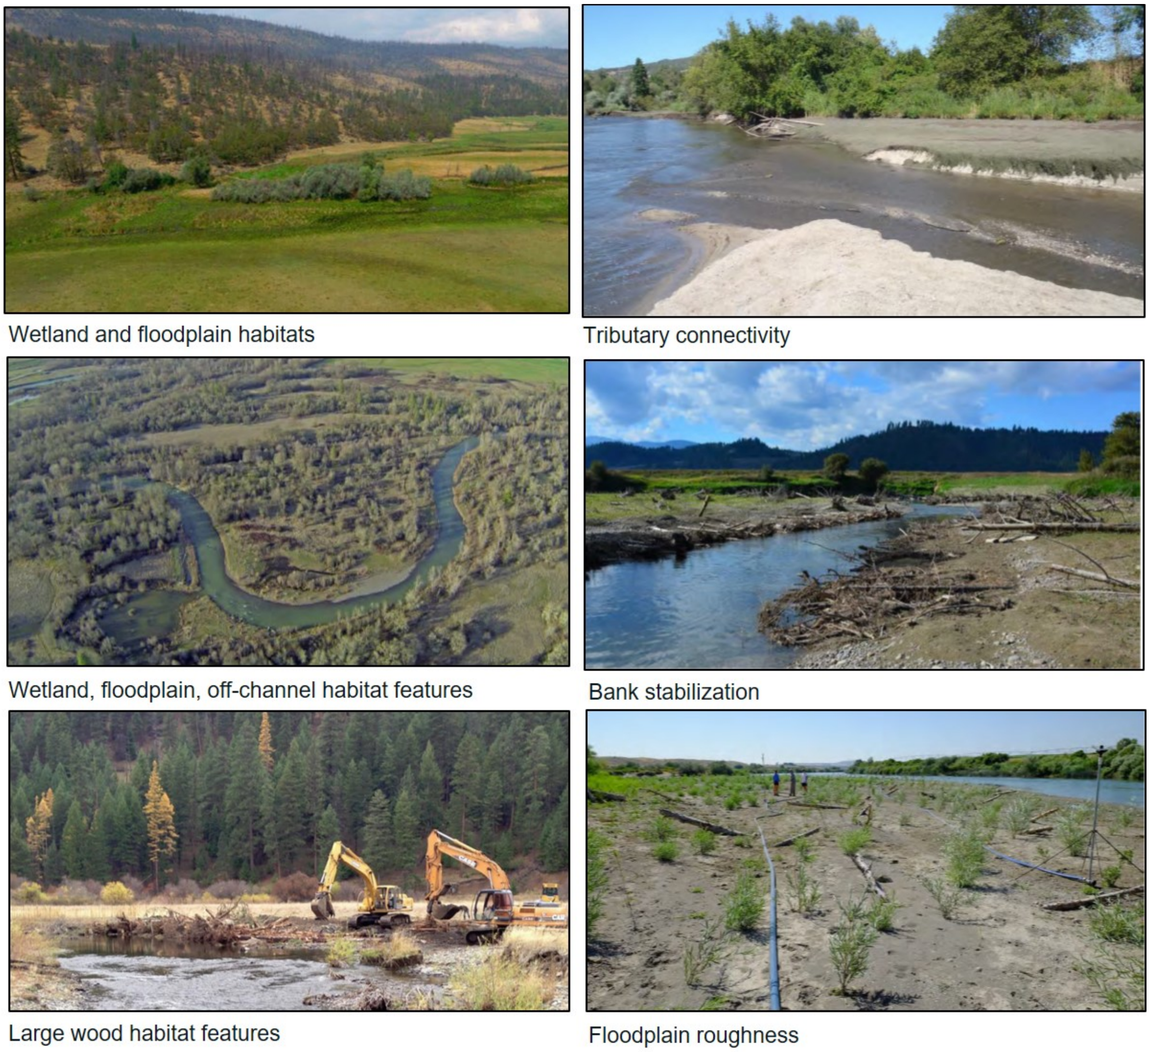

Figure 2.7-10. Examples of Restored Habitat Types and Components (Appendix B: *Definite Plan – Appendix H*).

During drawdown, a barge-mounted pressure sprayer would jet water onto newly exposed reservoir-deposited sediments (this process is called sediment jetting) as the reservoir water level decreases to support transport of reservoir-deposited sediments from the historical floodplain. The erosion of reservoir sediments from the historical floodplain, especially the two-year floodplain, would promote riparian bank and floodplain connectivity for restoration features by increasing river inundation on the floodplain during high flow events. Sediment jetting would also prepare areas for restoration by minimizing the necessary manual excavation and grading of sediments at those sites. Sediment jetting would be focused in the six areas where restoration actions are proposed within the Copco No. 1 Reservoir footprint (Figure 2.7-11) and the three areas where restoration actions are proposed within the Iron Gate Reservoir footprint (Figure 2.7-12). During the drawdown period between January and April of dam removal year 2, additional manual grading and transport of reservoir-deposited sediment would occur in proposed restoration areas near existing roads with easy access for machinery, such as bulldozers and excavators.

During and following reservoir drawdown, tributaries would flow over the area now submerged by the reservoirs toward the new riverbed of the Klamath River. Tributaries would likely transport fine sediment downstream (i.e., it would not deposit in the reservoir footprint), but some larger sediments and debris may deposit and create fish passage barriers or un-natural changes in slope in the tributary flow paths located within the reservoir footprints. KRRC proposes using light equipment and manual labor to move such barriers and enhance access and longitudinal connectivity of the tributaries with the mainstem Klamath River within the reservoir footprints (Figure 2.7-10). In addition, the KRRC may add large wood to tributaries to promote habitat complexity.

Incorporating floodplain features that create natural elevation variations (e.g., swales) into the newly exposed floodplains within the reservoir footprints is a restoration strategy that promotes habitat complexity and function. Based on historical images of the Project area, the KRRC has indicated that the following three main types of features could be supported on the newly exposed floodplain areas:

- Wetlands are low-lying features with standing water or saturated soils for a portion of the growing season sufficient to support wetland vegetation such as willows, sedges, and rushes. Wetlands provide a wide range of ecological functions such as water quality improvement, flood attenuation, and habitat for both terrestrial and aquatic organisms. Wetland restoration strategies for the reservoir areas include preservation of existing wetlands, hydrologic connection of off-channel wetlands with the river, or creation of new wetlands at lower elevations corresponding to the post-dam removal surfaces and hydrologic regime (see Figure 2.7-10).
- Floodplain swales are small depressions where floodplain vegetation can establish at slightly lower elevations (closer to the water table) than adjacent floodplain surfaces. These depressions provide storage for flood water and sediment at variable flows, in addition to broadening the range of ecological niches available on the floodplain surface to support different life stages (and behaviors) of wildlife species.
- Side channels are channels off the main channel that provide habitat for juvenile rearing and high flow refugia for other aquatic species. Like floodplains, side channels exchange water, sediment and nutrients between the main channel and off-channel areas, thus supporting diverse vegetation communities. Side channel restoration strategies are designed to improve instream habitat diversity and include modifying inlet and outlet hydraulics, improving hydraulic complexity with structures or realignment, and delivery of water to higher floodplain surfaces.

To provide a temporary replacement for the lack of established, stable vegetation in the reservoir footprints, the KRRC proposes to use ground-based equipment to ‘roughen’ the floodplain surface and partially bury wood, limbs, or brush in the sediment deposits that remain following drawdown (Figure 2.7-10). The KRRC has indicated that installing these features would create complexity and provide a location for seeds to establish, reduce erosion by reducing velocity, and promote soil development by introducing organic matter (Appendix B: *Definite Plan − Appendix H*).

To stabilize the banks and enhance the complexity of the channel fringe along the newly exposed Klamath River within the reservoir footprints, the KRRC has proposed installation of large wood features (e.g., trees, root wads) and planting of riparian vegetation (Figure 2.7-10) (Appendix B: *Definite Plan − Appendix H*). These features would reduce water velocities creating low velocity zones that would provide habitat for fish and wildlife. Placement of wood features along the river banks would be accomplished using ground-based equipment or helicopters.

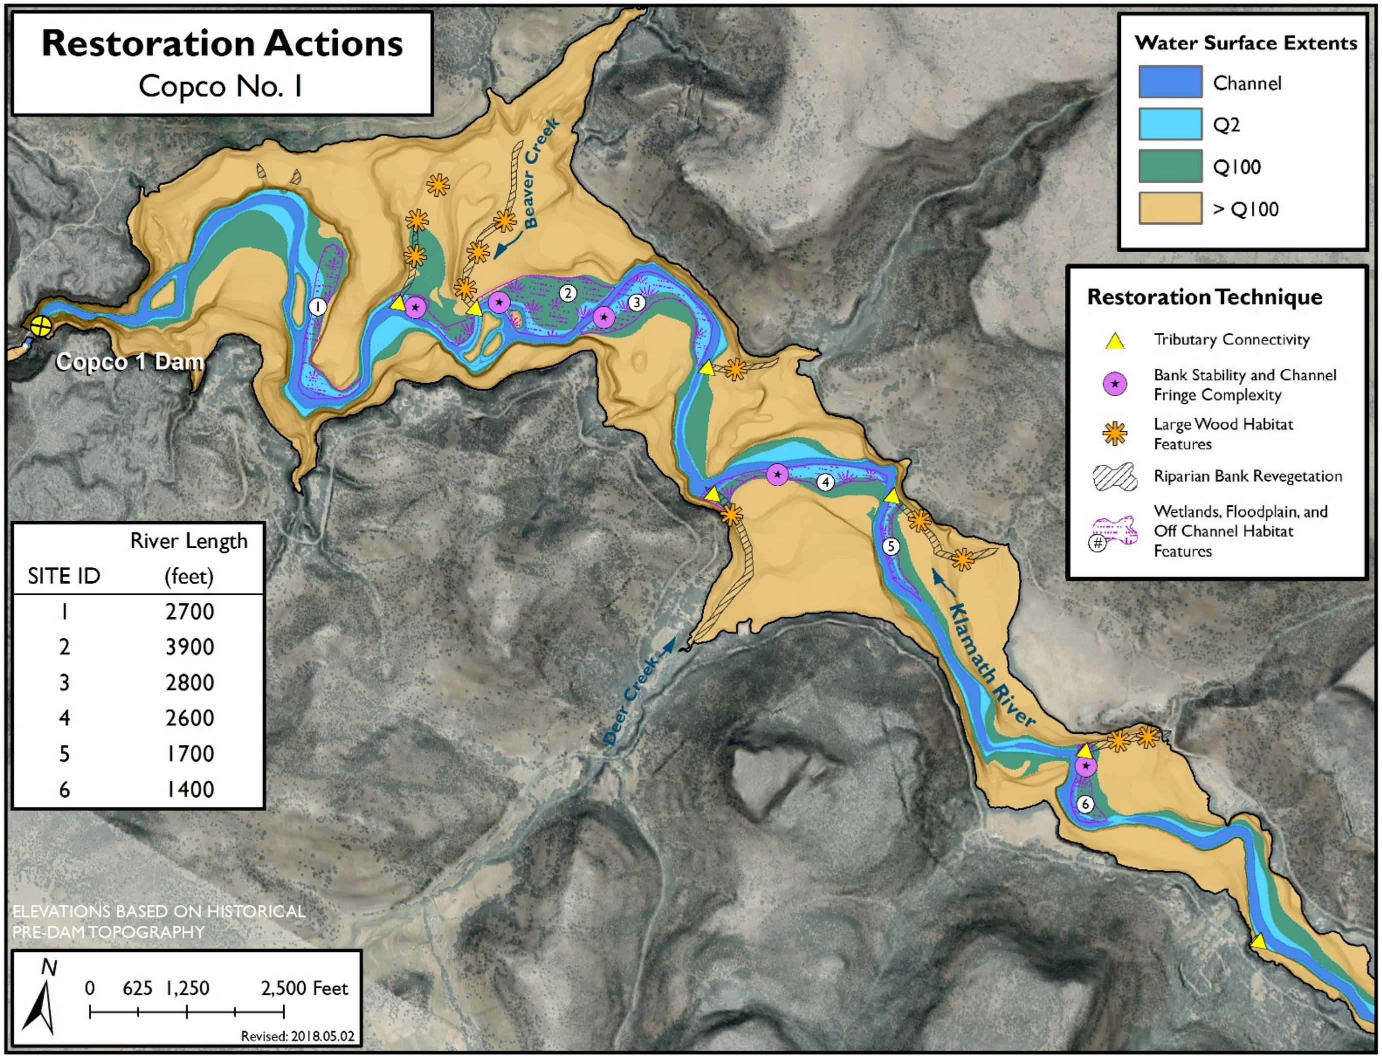

Figure 2.7-11. Restoration Actions Identified for the Copco No. 1 Reservoir Area (Appendix B: *Definite Plan – Appendix H*).

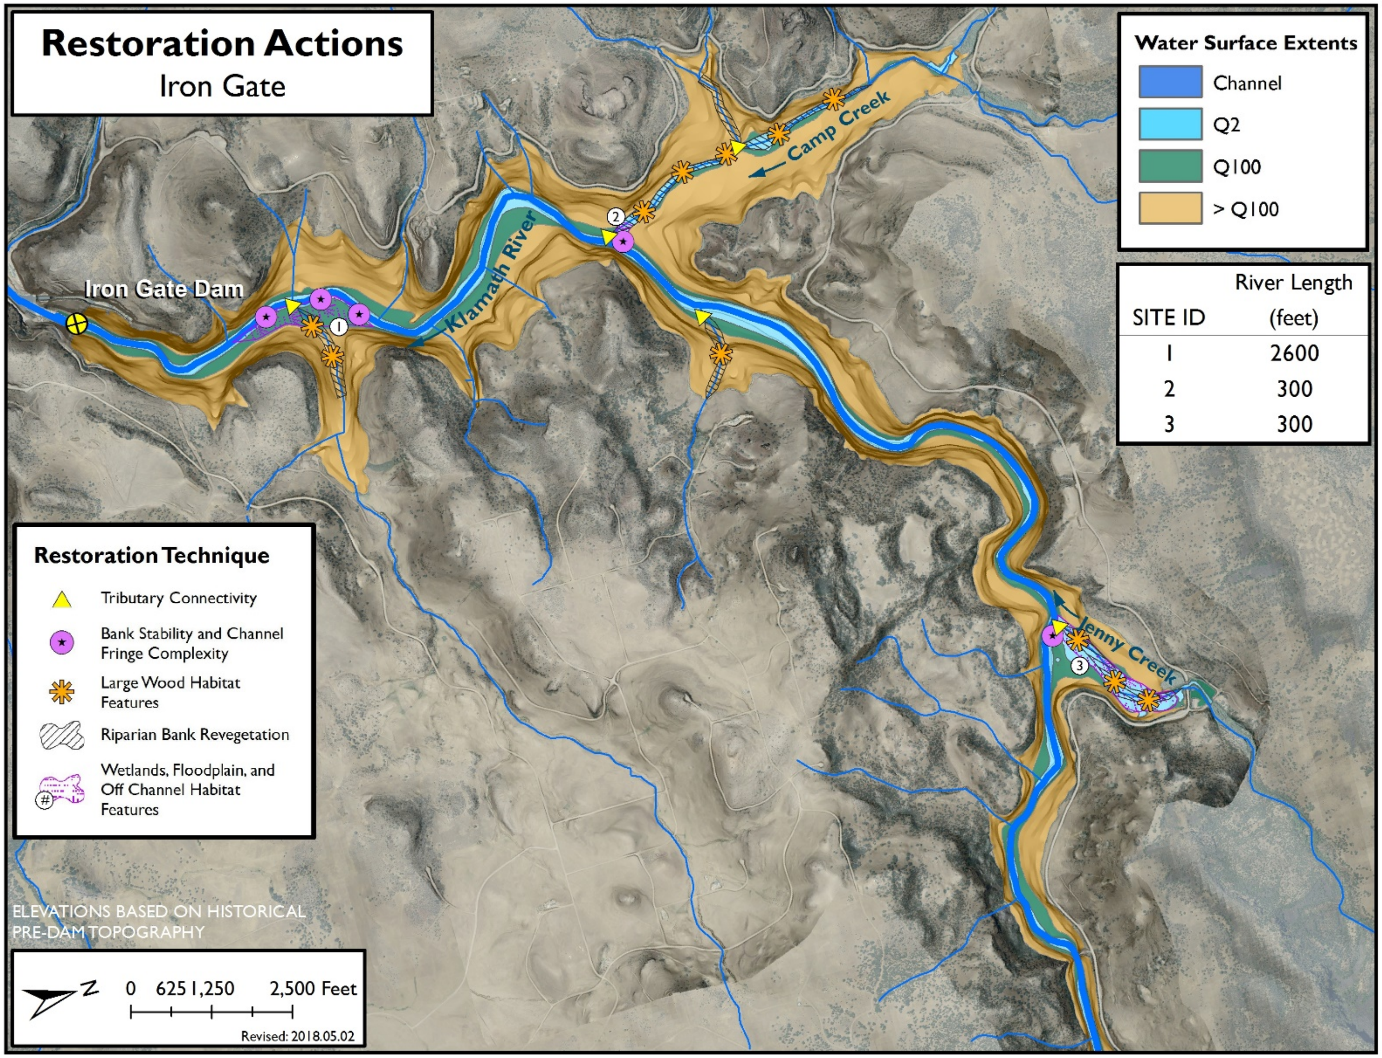

Figure 2.7-12. Restoration actions identified for the Iron Gate Reservoir area (Appendix B: *Definite Plan – Appendix H*).

2.7.5 Restoration of Upland Areas Outside of the Reservoir Footprint

Restoration activities would also occur in Project-affected upland areas surrounding the reservoirs. During the pre-dam removal period, native plants would be prepared for restoration activities by collecting seeds and working with local nurseries to grow trees and shrubs. Active management of invasive exotic vegetation species would be initiated prior to drawdown and would continue until the Proposed Project completion. The management techniques for invasive exotic vegetation may include grazing with cattle, sheep, and goats, manual weed extraction, solarization (covering of ground areas with black visqueen), tilling, and use of herbicides. See additional detail in KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*).

During the post-dam removal period, restoration would occur in upland areas outside of the reservoir footprints, including disposal areas used for placing embankment or concrete material, staging areas, temporary access roads, hydropower infrastructure demolition areas, and former recreation areas. Revegetation of these areas in the short term would be implemented in compliance with an approved Storm Water Pollution Prevention Plan (SWPPP)/Erosion Control Plan (see also Section 2.7.8.7 *Water Quality Monitoring*). In the long term, these areas would be revegetated similar to the upland planting zone areas, as described in the KRRC's Reservoir Area Management Plan (Appendix B: *Definite Plan − Appendix H*). Since upland soils would be highly compacted, soils would be disked and ripped (a process used to mechanically break up compacted soil layers) to prepare them for subsequent planting.

Existing native vegetation would be preserved and protected where feasible. Native trees within the Limit of Work that do not need to be removed for construction or demolition activities (as determined by KRRC authorized representative) would be retained (S. Leonard, Senior Water Resources Engineer, AECOM, pers. comm., July 2018). These native trees would be protected, to the maximum extent practical, by a work exclusion zone around the trunk with a radius equal to approximately one time the average tree canopy diameter. The work exclusion zone would be visibly demarcated in the field with non-moveable orange fencing, and adjacent protected trees may be fenced together in groupings, as appropriate. For native trees adjacent to construction and demolition activities where work exclusion zone establishment is not possible, large sheets of steel plate (minimum size of 4-foot width, 8-foot-long, 0.5-inch-tall) would be laid on the ground to distribute the potential point loads in order to prevent the crushing of tree roots underground.

2.7.6 Hatchery Operations

2.7.6.1 Iron Gate Hatchery

During demolition, the Iron Gate Hatchery facilities located at the base of Iron Gate Dam, including the adult fish ladder and holding tanks at the toe of the dam, would be removed, as would the cold-water supply and aerator for the hatchery (see also Figure 2.3-4 and Section 2.7.1.4 *Iron Gate Dam and Powerhouse*). Portions of the hatchery located downstream near the confluence of Klamath River and Bogus Creek would remain in place or would be altered, including conversion of two of the existing raceways to adult holding tanks, and construction of a new spawning facility, so limited operations could continue at the facility for eight years following dam removal. Consistent with the KHSA Section 7.6.6, the hatchery would be operated for eight years following the decommissioning[14] of Iron Gate Dam. Given that power generation at Iron Gate Powerhouse is scheduled to cease by January of dam removal year 2 (Table 2.7-1), the hatchery would operate from dam removal year 2 through post-dam removal year 7, for a total of eight years. Following the eight-year period, Iron Gate Hatchery would cease operations. It is currently unclear whether the Iron Gate Hatchery facility would be decommissioned in place, demolished, or partly or fully repurposed after the eight-year operational period.

Some operational components of Iron Gate Hatchery would be retained during dam removal (Figure 2.7-13). The operations during dam removal would include a maximum of 8.75 cfs of water to be diverted from Bogus Creek within 1,000 feet of the confluence with the mainstem Klamath River. This water would operate the Iron Gate Hatchery incubation building, two 300-foot adult holding ponds, three 400-foot raceway, and an auxiliary adult fish ladder and trap (to replace the one removed from the base of Iron Gate Dam during demolition). Iron Gate Hatchery would use between 3.75 and 8.75 cfs from October through May to rear the targeted goal of 3.4 million Chinook smolts for release in April through May of each year. The diversion for the hatchery water supply would be constructed as close to the confluence of Bogus Creek and the Klamath River as possible, in order to reduce the length of Bogus Creek rearing habitat affected by water withdrawals downstream of the diversion. An approximately 4,000 gallons per minute (gpm) screened, pump station would be used to divert water from Bogus Creek. Specific diversion rates from Bogus Creek would be as follows:

- 6.50 cfs October through November
- 8.75 cfs in December
- 3.50 cfs January through March
- 8.25 cfs April through May
- 0.00 cfs June through September

The Bogus Creek water diversion would be operated to maintain a minimum of 50 percent of the instream flow in the creek at the point of diversion. To provide context for the proposed Bogus Creek diversion rates, daily average flow rates of Bogus Creek from August 2013 to August 2017 are compared with the proposed water needs at Iron Gate Hatchery in Figure 2.7-14. In addition, Figure 2.7-14 shows the percent of Bogus Creek flow remaining after subtracting the Iron Gate Hatchery diversion, with a negative percentage indicating that there would not be enough flow in Bogus Creek to meet the Iron Gate Hatchery water needs. Between August 2013 and August 2017, the proposed flow diversions for Iron Gate Hatchery would have consistently diverted more than 50 percent of Bogus Creek flow during part of each year, especially during October, November, April, and May. In spring/early summer of 2014, Bogus Creek flows were insufficient to meet the proposed full water needs of the hatchery. These results may be due to the short duration of the dataset or drought conditions between 2013 and 2017 that may not represent long-term conditions. The KRRC proposes that if Bogus Creek flows are insufficient to meet minimum operational needs while balancing flow requirements in the creek, water reuse (recirculation) from the rearing raceways could be utilized. In addition to recirculation, early release of smolts (i.e., prior to April 1) may occur to reduce water use requirements in the hatchery. The effectiveness of

[14] Decommissioning is defined as PacifiCorp's physical removal from a facility of any equipment and personal property that PacifiCorp determines has salvage value, and physical disconnection of the facility from PacifiCorp's transmission grid (KHSA Section 1.4).

recirculation and early smolt release would be studied to determine whether they could be used to meet minimum operational flow and water temperature needs in the hatchery given annual variations in Bogus Creek flow and water temperature during the early release period.

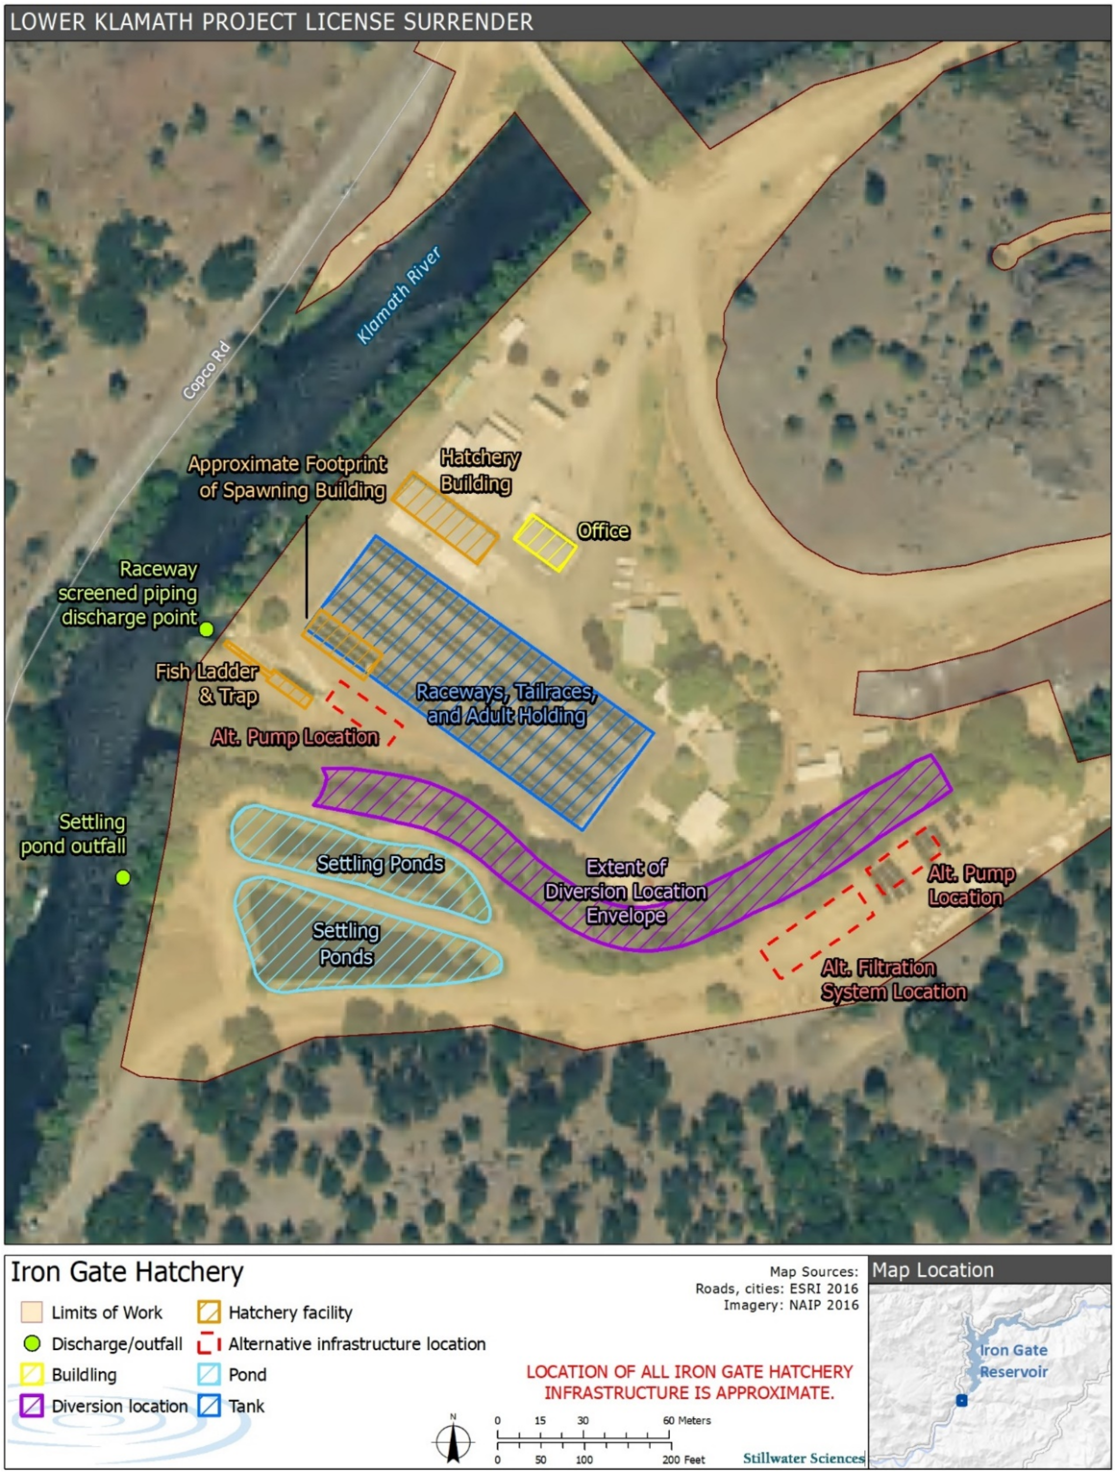

Figure 2.7-13. Iron Gate Hatchery Existing Features and Proposed Modifications.

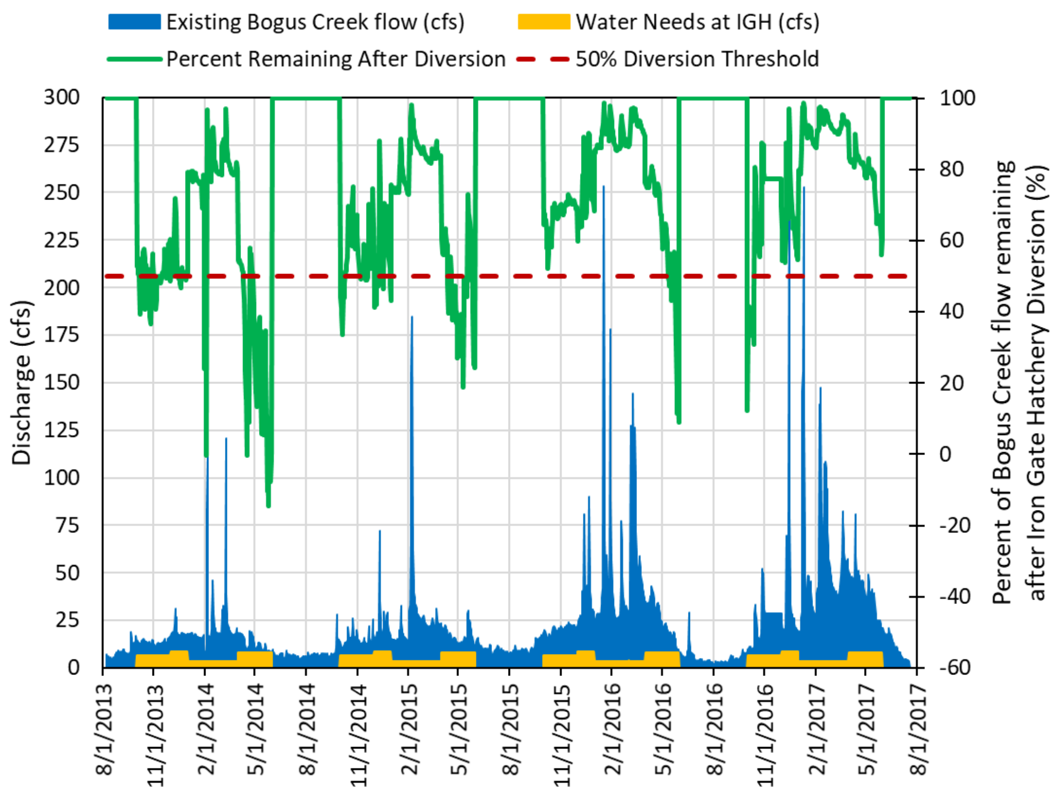

Figure 2.7-14. Bogus Creek Existing Flow and Proposed Flow Diversion to Support Production at Iron Gate Hatchery (ICH) for eight Years Following Dam Removal.

During dam removal year 2 and the subsequent seven years post-dam removal (i.e., eight years total), total hatchery production goals would be reduced from current levels (Table 2.7-13). Iron Gate Hatchery production would be limited to 3,400,000 Chinook salmon smolts, while coho salmon and Chinook salmon yearling production would cease at Iron Gate Hatchery. Steelhead production at the Iron Gate Hatchery has not occurred since 2012, and it would not be re-initiated. Fall Creek Hatchery production (see also Section 2.7.6.2 *Fall Creek Hatchery*) would include 75,000 coho yearlings and 115,000 Chinook yearlings. No Chinook smolts and no steelhead would be produced at Fall Creek Hatchery.

Table 2.7-13. Existing Goals and Proposed Hatchery Production for Operations at Iron Gate and Fall Creek Hatcheries (NMFS and CDFW 2018).

Species/Life Stage	Existing Production Goal[1] (at Iron Gate Hatchery)	Proposed Production (at Iron Gate Hatchery and Fall Creek Hatchery)
Coho Yearlings	75,000	75,000 at Fall Creek Hatchery
Chinook Yearlings	900,000	115,000 at Fall Creek Hatchery
Chinook Smolts	5,100,000	3,400,000 at Iron Gate Hatchery
Steelhead	200,000	0

[1] Ability to meet production goals varies annually based on adult returns and hatchery performance, with coho and Chinook yearling goals achieved on average since 2005 and actual Chinook Smolt production typically a million smolts less than production goals (K. Pomeroy, CDFW, pers. comm., 2018).

2.7.6.2 Fall Creek Hatchery

The KRRC also proposes to reopen the nearby Fall Creek Hatchery, as directed by NMFS and CDFW (2018). The KRRC proposes to reopen Fall Creek Hatchery with upgraded facilities (e.g., install circular tanks, UV treatment system, renovate existing raceways, upgrade plumbing, etc.) for raising coho salmon and Chinook salmon yearlings within the existing facility footprint and an area adjacent to the upper raceways (Figure 2.7-15). Additional space requirements needed for most operations (e.g., vehicle parking, pertinent buildings, tagging trailer, etc.) can be accommodated on existing developed or disturbed areas around the hatchery and powerhouse, but the settling pond would need to be located outside of this area. The settling pond would be constructed on one of two potential nearby sites located on Parcel B lands downstream of the Fall Creek Hatchery, with a minimally buried or at-grade conveyance pipeline transporting flows from the hatchery to the settling pond. Selection of the settling pond site is pending cultural resources investigations and consultation with tribes with historical and cultural connection to the area.

To operate the Fall Creek Hatchery, up to 10 cfs of water would be diverted from the PacifiCorp Fall Creek powerhouse return canal downstream of the City of Yreka's diversion facility at Fall Creek Dam A. Hatchery water would be diverted from Fall Creek Dam B to Dam A during periods when the powerhouse return canal is not flowing. While the Definite Plan specifies diverted water would be returned to Fall Creek at the fish ladder located in the lower tank area or the settling pond location (Appendix B: *Definite Plan −Section 7.8.3*), an October 2018 update specifies the upper rearing tank would discharge diverted water directly to Fall Creek, the lower rearing tank would discharge to the fish ladder adjacent to the tank, and the settling pond would discharge to Fall Creek further down, but upstream of the USGS 11512000 gage on Fall Creek (S. Leonard, AECOM as KRRC Technical Representative, pers. comm., October 2018). Fall Creek diverted water would be gravity fed and plumbed to each rearing location and all circular tanks. Specific diversion rates from Fall Creek would be as follows:

- 8.48 cfs in October
- 9.24 cfs in November
- 6.32 cfs in December
- 5.77 cfs in January
- 1.47 cfs in February
- 1.76 cfs in March
- 1.84 cfs in April
- 1.08 cfs in May
- 0.58 cfs in June
- 1.01 cfs in July
- 1.48 cfs in August
- 2.29 cfs in September

The non-consumptive water diversion for the Fall Creek Hatchery is downstream of the City of Yreka's diversions at Dam A on the PacifiCorp Fall Creek powerhouse return canal. Flows diverted for the hatchery (less evaporative losses) would be returned to

Fall Creek from the three hatchery discharge points (i.e., upper tank, fish ladder near the lower tank, and settling pond) upstream of the compliance point for the City of Yreka diversion, the USGS 11512000 gage on Fall Creek approximately 1,000 feet upstream of Daggett Road (S. Leonard, AECOM as KRRC Technical Representative, pers. comm., October 2018). At the compliance point, the City of Yreka must ensure Fall Creek has a minimum flow of 15.0 cfs, or the natural flow of Fall Creek whenever it is less than 15.0 cfs. To provide context about flows in Fall Creek, the historical daily average City of Yreka water diversion flows from October 2003 to October 2005 along with the historical daily average Fall Creek flows measured at the USGS 11512000 gage during this period are compared with the proposed Fall Creek Hatchery non-consumptive diversion flows in Figure 2.7-16. The proposed Fall Creek Hatchery diversion would not alter Fall Creek flows measured at the USGS 11512000 gage or compliance with minimum Fall Creek flow requirements since the diversion flows for Fall Creek Hatchery would be diverted and returned (less evaporative losses) to Fall Creek upstream of the USGS 1151200 gage under the Proposed Project.

Total hatchery production goals for Fall Creek Hatchery are presented in Table 2.7-13. Following the eight-year period, Fall Creek Hatchery would cease operations. As Fall Creek Hatchery is part of PacifiCorp's Klamath Hydroelectric Project No. 2082, the existing Fall Creek hatchery facilities are subject to the terms of any new FERC action for Project No. 2082. It is currently unclear whether the Fall Creek Hatchery facility would be decommissioned in place, demolished, or partly or fully repurposed after the eight-year operational period.

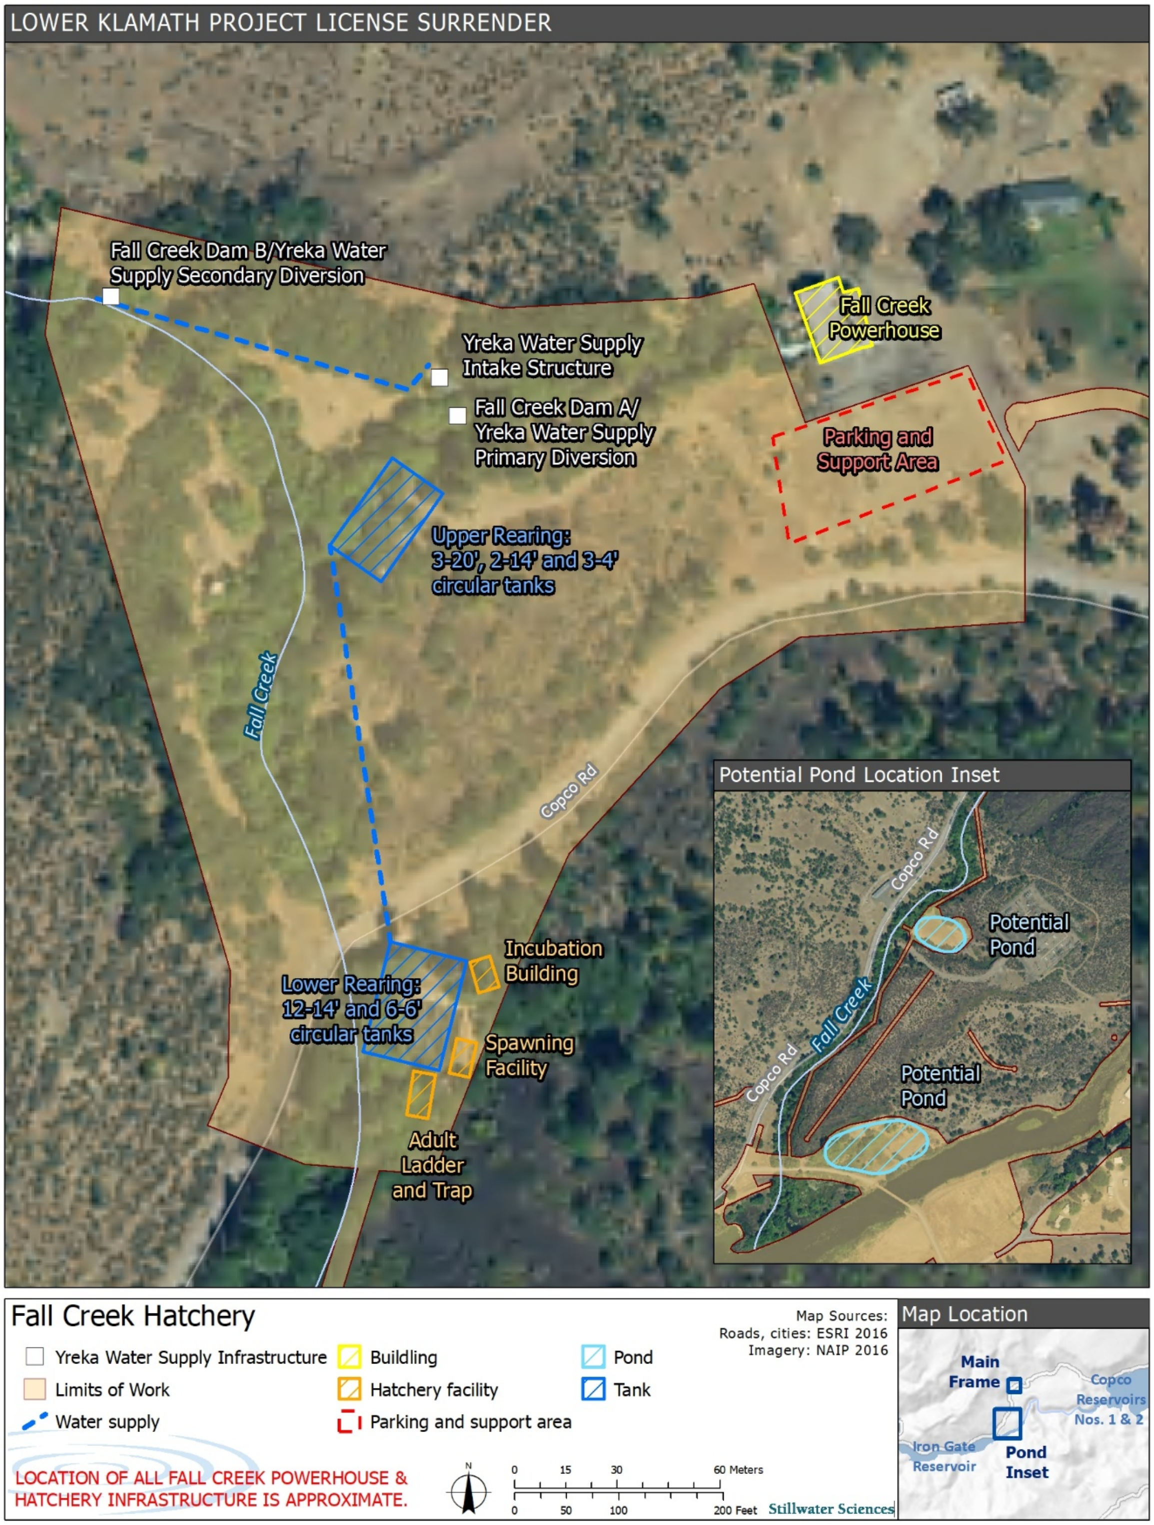

Figure 2.7-15. Fall Creek Hatchery Existing Features and Proposed Modifications.

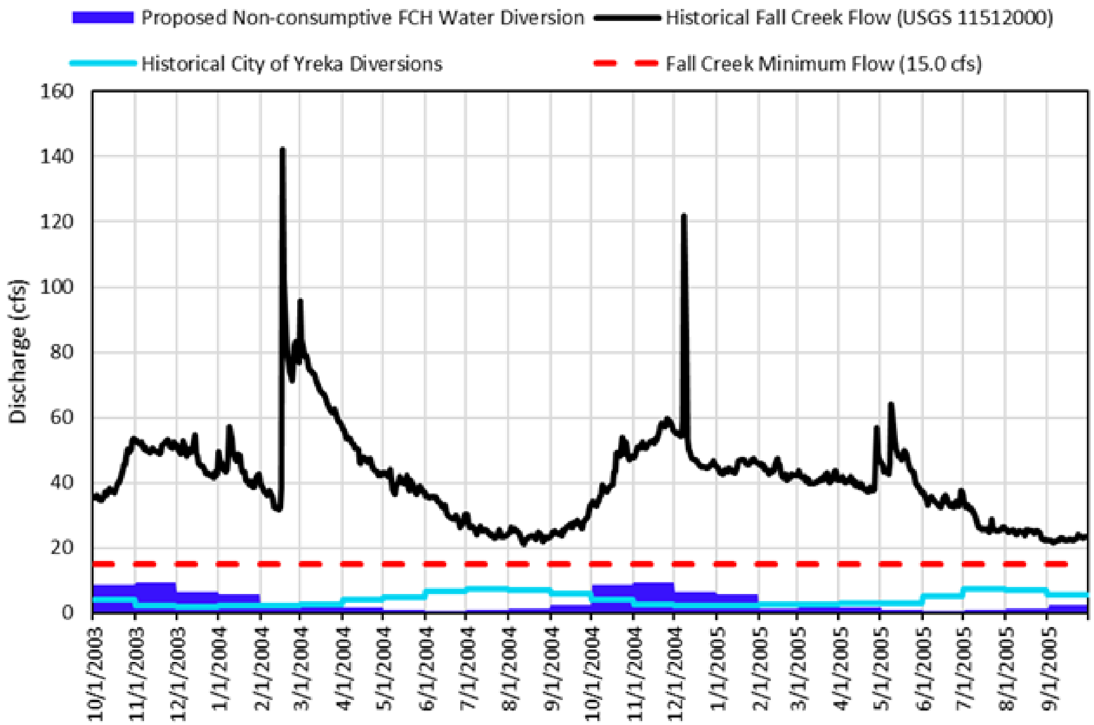

Figure 2.7-16. Proposed Non-consumptive Fall Creek Hatchery (FCH) Water Diversions to Support Production at the Fall Creek Hatchery Following Dam Removal, Historical Fall Creek Flow Measured at USGS 11512000 Downstream of the City of Yreka Diversion, Historical City of Yreka Diversion, and Fall Creek Minimum Flow Requirement (15.0 cfs) Downstream of Compliance Point (USGS 11512000).

2.7.7 City of Yreka Water Supply Pipeline Relocation

The City of Yreka receives part of its water supply from Fall Creek, which is a tributary to the Klamath River in the Upper Klamath Basin. Fall Creek is approximately 23 miles northeast of the city. The city diverts up to 15 cfs of water from Fall Creek through a 24-inch diameter steel pipe near the PacifiCorp's Klamath Hydroelectric Project Fall Creek dam complex. The primary water intake for this water pipeline is located along the PacifiCorp Fall Creek powerhouse return canal at Dam A, which diverts flow to a pumping station further downstream along Fall Creek (Figure 2.7-17). A secondary intake at Dam B on Fall Creek is used when the powerhouse is shut down and supplies water through a pipeline to the intake at Dam A. The pipeline crosses the Klamath River near the upstream end of Iron Gate Reservoir, and it extends to the City of Yreka's water distribution system.

At the upstream end of Iron Gate Reservoir, the pipeline is minimally buried in the reservoir bed (Figure 2.7-17). When Iron Gate dam is removed, the pipe would become exposed to high velocity river flows and would likely sustain damage. A replacement pipe crossing is needed before dam removal and reservoir drawdown to ensure uninterrupted water supply to the City of Yreka.

Additionally, the existing flat panel fish screens for the water supply intakes at Dams A and B may not meet current regulatory agency screen criteria for anadromous fish (USBR 2012a). These fish screens would have to meet the criteria from NMFS, USFWS, and CDFW, and would require updates, if found to be non-compliant.

Conceptual level buried and aerial relocation crossings of the pipeline across the Klamath River have been identified for feasibility and further evaluation. It is desired that any buried crossing should have adequate cover to compensate for the vertical scour during dam removal and the subsequent variations in the river flows and longitudinal profile. As the construction of the relocated crossing needs to happen prior to Iron Gate Dam removal, the cover over the pipe would likely have to exceed 12 feet. An open-cut construction approach would therefore, potentially require significant sediment and rock excavation under water and is not considered as a viable option. Considering this, the KRRC has identified and is proposing one of the following three options for the reconstruction of the Klamath River crossing of the Yreka pipeline:

1. A new buried pipeline by micro-tunneling in the immediate vicinity of the existing waterline crossing.
2. A new aerial pipeline on a dedicated utility pipe crossing in the immediate vicinity of the existing waterline crossing.
3. A new buried pipeline and an aerial pipeline crossing on the existing timber traffic bridge along Daggett Road located approximately 2,000 feet upstream of the existing waterline crossing.

The alignments for the three options are illustrated in Figure 2.7-17 and detailed in Appendix B: *Definite Plan*.

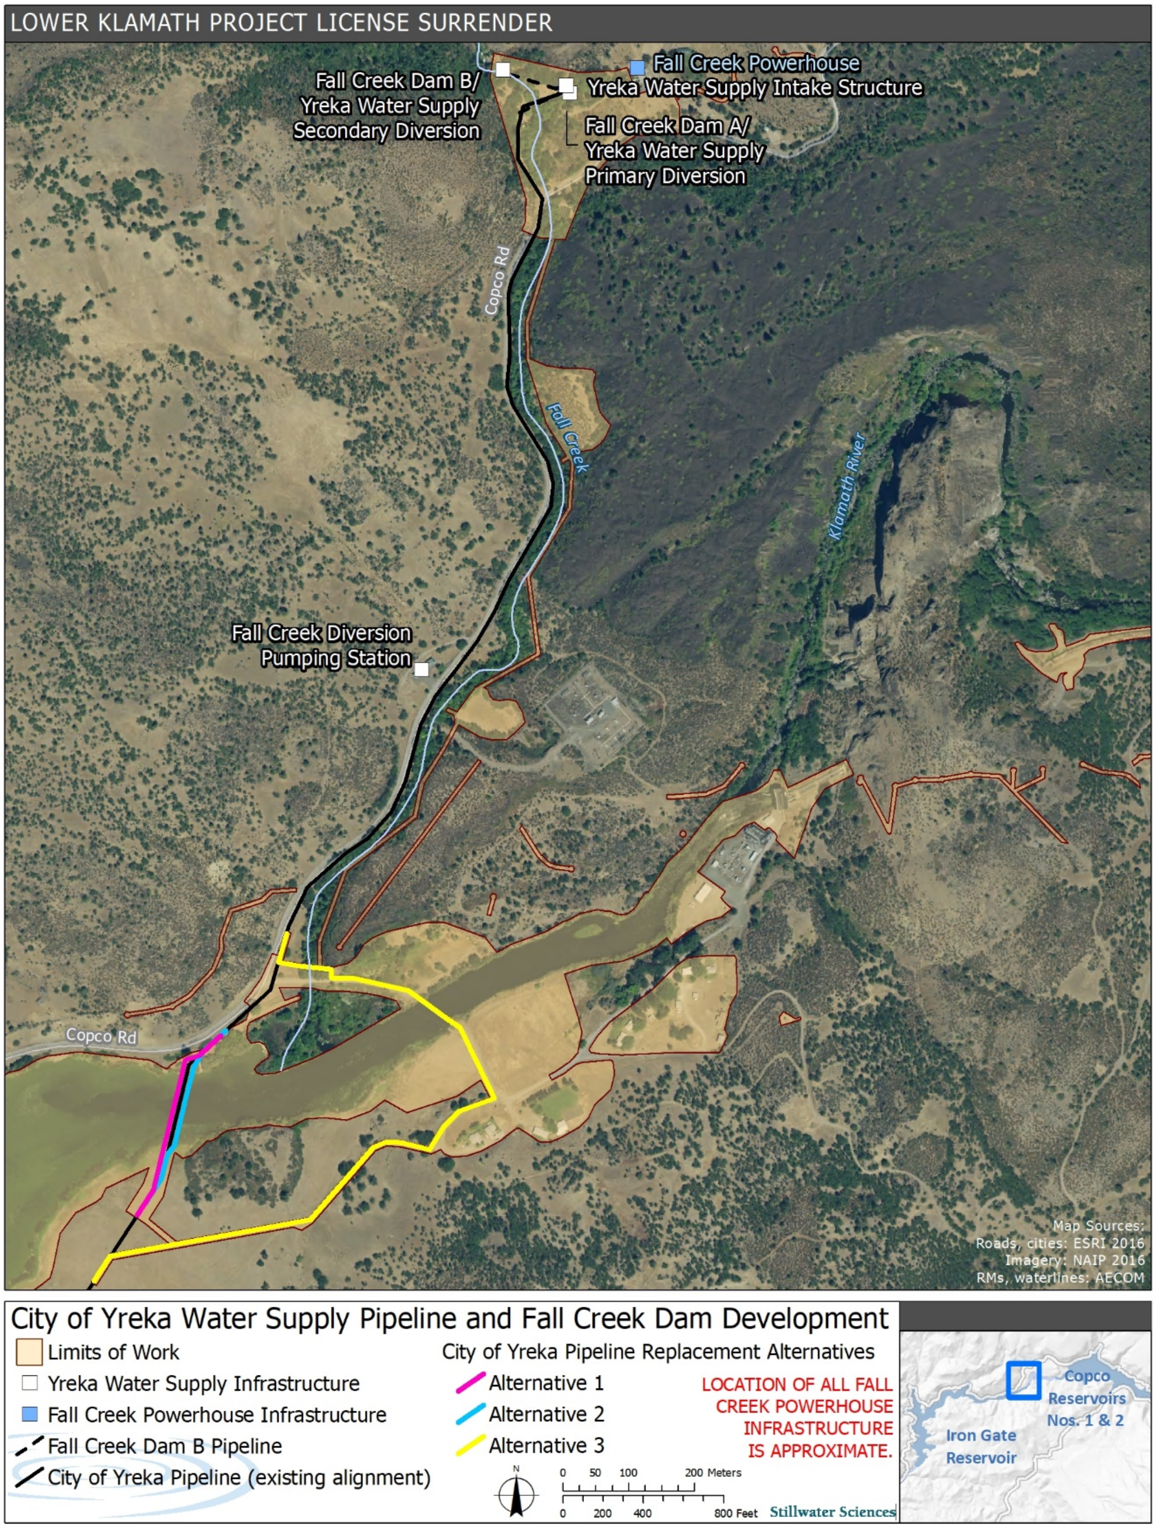

Figure 2.7-17. Alignments for Yreka Waterline Replacement - Klamath River Crossing Conceptual Alternatives.

2.7.8 Other Project Components

There are numerous Proposed Project components identified by the KRRC that fall outside of the major dam and powerhouse deconstruction, reservoir drawdown, reservoir restoration activities, hatchery operations, and City of Yreka water supply pipeline relocation activities described above. The KRRC has proposed these actions to address environmental, safety, and quality of life issues in relation to the major actions discussed above. These other project components summarized in Table 2.7-13 and discussed briefly below. Additional information, regarding these other project components are presented in the individual resource sections (see Section 3 *Environmental Setting, Potential Impacts, and Mitigation Measures*).

Table 2.7-14. Summary of Other Project Components.

Project Component		Summary Description	Location in Appendix B
Aquatic Resource Measures	Mainstem spawning	Surveys and protection measures	Definite Plan − Section 7.2 and Appendix I, including 2018 update
	Outmigrating juveniles		
	Iron Gate Fish Hatchery	Delayed release of hatchery fish to avoid poor water quality	
	Suckers	Surveys and relocation	
	Freshwater mussels	Surveys and relocation	
Terrestrial Resource Measures	Habitat restoration	Stabilization of remaining sediments and restoration of reservoir and other disturbed areas	Definite Plan − Section 7.3 and Appendix J
	Nesting birds	Surveys and avoidance and minimization measures	
	Bald and golden eagles		
	Special-status bats		
	Northern spotted owl		
	Special-status plants		
	Wetlands	Delineation, avoidance measures and restoration plan to result in no net loss	
Transportation	Construction access	Improve roads, bridges and culverts affected by the Proposed Project	Definite Plan − Section 7.4 and Appendix K
	Ongoing and post-project maintenance		

Project Component		Summary Description	Location in Appendix B
Recreation Facilities Management/ Recreation Plan	J.C. Boyle Reservoir	Removal of numerous existing recreation facilities, and restoration with native vegetation before, during, and after dam removal; initiates process to add new river-based recreation opportunities	Definite Plan − Section 7.6
	Copco No. 1 Reservoir		
	Iron Gate Reservoir		
	Dispersed Recreation Sites		
Downstream Flood Control		Maintain existing flood protection	Definite Plan − Section 7.7
Cultural Resources Plan		Framework for compliance with cultural resources protection laws	Definite Plan − Section 7.9
Traffic Management Plan		Framework and initial requirements, final plan to be developed by contractor	Definite Plan − Appendix O2
Water Quality Monitoring Plan		Water quality monitoring and analysis to support adaptive management	Definite Plan – Appendix M
Groundwater Well Management Plan		Well monitoring and return production rates of all affected groundwater wells to their pre-dam-removal condition, as necessary	Definite Plan – Appendix N
Fire Management Plan		Framework and initial requirements; final plan to be developed by contractors	Definite Plan – Appendix O1
Hazardous Material Management Plan		Framework and initial requirements; Phase 1 assessment in 2018	Definite Plan – Appendix O3
Emergency Response Plan		Framework and initial requirements; final plan to be developed by contractor	Definite Plan – Appendix O4
Noise and Vibration Control Plan		Framework and initial requirements; final plan to be developed by contractor	Definite Plan – Appendix O5

2.7.8.1 Aquatic Resource Measures

As noted above in Section 2.7 *Proposed Project*, the timing of reservoir drawdown activities was chosen to reduce impacts on anadromous fish species in the Klamath River. Additionally, the Proposed Project includes the aquatic resource (AR) measures summarized below. These measures reflect consultation with a group of fisheries scientists with established regional expertise that KRRC convened to review aquatic resources impact from the proposed project, with particular emphasis on reviewing the resources protection measures proposed in the 2012 KHSA EIS/EIR in light of new information. The ongoing feedback from the group would be used to refine and finalize the plans proposed in the AR measures. Appendix B: *Definite Plan − Appendix I* contains additional detail on background, the latest science, and proposed measures. These measures are subject to further consultation with aquatic resource agencies and the final Biological Opinions for the Proposed Project.

Mainstem Spawning (AR-1)

Short-term effects of dam removal (suspended sediment concentrations and bedload) are anticipated to result in high mortality of embryos and pre-emergent life stages of any fish species spawning in the mainstem Klamath River downstream of Iron Gate Dam during the drawdown year.

The Aquatic Resource Measure AR-1 proposes the development and implementation of a monitoring and adaptive management plan prepared with input from fishery experts to offset the impacts of sediment releases during Lower Klamath Project dam removal on mainstem spawning. The plan would include a 2-year tributary confluence monitoring effort following dam removal and active removal of potential sediment and debris obstructions related to dam removal to improve volitional upstream passage for adult fish species from the Klamath River into its tributaries (thus reducing spawning in mainstem habitat). Monitoring frequency would be variable based on the season and year.

Additionally, any 5-year flow event (estimated as > 10,895 cfs at the USGS gage no. 11516530) within the first two years following reservoir drawdown, would trigger a monitoring effort. AR-1 also includes a proposed spawning habitat evaluation on the Klamath River and its tributaries in the Hydroelectric Reach. If existing spawning habitat conditions for Chinook salmon and steelhead do not meet target metrics described in Appendix B: *Definite Plan – Appendix I*, spawning gravel augmentation would be completed on both the mainstem and key tributaries in the Hydroelectric Reach to offset impacts of Lower Klamath Project dam removal.

Outmigrating Juveniles (AR-2)

Short-term effects of dam removal (suspended sediment concentrations and bedload) are anticipated to result in mostly sublethal[15], and in some cases lethal impacts to a portion of the juvenile Chinook salmon, coho salmon, steelhead, and Pacific lamprey that are outmigrating from tributary streams to the Klamath River upstream of Trinity River (RM 43.3) during late winter and early spring of dam removal year 2.

The Aquatic Resource Measure AR-2 proposes three primary actions to reduce impacts to outmigrating juvenile fish: (1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; (2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River (in conjunction with AR-1 efforts); and (3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cool water tributaries or nearby off-channel ponds. Details on the monitoring and adaptive management actions are provided in Appendix B: *Definite Plan – Appendix I*.

Iron Gate Fish Hatchery Management (AR-4)[16]

Hatchery produced coho salmon smolts that are released into the Klamath River during dam removal year 2, could suffer high mortality if released during periods of high suspended sediment levels (Chinook salmon and steelhead, if any, are typically released during period that are not predicted to coincide with high suspended sediment levels).

[15] Impacts on fish that may cause a behavioral response or physiological damage, without causing direct mortality.

[16] Please note that there is no proposal submitted for an AR-3. The numbering in the EIR follows that in Appendix B: *Definite Plan – Appendix I.*

Aquatic Resource Measure AR-4 proposes that hatchery-reared yearling coho salmon to be released in the spring of dam removal year 2 be held at hatchery facilities until water quality conditions in the mainstem Klamath River improve to sublethal levels. Water quality monitoring stations would be used to determine when conditions in the mainstem Klamath River are suitable. Based on suspended sediment level predictions, a delay of approximately two weeks until mid-May for release of coho salmon smolts is anticipated.

Suckers (AR-6)[17]

Short-term effects of Lower Klamath Project dam removal are anticipated to result in mostly sublethal, and in some cases lethal impacts to Lost River and shortnose suckers within Hydroelectric Reach reservoirs. Lost River and shortnose suckers are lake-type suckers and are therefore not anticipated to persist in the Klamath River following restoration of the Hydroelectric Reach reservoirs to free-flowing riverine conditions.

The Aquatic Resource Measure AR-6 proposes two primary actions to reduce the effect on suckers. The first proposed action is to sample for suckers in the Klamath River and in Hydroelectric Reach reservoirs to document the population's abundance and genetics prior to Lower Klamath Project removal. The second proposed action is to capture as many suckers as feasible (not to exceed 3,000 fish) from within the Klamath River and in Hydroelectric Reach reservoirs and place them into the isolated waterbody of Tule Lake (to ensure hybridized suckers do not mix with sucker populations designated as recovery populations in Upper Klamath Lake). Additional detail is provided in Appendix B: *Definite Plan – Appendix I*.

Freshwater Mussels (AR-7)

Freshwater mussels in the Hydroelectric Reach and in the Klamath River downstream from Iron Gate Dam are anticipated to experience deleterious effects during dam decommissioning due to high suspended sediment levels, bedload movement, and low dissolved oxygen concentrations.

The Updated Aquatic Resource Measure AR-7 (Appendix B: *Definite Plan – Updated AR-7, October 2018 Update*) proposes a salvage and relocation plan to be prepared prior to Lower Klamath Project dam removal. Actions would include completing a reconnaissance of existing freshwater mussels from Iron Gate Dam to Cottonwood Creek to document abundance and distribution and identifying potential translocation habitat downstream from the Trinity River confluence (RM 43.3), and between J.C. Boyle Dam (RM 229.8) and Copco No. 1 Reservoir (RM 208.3). Freshwater mussels would be salvaged and relocated prior to reservoir drawdown. It is anticipated based on existing data that up to 20,000 mussels would be translocated.

2.7.8.2 Terrestrial Resource Measures

The Proposed Project includes Terrestrial Resource Measures for northern spotted owl, bald eagle and golden eagle, special-status wildlife species, bats, special-status plants, and vegetation communities and wetlands. The measures include ensuring the presence of a biological monitor during construction-related activities (e.g., structure demolition, ground disturbance), biological awareness trainings for all construction

[17] Please note that there is no proposal submitted for an AR-5. The numbering in the EIR follows that in Appendix B: *Definite Plan – Appendix I.*

personnel, requirements to delineate the Limits of Work and prohibit construction-related traffic outside the boundaries, wildlife exclusion and entrapment, willow flycatcher habitat surveys, nesting bird surveys, and other wildlife surveys. These measures are briefly described below, and additional detail is presented in Appendix B: *Definite Plan – Appendix J*. Analysis of the KRRC proposed Terrestrial Resource Measures as part of the Proposed Project is included in Section 3.5 *Terrestrial Resources* of this EIR.

The KRRC has initiated surveys associated with most of the measures described below, including (a) gathering information on habitat and identifying access for subsequent wildlife surveys (spring and summer 2018); (b) implementing General Wildlife Surveys to document baseline information on the presence of special-status species and their habitats, which included documenting any wildlife signs such as bird nesting, dens, or burrows (May and June 2018); (c) conducting surveys for osprey, peregrine falcon, greater sandhill crane, and heron colonies (May 2018); (d) implementing ground- and aerial-based surveys to document bald and golden eagles (January, February, and June 2018); and (e) assessing structure use by bats (2017 and 2018).

The results of these surveys are anticipated to be available soon and would be incorporated into the final resources protection plans and into construction planning to avoid and minimize effects. It is anticipated that avoidance and mitigation measures to be incorporated into regulatory approvals would be developed in coordination with the USFWS, the CDFW, and the ODFW. The work plans and planned avoidance and minimization measures are summarized below and presented in Appendix B: *Definite Plan – Appendix J*.

Northern Spotted Owl Measures

The Proposed Project includes identifying suitable habitat for the northern spotted owl using a Relative Habitat Suitability model within one mile of Copco No. 1, Copco No. 2, and Iron Gate dams and facilities. If suitable habitat is identified within a noise disturbance distance (i.e., one mile to account for blasting at dams, 0.5 miles of the Limits of Work to account for other construction-related noise disturbance), protocol-level surveys would be conducted. Survey methodology and Relative Habitat Suitability model results are detailed in the Northern Spotted Owl section of Appendix B: *Definite Plan − Appendix J*. If any nest locations are documented, the Proposed Project includes seasonal restrictions (March 1–September 30) to minimize disturbance to young prior to fledgling. Limited operating periods can be waved in the event of nest failure if confirmed by a biologist. To prevent direct injury of young resulting from aircraft, no helicopter flights would occur within or at an elevation lower than 0.8 km (0.5 mi) of suitable nesting and roosting habitat during the entire breeding season unless the protocol level surveys identify no activity centers.

Bald and Golden Eagle Measures

The Proposed Project includes conducting ground and aerial-based surveys to identify the presence of bald and golden eagles within 2 miles of construction and demolition sites, and 0.5 miles from other areas within the Limits of Work including reservoir boundaries (conducted in January/early February 2018 and June 2018). The KRRC also proposes to re-survey the area in the year prior to drawdown to establish a baseline of normal behavior prior to implementing construction. Additionally, the KRRC would develop an Eagle Avoidance and Minimization Plan in coordination with the USFWS that identifies procedures and protocols for avoiding and minimizing impacts. Avoidance and minimization measures would include cutting of vegetation and grubbing outside of the sensitive eagle nesting season and incorporating a 0.5-mile restriction buffer if a nest is within 2 miles of the Limits of Work (the buffer may be reduced if a topographic feature reduces the line of site). Surveys methodology, preliminary results, and avoidance and minimization measures are described in the Bald Eagle and Golden Eagles Measures sections in Appendix B: *Definite Plan – Appendix J*.

Special-status Wildlife Measures

Special-status wildlife measures incorporate a field reconnaissance effort; general wildlife surveys; nest location surveys for species that use the same nest locations in subsequent years (e.g., osprey, peregrine falcon, sandhill crane, heron colonies); pre-construction nesting bird surveys (between February and July) within 300 feet of the Limits of Work, and construction monitoring. Special-status species, such as the tricolored blackbird and western pond turtle would be noted during these surveys. The measure includes avoidance and minimization measures, such as construction monitoring, environmental awareness training, wildlife exclusion, and identification of nesting buffers, including consideration of the species, noise effects, line of sight, and other site-specific considerations. Survey methodology and avoidance and minimization measures are described in the Special-Status Wildlife Species Measure section in Appendix B: *Definite Plan – Appendix J*.

Bats Measures

The Proposed Project includes components to avoid and minimize both short and long-term construction-related impacts and loss of habitat on roosting bats. The measures would include a site reconnaissance and daytime visual inspection of structures to identify presence of bats, hibernacula (winter roost) surveys, and spring migration surveys using visual observation (e.g., emergence surveys) and acoustic monitoring. Avoidance and minimization measures may include exclusion, seasonal restrictions on demolition, preservation of existing habitat, and creation of alternative replacement bat habitat. Survey methodology, preliminary results, and avoidance and minimization measures are described in the Bat Measure section in Appendix B: *Definite Plan – Appendix J*.

Special-status Plants Measures

As part of the Proposed Project, comprehensive floristic surveys would be conducted for special status-plants within the construction Limits of Work where ground-disturbing activities would occur. An established buffer, like a 100-meter buffer around disposal sites and a 10-meter buffer off of access and haul roads would also be required. If any special-status plants are documented, the project design would be modified if possible to avoid them. Where avoidance is not feasible, a combination of relocation, propagation, and establishment of new populations in designated conservation areas would be implemented, as determined in coordination with the resource agencies. Additionally, as part of the Proposed Project, invasive plant species would be controlled by implementing measures such as routine washing of construction vehicles and equipment. Survey methodology and minimization measures are described in Appendix B: *Definite Plan – Appendix E –Special Status Plant Species*.

Vegetation Communities and Wetland Measures

The Proposed Project identifies a number of pre-construction measures to reduce impacts on wetland and riparian habitats. First, a wetland delineation would be conducted within the Limits of Work around the dams and facilities, access and haul roads, and disposal sites in accordance with the 1987 USACE Wetland Delineation

Manual (USACE 1987) and applicable Regional Supplements (i.e., Western Mountains, Valleys, and Coast Region [USACE 2010] and Arid West [USACE 2008]) (Appendix B: *Definite Plan – Appendix J*). The results of the wetland delineation would be incorporated into the project design to avoid and minimize direct impacts on wetlands to the maximum extent feasible. Wetland areas adjacent to the construction Limits of Work would be fenced to prevent inadvertent entry during construction. Additionally, the Proposed Project would include pollution and dust control measures to reduce potential impacts to water quality in wetlands and other waters during construction.

The Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) includes details for the installation of native plants that represent the vegetation communities and wetland habitats. Aerial, barge, or hand seeding would be implemented in appropriate areas to re-vegetate all areas disturbed during construction, including reservoir areas, demolition and disposal sites, staging, access and haul roads, and turn-arounds. The goal of the management plan would be no net loss of wetland or riparian habitat acreage and functions.

Wetlands established in restored areas would be monitored for five years or until the performance criteria (as defined in Appendix B: *Definite Plan – Appendix H*) have been met. To minimize the introduction of invasive plant species into construction areas, construction vehicles and equipment would be cleaned with compressed water or air within a designated containment area to remove pathogens, invasive plant seeds, or plant parts, and disposed of in appropriate disposal facilities. The plan also would contain metrics to evaluate success of minimizing invasive exotic vegetation (Section 2.7.4).

2.7.8.3 Recreation Facilities Management

While some existing recreational facilities would remain (Table 2.7-15), the Proposed Project would remove most of the existing recreational sites at Iron Gate, Copco No. 1, and J.C. Boyle reservoirs (which primarily provide fishing, boating, and reservoir day-use access) and initiates a process to add river-based recreation sites. KRRC has developed a Draft Recreation Plan which seeks to identify recreation opportunities, in coordination with stakeholders, that would offset the removal of reservoir recreation opportunities and the reduction in whitewater boating days associated with the Proposed Project (Appendix B: *Definite Plan – Appendix Q*). New river-based opportunities may include: (a) new routes and roads for river access; (b) two small to medium river recreation facilities that would accommodate 20 campsites, day use amenities, and access to the river for fishing and boating; and (c) a new trail between J.C. Boyle Dam and the Iron Gate Fish Hatchery.

The Proposed Project includes the complete removal of eight recreation sites (Table 2.7-15), including removal of structures, concrete, and pavement, and regrading and revegetating associated parking areas and trails (Appendix B: *Definite Plan – Appendix Q*). Removal of recreation sites would occur before, during, or after dam removal and the area would be planted with a native seed mix as described in the Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*).

Table 2.7-15. Recreation Facilities scheduled for removal under the Proposed Project.

Site Name	Existing Facilities
Copco No. 1 Reservoir	
Mallard Cove	Day-use picnic area, restrooms, boat launch with boarding dock, and interpretive signs
Copco Cove	Picnic area, restrooms, boat launch with boarding dock, and interpretive signs
Iron Gate Reservoir	
Wanaka Springs	Day-use area, campground, restrooms, fishing dock, and interpretive signs
Camp Creek (including Dutch or Scott Creek)	Day-use area, campground, boat and fishing dock, recreational vehicle (RV) dump station, interpretative display, and restrooms
Juniper Point	Day use area, campground, fishing dock, restroom, and interpretive signs
Mirror Cove	Day use area, campground, fishing dock, boat launch, interpretive signs, and restroom
Overlook Point	Picnic area and restrooms
Long Gulch	Picnic area, boat launch, and restrooms

Facilities at Fall Creek and Jenny Creek Day-Use Areas at Iron Gate Reservoir, and the Iron Gate Fish Hatchery Day-Use Area, would remain and may be upgraded or enhanced (Table 2.7-16, Appendix B: *Definite Plan – Appendix Q* and EIR Section 3.20 *Recreation*). Future enhancements at these locations would depend on the future ownership of Parcel B lands, where these three recreational facilities are located. Pursuant to the KHSA, Parcel B lands would be transferred to the respective states (or a designated third party) for public interest purposes such as tribal mitigation, river-based recreation, wetland restoration, etc. (see also Section 2.7.11 *Land Disposition and Transfer*).

Table 2.7-16. Recreation Facilities retained with potential modification under the Proposed Project.

Site Name	Existing Facilities	Potential Modification
Iron Gate Reservoir		
Fall Creek	Day-use area, picnic area, boat launch, restroom, and hiking trail	Potential modification to support continued and improved recreational access including reconstruction of the trail.
Jenny Creek	Day-use area, campground, restrooms, and hiking trails	Potential modification to support additional campsites and improved amenities.
Iron Gate Fish Hatchery Public Use Area	Day-use area, picnic areas, picnic shelter, visitor center, interpretive kiosks, restrooms, trail to the river, fishing dock, and boat launch	Potential modification to support additional facilities and a reconstructed boat ramp.

Sources: Appendix B: *Definite Plan – Appendix Q.*

2.7.8.4 Downstream Flood Control

The Proposed Project would alter the 100-year floodplain immediately downstream of Iron Gate Dam. KRRC proposes to work with the owners of the structures located within the altered 100-year floodplain to move or elevate legally established structures, where feasible. This EIR relies on modeled preliminary 100-year floodplain inundation from Iron Gate Dam to Happy Camp under an existing and Proposed Project condition (USBR 2012b), and on KRRC's categorization of downstream structures from Iron Gate Dam to Humbug Creek (the point downstream of which any change to the floodplain is expected to be less than 0.5 feet, as per USBR [2012b]) FEMA will make the final determination of the boundary of the 100-year floodplain after dam removal, and the KRRC is coordinating with FEMA to initiate the map revision process.

This Project Component replaces Mitigation Measure H-2 from the 2012 KHSA EIS/EIR. Please see Section 3.6 *Flood Hydrology* for further discussion.

2.7.8.5 Cultural Resources

KRRC is preparing a Cultural Resources Plan (Appendix B: *Definite Plan – Appendix L*) that would identify the cultural resources studies that KRRC has completed, those that are currently ongoing, and others that KRRC anticipates completing in order to comply with regulatory requirements under Section 106 of the National Historic Preservation Act and California Assembly Bill 52. The Draft Cultural Resources Plan, submitted with the Definite Plan CITE, describes consultation completed by the date of submission by KRRC and PacifiCorp, acting as FERC's non-federal representatives, for carrying out consultation pursuant to Section 106 and the status of consultation with affected tribes and other tribal organizations. The Draft Cultural Resources Plan also provides an update as of the date of submission regarding the status of consultation under Assembly Bill 52 with California Native American tribes. The final Cultural Resources Plan would incorporate mitigation measures developed through consultation under Assembly Bill 52. Please see Section 3.12 *Historical Resources and Tribal Cultural Resources* for more information.

2.7.8.6 Traffic Management

The Proposed Project includes an initial Transportation Management Plan (TMP) to minimize construction-related traffic delays and maintain safe movement of vehicles during project implementation. The Proposed Project would result in changes in traffic conditions from delivering construction equipment, hauling deconstructed materials for near- or off-site disposal, delivery of rehabilitation materials, worker access, fish hauling (as applicable), and road, bridge, and culvert improvements would be required to support the increased traffic (see also Section 2.7.1.2 *Copco No. 1 Dam and Powerhouse – Construction Access and Road Improvements*). The major access roads for each dam site are provided in Table 2.7-17 and Figure 2.7-3. The roads in Oregon associated with J.C. Boyle Dam are included in Table 2.7-17 given the likelihood that construction crews and equipment from one of the California dam sites may be moved to/from the Oregon J.C. Boyle Dam site.

Table 2.7-17. Major Local and Regional Access Roads.

Dam Site	Interstate Access Road	Regional Access Road	Local Access Road
Copco No. 1 and Copco No. 2	I-5 (in California)	Copco Road	Ager-Beswick Road
Iron Gate	I-5 (in California)	Copco Road	Lakeview Road

The major objectives of the initial Traffic Management Plan are to maintain efficient and safe movement of vehicles through the construction zone and to provide intensive public awareness of potential impacts to traffic on project haul routes and access roads. To reduce impacts from traffic delays resulting from planned work, KRRC proposes that implementation of the final Traffic Management Plan would maintain acceptable levels of service, traffic circulation, and safety during all work activities on the state and county highway/roadway system.

The initial Traffic Management Plan outlines the structure and key requirements that would be incorporated by the construction contractor into a final Traffic Management Plan (Appendix B: *Definite Plan – Appendix O2*). The final plan would incorporate the contractor's specific means and methods for construction, which could refine the approach to access and traffic management. KRRC proposes coordinating with Oregon Department of Transportation (ODOT), California Department of Transportation, Klamath and Siskiyou Counties, Oregon State Police, and California Highway Patrol.

The initial Traffic Management Plan proposes to incorporate the management strategies below into the final Traffic Management Plan.

- Public Information – adopt methods to share information regarding any current or upcoming interruptions with the public
- Motorist Information – provide advance notice to motorists detailing traffic delays
- Incident Management – develop a procedure to implement in the event of an incident

In addition, the KRRC proposes incorporating the construction strategies listed below into the final Traffic Management Plan.

- Roadway closures – consider road users when identifying the timing and location of long-term (i.e., more than one day) road closures.
- Traffic Handling and Stage Construction – provide signage and traffic control.
- Construction Access to Work Zones – install informational signs along the road to inform motorists of the construction presence.
- Haulage – haul waste material that would not remain on site during non-peak hour times.
- Emergency Detour Plan – identify detour routes for facilities that provide essential services in times of emergencies (e.g., hospitals, fire/police stations).
- Traffic Safety Effects – adopt best management practices of signage, traffic management, and dust control to reduce traffic safety hazards from hauling, use of blind or sharp corners, slow vehicles, reduced visibility due to dust.

- Pedestrians and Bicycles – provide signage to notify both construction vehicle drivers and non-motorized users of each other's presence and if an unacceptable level of risk to non-motorized user is deemed to persist, an appropriate detour would provide continued use.

2.7.8.7 Water Quality Monitoring and Construction BMPs

To reduce potential impacts on water quality in wetlands and other surface waters during construction, the Proposed Project includes the following construction best management practices (BMPs) to be implemented within the Limits of Work:

- Clean Water Act Section 402 National Pollutant Discharge Elimination System (NPDES) permits would be obtained from Oregon and California for construction activities.
- Pollution and erosion control measures would be implemented to prevent pollution caused by construction operations and to reduce contaminated stormwater runoff.
- Oil-absorbing floating booms would be kept onsite, and the contractor would respond immediately to aquatic spills during construction.
- Vehicles and equipment would be kept in good repair, without leaks of hydraulic or lubricating fluids. If such leaks or drips do occur, they would be cleaned up immediately.
- Equipment maintenance and/or repair would be confined to one location at each project construction site. Runoff in this area would be controlled to prevent contamination of soils and water.
- Dust control measures would be implemented, including wetting disturbed soils.
- A Stormwater Pollution Prevention Plan (SWPPP) would be implemented to prevent construction materials (fuels, oils, and lubricants) from spilling or otherwise entering waterways or water bodies.

In addition, the Proposed Project includes a Water Quality Monitoring Plan, which would implement water quality monitoring for 12 months of the year from at least one year prior to dam removal until up to three years following dam removal at seven locations in the Klamath Basin. According to the Water Quality Monitoring Plan, monitoring would occur at the following seven sites along the mainstem Klamath River:

- Klamath River below Keno Dam (RM 233.4; at or near USGS gage no. 11509500);
- Klamath River below J.C. Boyle Powerplant (RM 219.7; at or near USGS gage no. 11510700);
- Klamath River above Shovel Creek (RM 206.42; upstream of Copco No. 1 Reservoir)
- Klamath River below Iron Gate (RM 189.7; at or near USGS gage no. 11516530);
- Klamath River below Seiad Valley (RM 128.5; at or near USGS gage no. 11520500);
- Klamath River at Orleans (RM 59.1; at or near USGS gage no. 11523000); and
- Klamath River near Klamath (RM 6.0; at or near USGS gage no. 11530500).

Water quality monitoring immediately downstream of Keno Dam in the Upper Klamath River would assess baseline river conditions upstream of the Proposed Project Limits of Work. The Klamath River site above Shovel Creek is located approximately three river miles downstream from the Oregon-California state line and it is considered a possible location for the state line monitoring station. The final location, specifics, and duration of operation of the state line monitoring location would be determined in consultation with the State Water Board and ODEQ.

The water quality parameters measured at each of the monitoring locations in the Water Quality Monitoring Plan is summarized in Table 2.7-18. Time-series (continuous) water quality and stream discharge data along with discrete water quality samples would be collected to assess the water quality impacts of the Proposed Project. The Water Quality Monitoring Plan also contains laboratory testing of reservoir sediment samples collected in 2017 by the USGS to develop an SSC versus turbidity relationship for the reservoir sediments, including a laboratory protocol for the SSC/turbidity relationship to identify the accuracy and reliability of the relationship along with any uncertainties and specific field verification testing necessary during dam removal.

KRRC proposes to use results of the water quality monitoring and analysis to support adaptive management decision-making during and following dam removal and regarding potential impacts to aquatic resources.

Table 2.7-18. Water Quality Monitoring Plan Parameters.

Constituent	Frequency	Type of Data
Temperature	Hourly, 12 months per year	Time-series
Dissolved Oxygen	Hourly, 12 months per year	Time-series
pH	Hourly, 12 months per year	Time-series
Conductivity	Hourly, 12 months per year	Time-series
Turbidity	Hourly, 12 months per year	Time-series
SSC	Up to 24 samples pre-drawdown; weekly during drawdown, monthly following drawdown for 36 months or until TSS equals background at Keno	Discrete (auto-sampler)
SSC	4 storm events pre-drawdown; every two weeks during and after drawdown or until TSS equals background at Keno	Depth-width integrated sample
Chemical Oxygen Demand	Monthly, daily during drawdown	Discrete
Total Nitrogen	Monthly	Discrete
Total Phosphorous	Monthly	Discrete
Microcystin [-Producing Blue-green Algae] Cell Count	Monthly	Discrete

The Water Quality Monitoring Plan also specifies that the KRRC would develop a sediment characterization plan with consistent sampling and testing protocols and procedures in consultation with California and Oregon regulatory agencies to satisfy state requirements in Section 401 Water Quality Certifications to characterize the sediment quality in reservoir and riverbed sediments upstream and downstream of the Proposed Project Lower Klamath Project reservoirs, and in the Klamath River Estuary.

The Water Quality Monitoring Plan presents the KRRC's approach to monitoring water quality parameters during dam decommissioning based on Interim Measure 15 - Water

Quality Monitoring (IM-15). The Water Quality Monitoring Plan would be revised to be consistent with the water quality monitoring requirements of the final Clean Water Act Section 401 Water Quality Certifications from California and Oregon, since the Draft Clean Water Act Section 401 Water Quality Certifications from California and Oregon were under public review when this Water Quality Monitoring Plan was developed. The information collected under this plan and the development of the SCC/turbidity relationship would assist the KRRC in making adaptive management decisions during and following dam removal, in assessing the impacts of sediment decomposition, and other biological activities, on the dissolved oxygen concentrations in the Klamath River, in determining attainment of existing health related water quality standards for microcystin producing blue-green algae cell counts, and in understanding the impacts to aquatic resources. Additional Water Quality Monitoring Plan details are presented in Appendix B: *Definite Plan – Appendix M*.

2.7.8.8 Groundwater Well Management

The Proposed Project includes a Groundwater Well Management Plan, which is intended to identify groundwater wells that may be impacted by the project and provide sufficient monitoring to understand the effects, if any, on groundwater levels and water quality. If groundwater wells are found to have been adversely impacted following dam decommissioning, the KRRC would undertake measures (e.g., well deepening) to return the production rate of any affected domestic or irrigation groundwater supply well to conditions prior to dam decommissioning. There are six steps in the KRRC's proposed Groundwater Well Management Plan:

1. Database search and agency coordination
2. Outreach to land owners and residents
3. Installation of groundwater monitoring wells
4. Groundwater monitoring
5. Post-Dam removal outreach/notification of findings
6. Proposed actions to improve production rates

If the data collected during or following dam decommissioning confirms an adverse impact (i.e., loss of supply due to lowering groundwater level or adverse effect on water quality) to any potable or irrigation well, the KRRC would act to return the water well owner's supply to pre-dam decommissioning conditions. These actions could include providing temporary water supplies until long-term measures such as motor replacement, well deepening, or full well replacement are identified and implemented. Additional details are presented in Appendix B: *Definite Plan – Appendix N.*

2.7.8.9 Fire Management

The Proposed Project includes a Fire Management Plan, which sets forth fire prevention and response methods during Proposed Project activities (Appendix B: *Definite Plan – Appendix O1*). The KRRC would designate a Safety Officer available on-call 24 hours a day and 7 days a week in the event of a fire at the Proposed Project site. This Safety Officer is responsible for immediately contacting appropriate fire dispatch units, initiating fire suppression protocols, and instructing other workers in required fire prevention, fire watch, and suppression. The prevention and response methods in the Fire Management Plan are consistent with the policies and standards in local, county, state, and federal jurisdictions. Best management practices include, but are not limited to, clearing of dried vegetation or wetting-down areas to prevent wildfires in construction and deconstruction work areas where construction activities could result in open sparks or flames; maintaining all equipment to working standards; and keeping equipment clean of flammable material. The KRRC's Fire Management Plan also requires fire suppression equipment be on-site at all times and emergency contact numbers be posted, in case of a fire.

In addition to the above measures to be implemented during Proposed Project activities, the Fire Management Plan also addresses the water supply to fight wildfires following the removal of the reservoirs. KRRC's Fire Management Plan includes the development of alternative sources of water for firefighting which include installing permanent dry hydrants from which water trucks and fire engines could draw directly from the Klamath River and larger tributaries. In addition, KRRC would develop a map for use by air-based firefighting crews identifying potential water refueling locations on the Klamath River (i.e., pool features). Additional detail is presented in Appendix B: *Definite Plan – Appendix O1*.

2.7.8.10 Hazardous Materials Management

The Proposed Project would follow the Hazardous Materials Management Plan, which includes the measures described below, that are based on data from PacifiCorp, Environmental Data Resources, Inc., and local agencies. It is possible that additional recommendations would be made following the planned Phase I-Environmental Site Assessment (ESA) visits and interviews and the following any necessary Phase II Site Investigation. The Phase I report is anticipated to be released soon.

- All structures expected to be removed would be sampled and tested for asbestos containing material, lead based paint, and polychlorinated biphenyls (PCBs). Any abated material which exceed hazardous waste criteria levels for these hazards would be handled and disposed of at approved hazardous waste facilities in accordance with applicable federal and state regulations. Remaining materials would be disposed of as non-hazardous construction debris.
- All hazardous materials removed from the sites (e.g., paints, oils, and welding gases) would be either returned to the vendor, recycled, or managed and disposed of at an approved hazardous waste facility in accordance with applicable federal and state regulations.
- Transformer oils would be tested for PCBs if no data exists.
- Any tanks which contained hazardous materials would be decontaminated prior to disposal.
- Universal hazardous waste (e.g., lighting ballasts, mercury switches, and batteries) would be handled in accordance with applicable federal and state universal waste regulations.

Additional detail is presented in Appendix B: *Definite Plan – Appendix O3*.

2.7.8.11 Emergency Response

The Proposed Project includes an Emergency Response Plan. According to the plan, the construction contractor would be required to develop written procedures to help prevent incidents, to assure preparedness in the event incidents occur, and to provide a systematic and orderly response to emergencies. This plan would be closely coordinated with the chosen contractor's Health and Safety Plan, Spill Prevention and Response Plan and Fire Management Plan. Procedures documented in the plan would apply to all personnel working on site, including reviewing of emergency response procedures with all personnel assigned to the site to the extent necessary.

The plan would address, but would not be limited to, the following:

- Medical emergency—locations of hospitals
- Fire management–procedures and contacts
- Traffic incident–protocol for notification and direction for if medical attention is required
- Hazardous material spill management–development of a Spill Prevention and Response Plan to detail procedures and documentation forms to prevent and respond to spills
- Downstream hydraulic change planning–notification to the National Weather Service River Forecast Center (federal agency that provides official public warning of floods) of any planned major hydraulic change (removal of one or more of the dams) that could potentially affect the timing and magnitude of flooding below Iron Gate
- Dam or tunnel failure–notification procedures, evacuation procedures
- Catastrophic emergency (e.g., earthquake, high wind event, etc.)–notification procedures, accountability procedures to confirm all personnel are accounted for
- Security threat–cessation of all activity, notification procedures

Additional detail is presented in Appendix B: *Definite Plan – Appendix O4.*

2.7.8.12 Noise and Vibration Control

The Proposed Project includes an initial Noise and Vibration Control Plan (NVCP). The initial NVCP identifies measures to be incorporated into the final NVCP to reduce effects from day and nighttime noise levels on sensitive receptors resulting from Proposed Project construction activities. These measures would include, but are not limited to, scheduling activities during a time that would be less impactful on residents, installing sound barriers, employing blasting techniques to minimize noise and vibration disturbance, notifying residents of activities, and promptly addressing complaints.

The final NVCP, which the chosen contractor would develop, would document noise and vibration objectives based on regulatory and industry guidelines, discuss contractor staff roles and responsibilities for noise and vibration control, define noise intensive activities and timing, clearly identify sensitive receptors, evaluate construction noise levels, and outline the monitoring program for noise and vibration. Additional detail is presented in Appendix B: *Definite Plan – Appendix O5.*

2.7.9 KHSA Interim Measures

The KHSA includes series of “interim measures” (IMs) (KHSA Appendices C, D) that have been implemented by PacifiCorp since 2010 to assess and address environmental conditions and improve fisheries prior to dam removal. The KHSA defines the interim period as the period between the date that the KHSA was originally executed (February 18, 2010) and the decommissioning of the dams, which would occur once there has been a physical disconnection of the facility from PacifiCorp’s transmission grid. (KHSA, Section 1.4.) Because the IMs were developed to offset impacts from Klamath Hydroelectric Project operations, the majority of the IMs would not continue under the Proposed Project (Table 2.7-19).

Table 2.7-19. KHSA Interim Measures Relevant to California Under Existing Conditions and the Proposed Project.

Interim Measure	Interim Conservation Plan (ICP)[1]	Description	Existing Conditions	Proposed Project
IM1 – Interim Measures Implementation Committee (IMIC)	ICP	The IMIC is comprised of representatives from PacifiCorp, other parties to the KHSA (as amended on November 30, 2016), and representatives from the State Water Board and Regional Water Board (KHSA Appendix B, Section 3.2). The purpose of the IMIC is to coordinate with PacifiCorp on ecological and other issues related to the implementation of the Non-Interim Conservation Plan Interim Measures set forth in Appendix D of the Amended KHSA.	Ongoing	Would continue separate from the Proposed Project[2]
IM2 – California Klamath Restoration Fund/Coho Enhancement	ICP	PacifiCorp would fund actions to enhance survival and recovery of coho salmon, including habitat restoration and acquisition.	Ongoing	Would not continue
IM3 – Iron Gate Turbine Venting	ICP	PacifiCorp shall implement turbine venting on an ongoing basis beginning in 2009 to improve dissolved oxygen concentrations downstream of Iron Gate Dam.	Construction complete, implementation ongoing	Would not continue[3]
IM4 – Hatchery and Genetics Management Plan	ICP	PacifiCorp would fund the development and implementation of a Hatchery and Genetics Management Plan for the Iron Gate Hatchery.	Plan development is complete, implementation ongoing	Implementation would occur for eight years after removal of Iron Gate Dam as part of the Proposed Project, see also IM19 and IM20

Interim Measure	Interim Conservation Plan (ICP)[1]	Description	Existing Conditions	Proposed Project
IM5 – Iron Gate Flow Variability	ICP	PacifiCorp and USBR would annually evaluate the feasibility of enhancing fall and early winter flow variability to benefit salmonids downstream from Iron Gate Dam. In the event that fall and early winter flow variability can feasibly be accomplished, PacifiCorp would develop and implement flow variability plans. This IM would not adversely affect the volume of water available for Reclamation's Klamath Project or wildlife refuges.	Ongoing	Would not continue
IM6 – Fish Disease Relationship and Control Studies	ICP	PacifiCorp has established a fund to study fish disease relationships downstream from Iron Gate Dam. PacifiCorp would consult with the Klamath River Fish Health Workgroup regarding selection, prioritization, and implementation of such studies.	Ongoing	Would not continue
IM7 – J.C. Boyle Gravel Placement and/or Habitat Enhancement (one-year)	Non-ICP	PacifiCorp would provide funding for the planning, permitting, and implementation of gravel placement or habitat enhancement projects, including related monitoring, in the Klamath River upstream of Copco No. 1 Reservoir.	Ongoing	Would not continue
IM8 – J.C. Boyle Bypass Barrier Removal	Non-ICP	PacifiCorp would remove the sidecast rock barrier approximately 3 miles upstream of the J.C. Boyle Powerhouse in the Bypass Reach. This IM would help with safe, timely, and effective upstream passage of Chinook and coho salmon, steelhead trout, Pacific lamprey, and redband trout.	Complete	Completed, part of existing conditions
IM9 – J.C. Boyle Powerhouse Gage	Non-ICP	Upon the Effective Date, PacifiCorp shall provide the U.S. Geological Survey with continued funding for the operation of the existing gage below the J.C. Boyle Powerhouse.	Ongoing	Would not continue

Interim Measure	Interim Conservation Plan (ICP)[1]	Description	Existing Conditions	Proposed Project
IM10 – Water Quality Conference	Non-ICP	PacifiCorp shall provide one-time funding of $100,000 to convene a basin-wide technical conference on water quality within one year from the Effective Date of the KHSA.	Complete	Completed, part of existing conditions
IM11 – Interim Water Quality Improvements	Non-ICP	PacifiCorp shall spend up to $250,000 per year to be used for studies or pilot projects developed in consultation with the Implementation Committee to improve water quality in the Klamath River. Additionally, PacifiCorp shall provide funding of up to $5.4 million for a water quality improvement project after KRRC acceptance of license surrender order, with an additional amount of up to $560,000 annually for operation and maintenance.	Studies and pilot projects ongoing	Studies and pilot projects would not continue. Water Quality Improvement Project would begin[2]
IM12 – J.C. Boyle Bypass Reach and Spencer Creek Gaging	Non-ICP	PacifiCorp shall install and operate stream gages at the J.C. Boyle Bypass Reach and at Spencer Creek.	Complete	Gage operation would not continue
IM13 – Flow Releases and Ramp Rates	Non-ICP	PacifiCorp would maintain current operations including instream flow releases of 100 cfs from J.C. Boyle Dam to the J.C. Boyle Bypass Reach and a 9-inch per hour ramp rate below the J.C. Boyle Powerhouse prior to transfer of the J.C. Boyle facility.	Ongoing	Would not continue
IM14 – 3,000 cfs Power Generation	Non-ICP	Upon approval by Oregon Water Resources Department, PacifiCorp would continue maximum diversions of 3,000 cfs at J.C. Boyle Dam for power generation.	Ongoing	Would not continue

Interim Measure	Interim Conservation Plan (ICP)[1]	Description	Existing Conditions	Proposed Project
IM15 – Water Quality Monitoring	Non-ICP	PacifiCorp shall fund long-term baseline water quality monitoring to support dam removal, nutrient removal, and permitting studies, and also will fund blue-green algae and blue-green algae toxin monitoring as necessary to protect public health. Funding of $500,000 shall be provided per year. The funding shall be made available beginning April 1, 2010 and annually on April 1.	Ongoing	Would not continue
IM16 – Water Diversions	Non-ICP	PacifiCorp shall seek to eliminate three screened diversions from Shovel (2) and Negro (1) Creeks and shall seek to modify its water rights as listed above to move the points of diversion from Shovel and Negro Creek to the mainstem Klamath River.	Not yet occurred	PacifiCorp would undertake separate from the Proposed Project – see Section 3.24 *Cumulative Effects*
IM17 – Fall Creek Flow Releases	Non-ICP	PacifiCorp would continue to provide a continuous flow release to the Fall Creek Bypass Reach targeted at 5 cfs.	Ongoing	Would continue as part of existing operations
IM18 – Hatchery Funding	Non-ICP	PacifiCorp shall fund 100 percent of Iron Gate Hatchery operations and maintenance necessary to fulfill annual mitigation objectives developed by the California Department of Fish and Wildlife in consultation with the National Marine Fisheries Service (NMFS) and consistent with existing FERC license requirements.	Ongoing	Would not continue, see IM19 and IM20

Interim Measure	Interim Conservation Plan (ICP)[1]	Description	Existing Conditions	Proposed Project
IM19 – Hatchery Production Continuity	Non-ICP	PacifiCorp will begin a study to evaluate hatchery production options that do not rely on the current Iron Gate Hatchery water supply. Based on the study results, and within six months following the DRE's acceptance of the FERC surrender order, PacifiCorp will propose a post-Iron Gate Dam Mitigation Hatchery Plan (Plan) to provide continued hatchery production for eight years after the removal of Iron Gate Dam.	Ongoing	Would be complete
IM20 – Hatchery Funding After Removal of Iron Gate Dam	Non-ICP	After removal of Iron Gate Dam and for a period of eight years, PacifiCorp shall fund 100 percent of hatchery operations and maintenance costs necessary to fulfill annual mitigation objectives developed by CDFW in consultation with NMFS.	Not yet occurred	Would occur

[1] The Interim Conservation Plan refers to the plan developed by PacifiCorp through technical discussions with NMFS and USFWS regarding voluntary interim measures for the enhancement of coho salmon and suckers listed under the ESA, filed with FERC on November 25, 2008, or such plan as subsequently modified.

[2] Per the KHSA Appendix D, Non-Interim Conservation Plan Interim Measures, following the DRE's (Dam Removal Entity or KRRC) acceptance of the license surrender order, PacifiCorp shall provide funding of up to $5.4 million for implementation of projects approved by the Oregon Department of Environmental Quality (ODEQ) and the California State and Regional Water Quality Control Boards, and an additional amount of up to $560,000 per year to cover project operation and maintenance expenses related to those projects, these amounts subject to adjustment for inflation as set forth in Section 6.1.5 of the KHSA. PacifiCorp would provide funding for these nutrient reduction projects separate from the Proposed Project (see Section 3.25 Cumulative Effects).

[3] Turbine venting at Iron Gate would not occur under the Proposed Project as the Klamath River would be restored to natural conditions that would not require turbine venting to offset the operational impacts of the Iron Gate Dam complex.

2.7.10 Land Disposition and Transfer

The Proposed Project includes the transfer of PacifiCorp lands immediately surrounding the Lower Klamath Project ("Parcel B lands") (Figure 2.7-18) from PacifiCorp to the KRRC prior to dam removal (this transfer is the subject of a separate FERC application). The Proposed Project then provides that following dam removal, the KRRC would transfer Parcel B lands to the states, or to a designated third-party transferee. The lands would thereafter be managed for public interest purposes (e.g., tribal mitigation, river-based recreation, wetland restoration, etc.) (KHSA Section 7.6.4). Pursuant to the KHSA, decisions about the land transfer would occur following dam removal, and the outcome of who the lands will ultimately be transferred to and what they will be used for is uncertain. While this draft EIR analyzes the disposition and transfer of Parcel B lands at a general level, the specific impacts associated with the transfers and any future land uses remain uncertain.

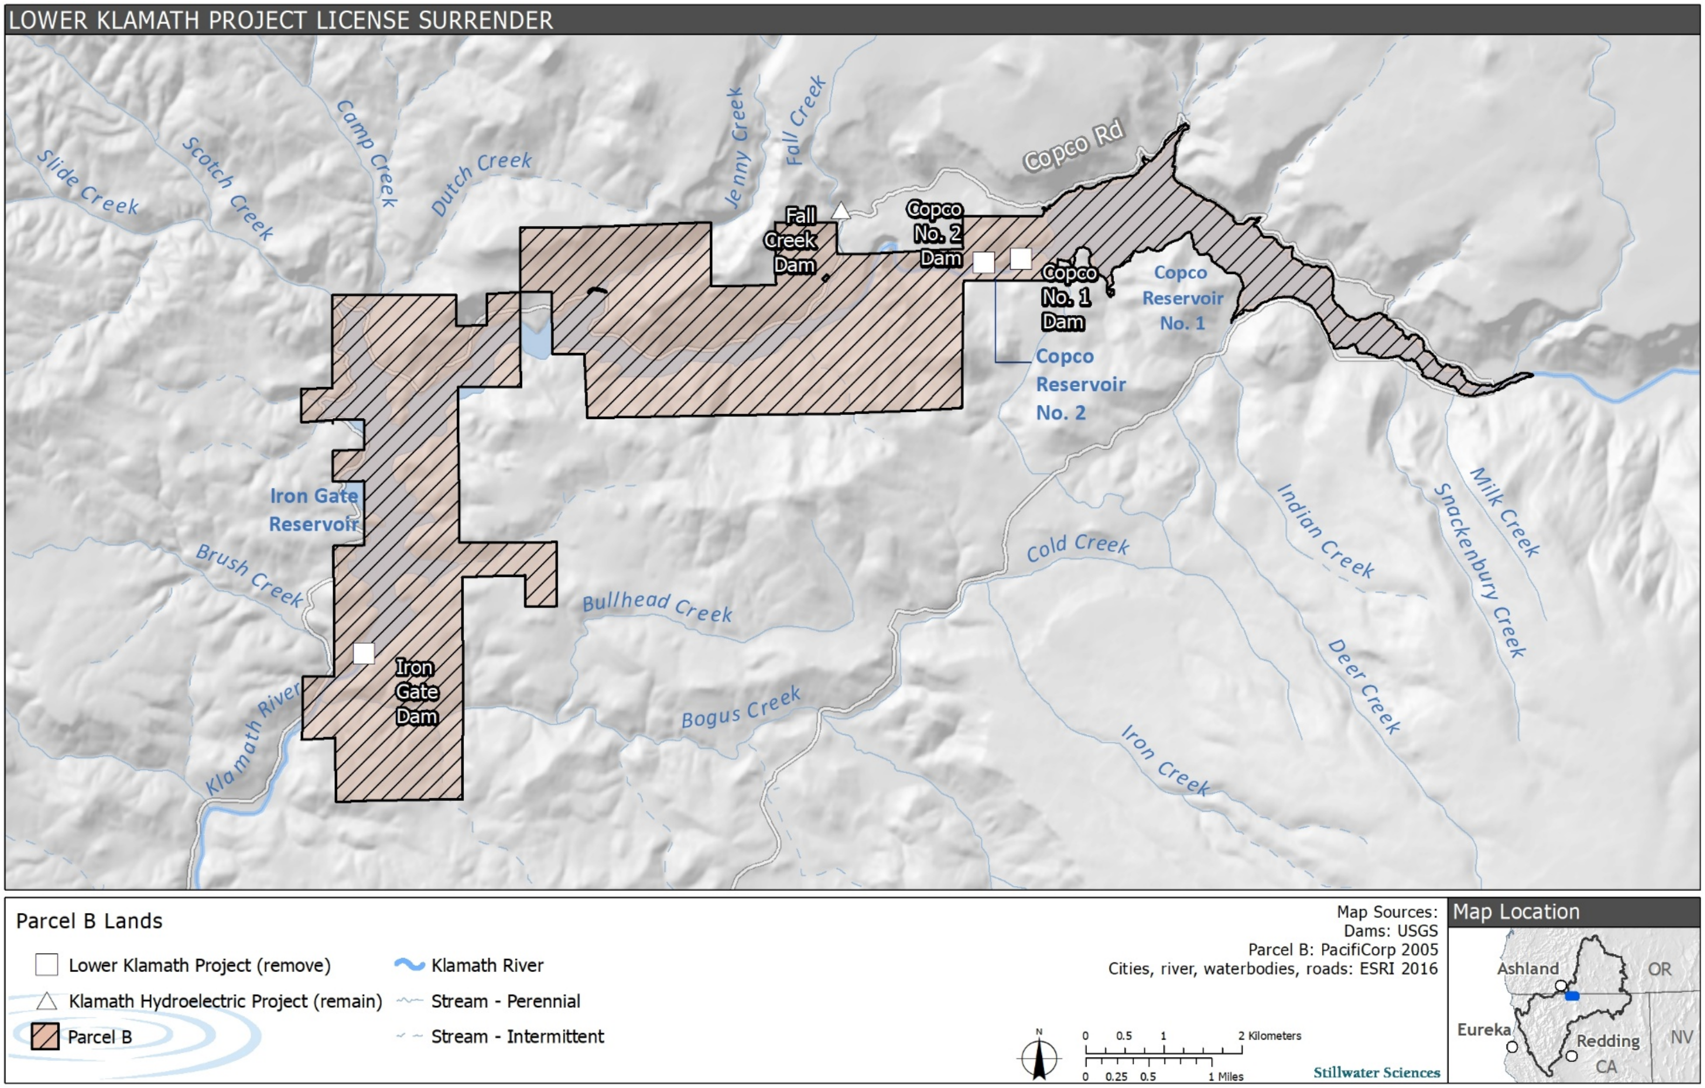

Figure 2.7-18. Parcel B Lands – California Portion.

2.8 Intended Uses of the EIR

In accordance with CEQA Guidelines section 15124, subdivision (d), this section describes the intended uses of the EIR.

The State Water Board intends to rely on this EIR for any issuance of a water quality certification for the Proposed Project under Clean Water Act section 401, including certification for a proposed decommissioning license from FERC and an anticipated application to the U.S. Army Corps of Engineers (USACE) for a discharge permit under Clean Water Act section 404. Additionally, to the extent the project requires any other water quality or water rights permits, such as any NPDES permits for hatchery operation and construction work, the State Water Board or the Regional Water Quality Control Board for the North Coast would rely on this EIR.

The Federal Power Act broadly preempts the state's authority over hydroelectric facilities. (*California v. FERC*, 495 U.S. 490 (1990); *Sayles Hydro Assocs. v. Maughan* 985 F.2d 451 (9th Cir. 1993). One of the limited exceptions to this rule is issuance of water quality certifications under Clean Water Act section 401 for FERC licensing decisions. Clean Water Act section 401 requires every applicant for a federal license or permit that could result in a discharge to the waters of a state to apply for certification from that state that their activities will be in compliance with state and federal water quality standards and other relevant requirements of state law. Conditions of a water quality certification become conditions of the federal permit or license. Thus, since there is an application before FERC to remove the Lower Klamath Project dams, the State Water Board can issue a water quality certification under certain water quality conditions or deny water quality certification based on a proposed activity's impact on the state's waters. The Federal Power Act preempts other state authority. Accordingly, the State Water Board does not anticipate that other state or local agencies would undertake permitting or other discretionary actions subject to CEQA for the proposed project. Additionally, although this draft EIR analyzes impacts of the Proposed Project to a broad range of environmental resource areas, implementation of any developed mitigation measures will depend on agreements to implement mitigation measures by the KRRC or FERC. During EIR development, this issue was discussed in multiple stakeholder forums, and this issue is discussed in greater detail throughout this draft EIR.

The California Coastal Commission has indicated that it may issue a determination of consistency with the Coastal Zone Management Act, should the KRRC prepare and submit a consistency certification and should the National Oceanic and Atmospheric Administration's (NOAA's) Office for Coastal Management grant such authority (January 31, 2017 public scoping letter, see Appendix A). The California Coastal Commission has indicated that, should it issue such a determination, the California Coastal Commission would rely on this EIR.

Multiple federal agencies would issue decisions on the Proposed Project. As previously mentioned, FERC has before it the application for decommissioning. The State Water Board anticipates that the application would also seek a "dredge and fill" permit under Clean Water Act section 404 from the USACE. The National Marine Fisheries Service and the United States Fish and Wildlife Service are the federal agencies with the authority to issue Biological Opinions on the proposed project, under the Endangered Species Act. National Marine Fisheries Service, the United States Fish and Wildlife

Service, Bureau of Land Management additionally have specific mandatory conditioning authority under sections 4(e) and 18 of Federal Power Act (16 U.S.C. § 797(e), 811). To the extent that this EIR is issued at a point in which it is useful to these federal agencies' analyses, the information contained herein may help to inform these decisions, and any environmental review under the federal National Environmental Policy Act.

Additionally, the KRRC has proposed, and FERC has approved, an Independent Board of Consultants to evaluate aspects of the KRRC's application. This EIR may provide useful information for the Board of Consultants' review.

3 ENVIRONMENTAL SETTING, IMPACTS, AND MITIGATION MEASURES

3.1 Introduction

Section 3 of this EIR describes the environmental resources that may be affected by the Proposed Project (Sections 3.2 to 3.23), including potential cumulative effects (Section 3.24). Additionally, Section 3 provides a summary of hydrologic information (Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*) that is referenced by multiple environmental resource areas as part of the impact analyses.

Within Section 3, the environmental resource areas are organized as follows:

- 3.2 Water Quality
- 3.3 Aquatic Resources
- 3.4 Phytoplankton and Periphyton
- 3.5 Terrestrial Resources
- 3.6 Flood Hydrology
- 3.7 Groundwater
- 3.8 Water Supply/Water Rights
- 3.9 Air Quality
- 3.10 Greenhouse Gas Emissions
- 3.11 Geology, Soils, and Mineral Resources
- 3.12 Historical Resources and Tribal Cultural Resources
- 3.13 Paleontologic Resources
- 3.14 Land Use and Planning
- 3.15 Agriculture and Forestry Resources
- 3.16 Population and Housing
- 3.17 Public Services
- 3.18 Utilities and Service Systems
- 3.19 Aesthetics
- 3.20 Recreation
- 3.21 Hazards and Hazardous Materials
- 3.22 Transportation and Traffic
- 3.23 Noise
- 3.24 Cumulative Effects

Each environmental resource area section includes five parts: (1) Area of Analysis; (2) Environmental Setting; (3) Significance Criteria; (4) Impact Analysis Approach; and (5) Potential Impacts and Mitigation. A general description of each part is provided below.

3.1.1 Area of Analysis

The Area of Analysis describes the physical limits or boundaries of the Proposed Project's effects on the different environmental resource areas. Since the Proposed Project may affect each of the resources differently, the geographic scope for each resource area varies and is described in a separate Area of Analysis in each environmental resource area section.

3.1.2 Environmental Setting

The analysis of potential impacts requires a description of a project's current environmental setting as a basis for comparison against which to evaluate project impacts. Pursuant to the CEQA Guidelines Section 15125 (a), the environmental setting for comparison is conditions at the time of issuance of the Notice of Preparation. This EIR describes the relevant environmental setting characteristics of the Proposed Project for each resource area.

3.1.3 Significance Criteria

CEQA Guidelines Section 15382 defines a significant effect as a "substantial, or potentially substantial, adverse change in any of the physical conditions within the area affected by the project…" In setting criteria for evaluating significance, this EIR relies on scientific and factual data, analysis, consideration of relevant local, regional and state standards, and the questions presented in Appendix G of the CEQA Guidelines.

3.1.4 Impact Analysis Approach

This EIR analyzes the potential direct and reasonably foreseeable indirect effects on the environment associated with the implementation of the Proposed Project (see CEQA Guidelines Section 15358).

The impact analysis approach section describes how the analysis of potential direct and indirect effects associated with the Proposed Project was undertaken for each environmental resource area, including summaries of the data and models used in the impact analysis.

3.1.5 Potential Impacts and Mitigation

The potential impacts of the Proposed Project are evaluated by resource area. Each potential impact is introduced by a **numbered, bolded** potential impact title, followed by an analysis of how the resource area under consideration would be affected by the impact. Where appropriate, the analysis separates short-term and long-term impacts. Where the analysis indicates that the unmitigated potential impact could be significant, the EIR identifies feasible mitigation measures, if they exist. Under CEQA, mitigation can include avoiding, minimizing, rectifying, or compensating for the potential impact, or reducing or eliminating the potential impact over time (CEQA Guidelines Section 15370).

Further, CEQA Guidelines Section 15126.4 (a)(2) states that mitigation measures must be fully enforceable through permit conditions, agreements, or other legally-binding instruments. Because CEQA requires analysis of potential impacts and mitigation measures that are outside the State Water Board's regulatory purview for the Proposed Project, this EIR discusses and analyzes the effects of some mitigation measures that would not be enforceable by the State Water Board. It is the State Water Board's understanding that the KRRC may agree to implement certain mitigation measures through good neighbor agreements or other legally enforceable mechanisms (Appendix B: *Definite Plan – Section 1*). Therefore, this EIR discloses and discusses the potential effects of such mitigation, even though a legally-binding enforcement mechanism is not in place at this time.

Mitigation measures are introduced by a **numbered, bolded** mitigation measure title, followed by a description of the measure, the first time that each measure is invoked in the document. Subsequent references to a particular mitigation measure point back to the original description in this EIR.

Each resource area impact analysis concludes with a significance determination of:

- No significant impact – potential effect either would not cause any adverse alterations to existing conditions or would cause alterations but they would not result in a significant adverse effect.
- No significant impact with mitigation – significant or potentially significant adverse effect would be eliminated or reduced to an effect that is not significant with implementation of an identified mitigation measure(s).
- Significant and unavoidable – effect would be adverse and substantial, or potentially substantial, and cannot be mitigated to less than significant.
- Beneficial – effect on the resource is positive.

The cumulative effects analysis concludes with a significance determination of:

- Beneficial cumulative effects – combined effects are beneficial.
- No significant cumulative impact – combined impact of the Proposed Project and other projects would not be significant and adverse (and would also not be beneficial).
- Not cumulatively considerable – combined impact of the Proposed Project and other projects would be significant and adverse, but the incremental contribution of the Proposed Project would not be cumulatively considerable.
- Not cumulatively considerable with mitigation – combined impact of the Proposed Project and other projects would be significant and adverse, and the incremental contribution of the Proposed Project requires mitigation to reduce it to less than cumulatively considerable.
- Cumulatively considerable – combined impact of the Proposed Project and other projects would be significant and adverse, and the incremental contribution of the Proposed Project is cumulatively considerable (and there is no feasible mitigation).

3.1.6 Summary of Available Hydrology Information for the Proposed Project

The 2012 KHSA EIS/EIR evaluated the potential environmental impacts of removing J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams. As part of the analyses, Klamath River flows were modeled for periods before, during, and after dam removal in a number of technical studies referenced in the 2012 KHSA EIS/EIR[18], as well as in the environmental document itself. Flow assumptions for the model largely were based on the forecasted operations of the USBR's Klamath Irrigation Project, located in the Upper Klamath Basin. In the 2012 KHSA EIS/EIR, implementation of the Klamath Basin Restoration Agreement (KBRA) (see Section 2.6.3 *Klamath Settlement Agreements*) was considered to be a "connected action" to dam removal. Thus, the model used

[18] Key technical studies are the Klamath River total maximum daily loads (TMDL) Final Staff Report (North Coast Regional Board 2010) and the Hydrology, Hydraulics, and Sediment Transport Studies for the Secretary's Determination on Klamath River Dam Removal and Basin Restoration (USBR 2012a).

NMFS 2010 Biological Opinion (2010 BiOp) flows for analysis of the scenario where dams would remain in place, and it modified 2010 BiOp flows based on KBRA operations criteria for the Klamath Irrigation Project ("KBRA Flows") for analysis of the scenario where dams would be removed (USBR and CDFG 2012). The KBRA expired on December 31, 2015 due to a lack of Congressional authorization. Consequently, this EIR considers the potential effects of dam removal using Klamath River flows as defined by the current operational standard, the NMFS and USFWS 2013 Joint Biological Opinion for the Klamath Irrigation Project (2013 BiOp Flows) (NMFS and USFWS 2013).

The estimated Klamath River flows under the 2013 BiOp (2013 BiOp Flows) were compared to the previously modeled flows, which included KBRA operations criteria (KBRA Flows), to determine whether 2013 BiOp Flows were sufficiently similar that hydrologic model outputs developed for the 2012 KHSA EIS/EIR would still be applicable. The comparison references and builds upon an analysis conducted in the 2012 KHSA EIS/EIR Supplemental Information Report (SIR) (USBR 2016) for the same purpose. USBR (2016) concluded that the relatively small flow differences between 2013 BiOp and KBRA Flows would not substantively alter the conclusions in the 2012 KHSA EIS/EIR for those environmental resources that would be affected by flows (i.e., water quality, aquatic resources, flood risk, recreation). While the specific timing of flows changed between the 2013 BiOp and KBRA flows, the range of 2013 BiOp Flows is within the range of modeled KBRA Flows, so the previously modeled results still represent the range of conditions under 2013 BiOp Flows (USBR 2016).

Additionally, the sediment transport model developed for the 2012 KHSA EIS/EIR would produce nearly identical suspended sediment concentrations during the main drawdown period between January and May if it was run using 2013 BiOp Flows, because the 2013 BiOp and KBRA Flows are nearly identical for all water year types (generally within a few percentage points) (USBR 2016). Additional analysis presented below assesses the magnitude, timing, and distribution of flows across multiple water years to verify that the range of flows modeled under KBRA Flows are still appropriate for analyses in this EIR.

USBR's consultation with NMFS and USFWS on the 2013 BiOp Flows for the Klamath Irrigation Project is currently underway and it is expected to be completed by August of 2019. The schedule for the biological opinion has been accelerated at the direction of the President, pursuant to a Presidential Memorandum issued on October 19, 2018. At this time, estimates of flows that will be required under the future Klamath Irrigation Project biological opinion are still speculative, so they are not included in hydrologic modeling. However, the flow-related analyses in this EIR acknowledge the re-initiation of consultation on the 2013 BiOp Flows by considering the 2017 court-ordered flushing and emergency dilution flow requirements downstream of Iron Gate Dam as interim flow requirements until formal consultation is completed. The 2017 court-ordered flushing flows are not modeled as part of existing conditions hydrology for the Proposed Project, because they went into effect in February 2017 after the December 2016 Notice of Preparation was filed. These flows are discussed in several locations in this EIR, including, but not limited to, Section 3.24 *Cumulative Effects*, Section 4.2 *No Project Alternative*, and Section 4.4 *Continued Operations with Fish Passage Alternative*, where the aforementioned two alternatives assume that Iron Gate Dam would remain in place.

As appropriate, this EIR assumes that the 2013 BiOp flows in combination with the court-ordered flushing flows are the best estimate for future biological opinion flows.

3.1.6.1 Klamath River Flows under the Klamath Irrigation Project's 2013 BiOp Flows

Under the 2013 BiOp Flows, current and future (2013−2023) operations of the Klamath Irrigation Project in the Upper Klamath Basin include irrigation deliveries consistent with historic operations (subject to water availability), while maintaining Upper Klamath Lake and Klamath River hydrologic conditions that avoid jeopardizing the continued existence of listed species and adverse modification of designated critical habitat (NMFS and USFWS 2013). Operations under the 2013 BiOp Flows include two distinct, real-time water management approaches during the fall/winter (October through February) and spring/summer (March through September) periods. The fall/winter and spring/summer water management approaches prioritize different goals during the two periods, but they are designed to meet the ecological needs of the Upper Klamath Lake ESA-listed Lost River Sucker and Shortnose Sucker and ESA-listed coho salmon downstream of Iron Gate Dam, while also maintaining full irrigation deliveries in accordance with existing contracts, contingent upon available water supplies. Minimum flows downstream of Iron Gate Dam under the 2013 BiOp Flows are presented in Table 3.1-1.

Table 3.1-1. Minimum Klamath River Discharge below Iron Gate Dam under the 2013 BiOp Flows.

Month	Iron Gate Dam Average Daily Minimum Target Flows (cfs)
January	950
February	950
March	1,000
April	1,325
May	1,175
June	1,025
July	900
August	900
September	1,000
October	1,000
November	1,000
December	950

3.1.6.2 Comparison of Klamath River Flows under 2013 BiOp Flows and KBRA Operations Criteria

In the 2012 KHSA EIS/EIR, the projected Klamath River flows were modeled using the Water Resources Integrated Modeling System (WRIMS) coupled with a RiverWare-based model called the Klamath Dam Removal Model (KDRM) (USBR 2012a, 2016). The coupled model was used to analyze the Klamath River conditions using either the 2010 BiOp Flows or the KBRA Flows based on the KBRA operations criteria for the Klamath Irrigation Project. The 2010 BiOp and the KBRA Flows are generally very similar, particularly from January through May when flows are effectively the same between the two flow scenarios (USBR 2012a). The estimated Klamath River flows under the 2013 BiOp Flows were modeled using an updated and modified WRIMS model (USBR 2012b). The WRIMS model used to evaluate the 2013 BiOp Flows is also known as the Klamath Basin Planning Model (KBPM) and the modeled flow results are sometimes referred to as the "2013 BO" in USBR documents (USBR 2012b, 2016).

Modeled Klamath River flows under the 2013 BiOp and the KBRA operations criteria are nearly identical when examined on an average annual basis, with flows downstream of Iron Gate Dam averaging approximately 1,920 cfs and 1,932 cfs, respectively. The average annual 2013 BiOp and KBRA Flows downstream of Keno Dam are also nearly identical, averaging approximately 1,413 cfs and 1,434 cfs, respectively. While the modeled flows upstream and downstream of the Hydroelectric Reach are within a few percentage points on an average annual basis, some average monthly flows differ between the 2013 BiOp and KBRA flows (Tables 3.1-2 and 3.1-3). The most prominent difference is that the 2013 BiOp Flows when compared to KBRA Flows generally require higher flows in the fall months (October through December) and allow lower flows in the summer months (June through August). Downstream of Iron Gate Dam, fall 2013 BiOp Flows average approximately 200 cfs more than fall KBRA Flows; summer 2013 BiOp Flows average approximately 100 cfs less than summer KBRA Flows (Tables 3.1-2 and 3.1-3). The seasonal differences in 2013 BiOp Flows versus KBRA Flows reflect the joint goal of NMFS and USFWS to protect ESA-listed fish that rely on a shared but finite aquatic resource (most notably, the two endangered sucker species in Upper Klamath Lake and threatened coho salmon in the Klamath River below Iron Gate Dam) (NMFS and USFWS 2013).

Table 3.1-2. Average Monthly Flow at Iron Gate Dam for 2013 Joint Biological Opinion and KBRA Operations Criteria.

Month	Average monthly flow downstream of Iron Gate Dam		Differences (2013 BiOp vs. KBRA Flows)	
	KBRA Operations Criteria	2013 BiOp Operations Criteria		
	(cfs)	(cfs)	(cfs)	(percent)
Oct	1050	1263	213	20 percent
Nov	1149	1387	239	21 percent
Dec	1546	1744	197	13 percent
Jan	2061	2131	70	3 percent
Feb	2628	2545	-83	-3 percent
Mar	3390	3381	-9	0 percent
Apr	3340	3119	-222	-7 percent
May	2431	2523	92	4 percent

Source: Modified from USBR (2016).

Figures 3.1-1 and 3.1-2 present monthly flow exceedances for modeled 2013 BiOp and KBRA Flows downstream of Iron Gate Dam and Keno Dam, respectively. In the figure legends, modeled 2013 BiOp Flows are labeled as “2013 BO”, while modeled KBRA Flows are labeled as “KDR KBRA.” Monthly flow exceedance plots are particularly useful for comparing differences between modeled 2013 BiOp and KBRA Flows for different water year types (i.e., wet, median, and dry year types). Here, a wet year type is defined as the highest 10 percent of flows, such that wet year flows are characterized by those at the 10 percent exceedance point in Figure 3.1-1 and 3.1-2 (i.e., typical wet year flows would be exceeded 10 percent of the time). Similarly, a median year is characterized by flows at the 50 percent exceedance point, while a dry year is characterized by flows at the 90 percent exceedance point. While Table 3.1-2 and Table 3.1-3 summarize modeled *average* monthly flows under the 2013 BiOp and KBRA operations criteria, the monthly flow exceedance plots in Figure 3.1-1 and Figure 3.1-2 present the range of possible flows by month under the two operations scenarios.

The monthly flow exceedance plots generally indicate either a temporal shift in the distribution of flows expected within a given month or a shift in the water year type distribution of. In either case, the overall range of 2013 BiOp and KBRA Flows is similar between the two curves (Figures 3.1-1 and 3.1-2). A temporal shift in the distribution of flows expected within a given month is indicated by comparing modeled 2013 BiOp and KBRA Flows across different months. For example, the first panel in Figure 3.1-1 shows that flows in the Klamath River downstream of Iron Gate Dam in October under the 2013 BiOp Flows would be 150 to 400 cfs greater than under the KBRA Flows, regardless of whether it is a wet year (i.e., 10 percent exceedance), a median year (i.e., 50 percent exceedance), or a dry year (i.e., 90 percent exceedance). In October, the modeled 2013 BiOp Flows at Iron Gate Dam range from slightly greater than 1,600 cfs to approximately 1,000 cfs, which is different from the range of modeled KBRA Flows in October, but very similar to the range of modeled KBRA Flows in September. The KBRA Flow exceedance curve for the month of September ranges from slightly less than 1,600 cfs to slightly less than 1,000 cfs with a similar shape as the October 2013 BiOp Flows, such that the October 2013 BiOp Flows represent a one-month temporal shift of the September KBRA Flows. Similar shifts in the monthly distribution of flows also occur in July and August downstream of Iron Gate Dam where the range and shape of the July 2013 BiOp Flows are within approximately 100 cfs or less of the August KBRA Flows (Figure 3.1-1).

The shift in the distribution of flows by water year type is characterized by whether the flow within individual months is higher during some water year types and lower during other water year types when comparing between 2013 BiOp and KBRA Flows. Variations between the modeled 2013 BiOp and KBRA Flows during different water year types is evaluated by comparing the flows at the 10 percent exceedance for wet years, 50 percent exceedance for median years, and 90 percent exceedance for dry years. At both Iron Gate and Keno dams from July through September, the modeled 2013 BiOp Flows are less than modeled KBRA Flows during wet years (e.g., 10 percent exceedance), while the 2013 BiOp Flows are greater than KBRA Flows during dry years (e.g., 90 percent exceedance) (Figure 3.1-1 and 3.1-2). The lower left panel of Figure 3.1-1 highlights this trend during July at Iron Gate Dam where the wet year 2013 BiOp Flow is approximately 700 cfs less than the KBRA Flow, the median year 2013 BiOp Flow is approximately 100 cfs less than the KBRA Flow, and the dry year 2013 BiOp Flow is approximately 200 cfs greater than the KBRA Flow. At both Iron Gate and Keno dams, June is a unique month where there is both a monthly temporal shift in the range of flows (i.e., KBRA Flows in May bracket the range of 2013 BiOp Flows in June) and a water year type shift (i.e., 2013 BiOp Flows are greater than KBRA Flows in wet years, less in median years, and approximately the same in dry years).

Despite the aforementioned differences between the modeled 2013 BiOp and KBRA Flows, the KBRA Flows capture the range of possible 2013 BiOp Flows in the Klamath River at Iron Gate and Keno dams (Figure 3.1-3). At Iron Gate Dam, a comparison of the maximum flow exceedances under the 2013 BiOp and KBRA operations criteria in Figure 3.1-3 shows the maximum range of 2013 BiOp Flows in the Klamath River is represented by KBRA Flows, because maximum monthly KBRA Flows are greater than the maximum monthly 2013 BiOp Flows for flow exceedances of 10 percent or less (representing wet water years). Additionally, at Iron Gate Dam, the minimum monthly KBRA Flows capture the range of the minimum monthly 2013 BiOp Flows as shown by how flow exceedances of 90 percent or more (representing dry water years) for KBRA Flows are less than flow exceedances of 90 percent or more for 2013 BiOp Flows (Figure 3.1-3). Flow exceedances where the minimum 2013 BiOp Flows are less than minimum KBRA Flows (i.e., minimum flow exceedances 50 percent or less) or the maximum 2013 BiOp Flows are greater than the maximum KBRA Flows (i.e., maximum flow exceedances 40 to 15 percent) are due to shifts in the distribution of flows by water year type as previously discussed. All flow exceedances where the minimum or maximum 2013 BiOp Flows are different than the minimum or maximum KBRA Flows are still contained within the flow exceedances less than 10 percent or greater than 90 percent for KBRA Flows, so the range of 2013 BiOp Flows are still bracketed by the range of KBRA Flows.

It is reasonable to assume the outputs of hydrologic models using the KBRA Flows represent the entire range of results of hydrologic models using the 2013 BiOp Flows because the entire range of modeled 2013 BiOp Flows at Iron Gate and Keno dams is captured by modeled KBRA Flows. Farther downstream of Iron Gate Dam, Klamath River flow estimates are only affected by assumptions regarding tributary inflows (accretions) that are not affected by operations of the Klamath Irrigation Project[19]. While variations may exist in timing between 2013 BiOp and KBRA Flows, the range of model results would be similar if the 2013 BiOp Flows were used in the hydrologic model rather than the KBRA Flows, since the KBRA Flows bracket the 2013 BiOp Flows.

In summary, the hydrologic model outputs previously developed using the KBRA Flows for the 2012 KHSA EIS/EIR are sufficient to estimate conditions under 2013 BiOp Flows. As explained above, the primary differences are temporal shifts in the flow distribution within some months and changes in expected flows in different water year types. The previous KBRA Flows bracket the range of 2013 BiOp Flows, supporting the conclusion that the prior modeling using the KBRA Flows sufficiently represents the range of potential effects of Klamath River flows under the 2013 BiOp Flows.

Consequently, this EIR considers the potential effects of dam removal under the Proposed Project by applying existing hydrology information presented in the 2012 KHSA EIS/EIR, as well as in the numerous technical studies that were foundational to that effort.

[19] PacifiCorp coordinates operations with the USBR and operates the Lower Klamath Project in compliance with the 2013 BiOp for the Klamath Irrigation Project. The 2013 BiOp does not require independent releases from the Lower Klamath Project to supply the minimum flow requirements downstream of Iron Gate Dam.

3.2 Water Quality

This section focuses on potential water quality effects due to the Proposed Project. Other sections of this EIR discuss *Flood Hydrology (*Section 3.6*)*, *Groundwater (*Section 3.7*)*, and *Water Supply/Water Rights (*Section 3.8*)*.

Many comments were received during the NOP public scoping process relating to water quality (see Appendix A). A number of comments focused on the potential effects of dam removal on Klamath River water quality, including short-term exceedances of federal, state, and/or tribal water quality objectives and the potential for release of contaminants contained within reservoir sediments. With respect to long-term impacts on water quality, several comments noted that analyses in the EIR need to consider dam removal, as well as alternatives where dams remain in place, within the context of the existing Klamath River total maximum daily loads (TMDLs). There were numerous comments regarding the potential for dam removal to alleviate existing impaired conditions for water temperature, dissolved oxygen, and blue-green algae[20] and associated algal toxins. Conversely, some commenters indicated their belief that the Lower Klamath Project reservoirs improve water quality by serving as a sink for phosphorus and reducing downstream summer time water temperatures, or otherwise improving water quality in an unspecified manner. Additional summary of the water quality comments received during the NOP public scoping process, as well as the individual comments, are presented in Appendix A.

3.2.1 Area of Analysis

The Area of Analysis for water quality includes multiple reaches of the Klamath River, as listed below and shown in Figure 3.2-1.

Upper Klamath Basin

- Hydroelectric Reach[21] (upstream end of J.C. Boyle Reservoir to Iron Gate Dam)

Mid-Klamath Basin

- Klamath River from Iron Gate Dam downstream to the confluence with the Salmon River
- Klamath River from the confluence with the Salmon River to the confluence with the Trinity River

Lower Klamath Basin

- Lower Klamath River from the confluence with the Trinity River to the estuary
- Klamath River Estuary

[20] Blue-green algae are a type of phytoplankton that are naturally found in lakes, streams, ponds, and other surface waters which can produce toxic compounds (e.g., microcystin) that have harmful effects on fish, shellfish, mammals, bird, and people (USEPA 2014). Though blue-green algae is technically a cyanobacteria, it is commonly referred to as an algae. For readability, and to reduce confusion, this EIR refers to cyanobacteria as blue-green algae except when a cited reference specifically uses the term cyanobacteria.
[21] Note that the portion of the Hydroelectric Reach that extends into Oregon (i.e., from the Oregon-California state line [RM 214.1] to the upstream end of J.C. Boyle Reservoir) is only being considered to the extent that conditions in this reach influence water quality downstream in California.

- Pacific Ocean nearshore environment

Table 3.2-1 lists the river mile locations of the above reaches and of features relevant to the water quality Area of Analysis.

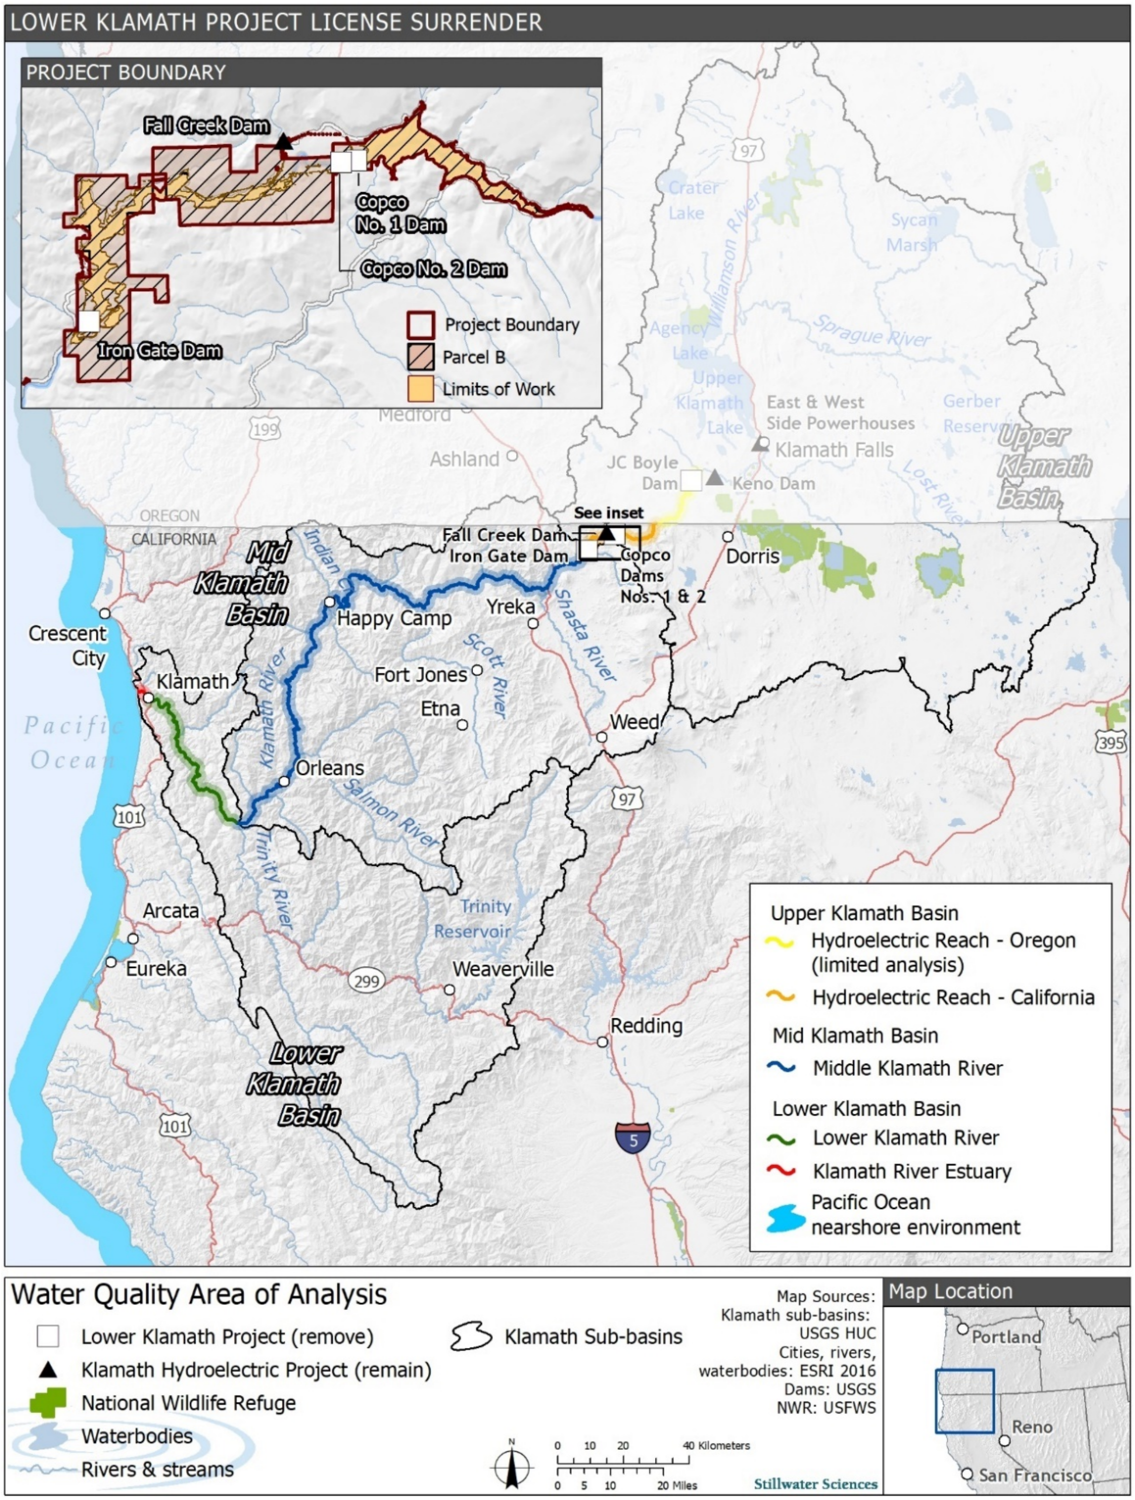

Figure 3.2-1. Klamath River Reaches Included in the Area of Analysis for Water Quality.

Table 3.2-1. River Mile Locations of Klamath River Features Relevant to the Water Quality Analysis.

Feature	River Mile[1]
Upper Klamath Basin	
J.C. Boyle Reservoir	229.8 to 233.3
Oregon-California state line	214.1
Copco No. 1 Reservoir	201.8 to 208.3
Copco No. 2 Reservoir	201.5 to 201.8
Iron Gate Reservoir	193.1 to 200.0
Mid-Klamath Basin	
Klamath River confluence with Shasta River	179.5
Klamath River confluence with Scott River	145.1
Seiad Valley	132.7
Klamath River confluence with Salmon River	66.3
Orleans	58.9
Hoopa Valley Tribe Reservation lands	44.8 to 45.8
Weitchpec	43.6
Lower Klamath Basin	
Yurok Reservation Lands	0 to 45
Klamath River confluence with Trinity River	43.3
Klamath River confluence with Turwar Creek	5.6
Klamath River Estuary	0 to 3.9

Notes:
[1] River Mile (RM) refers to distance upstream of the mouth of the Klamath River. RM's have been updated from the Detailed Plan (see Appendix B: *Detailed Plan*) to those of the Definite Plan (see Appendix B: *Definite Plan – Section 1.4*).

3.2.2 Environmental Setting

This section provides a description of the environmental setting for water quality resources in the Area of Analysis, including a brief overview of water quality processes in the Klamath Basin to inform subsequent impact analyses.

3.2.2.1 Overview of Water Quality Processes in the Klamath Basin

Water quality in the Klamath River is affected by the geology and meteorology of the Klamath Basin, as well as current and historical land- and water-use practices. Cold air temperatures and precipitation generally occur from November to March, corresponding to periods of higher flows and colder water temperatures. Warmer air temperatures and drier conditions occur from April to October, corresponding to periods of lower flows and warmer water temperatures. The Upper Klamath Basin has naturally elevated levels of phosphorus that combine with human activities (e.g., wetland draining, agriculture, ranching, logging, water diversions), to increase concentrations of nutrients (nitrogen and phosphorus) and suspended sediment, to degrade water quality parameters (e.g., water temperature, pH, dissolved oxygen). This, in turn, affects the water quality entering California. Within California, the Middle and Lower Klamath River is composed of generally steep, mountainous terrain (see Section 3.11 *Geology, Soils, and Mineral Resources*). Historically, hillslope and in-channel gold mining and extensive logging have occurred, along with agricultural and ranching activities that divert water in many of the lower tributary basins. These activities have altered stream flows, increased concentrations of suspended sediment and nutrients in watercourses, and increased summer water temperatures.

The presence and operations of the Lower Klamath Project facilities in the Klamath Hydroelectric Reach affect many aspects of water quality in the Klamath River. In general, the most common effects of hydroelectric project operations on water quality result from changes in the physical structure of the aquatic ecosystem. The dams alter the flow patterns in a river by slowing the transport of water downstream and modifying the timing and magnitude of flows on a short-term basis. Dams intercept and retain sediment, organic matter, nutrients, and other constituents that would otherwise be transported downstream. Dams additionally alter seasonal water temperatures when compared to free-flowing stream reaches.

In general, effects on water quality from hydroelectric project operations include:

- **River and reservoir water temperatures.** The primary effects of hydroelectric project operations on the natural temperature regime of streams and rivers are related to alterations in water surface area, depth, and velocity due to water diversions into or out of the stream corridor, including reservoir impoundments and conveyance through canals, pipelines, or penstocks. These changes influence the amount of heat entering and leaving waterbodies (such as from solar radiation and nighttime cooling), which influences the water temperature. As large reservoirs are often deep, they can retain their water temperature for weeks or months, thereby shifting the natural water temperature patterns in river reaches downstream of the reservoirs. For example, water released from reservoirs in the late spring is typically cooler than would naturally occur because the reservoir retains some of the cold water it received in the winter. Similarly, water released from reservoirs in the early fall is typically warmer than would naturally occur because the reservoir still contains water that was heated during the summer months. Additionally, due to surface heating of the reservoir in the late spring and summer, a warmer, less dense layer of water forms on the reservoir surface (the epilimnion), which overlies colder, denser water (the hypolimnion) (Figure 3.2-2). This process, called thermal stratification, often persists for months.

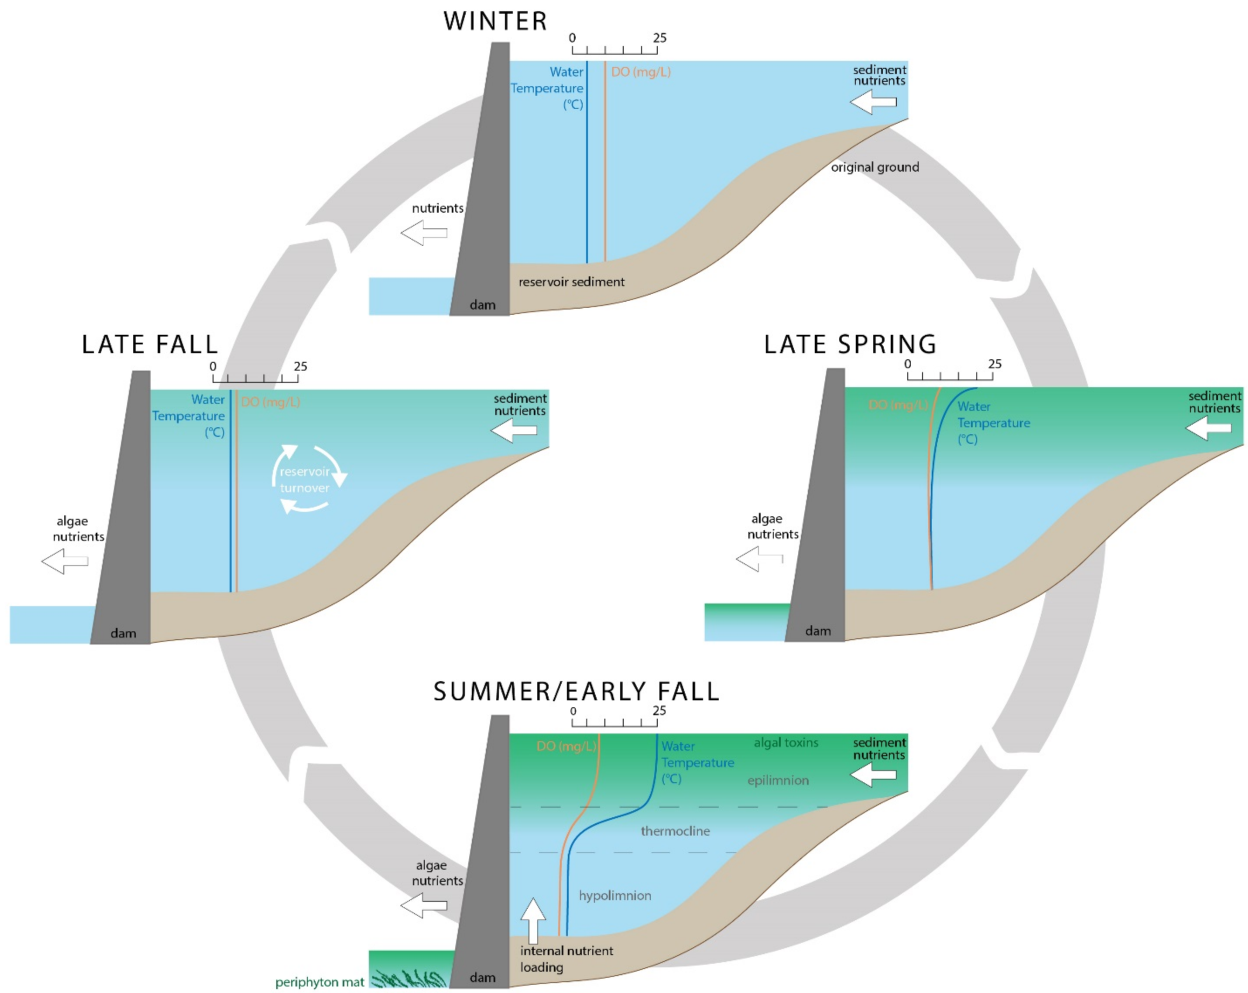

Figure 3.2-2. General Seasonal Pattern of Thermal Stratification, Dissolved Oxygen Concentrations, and Algae Blooms in Relatively Deep, Productive Reservoirs in Temperate Climates, With Darker Green Shading In Surface Waters Representing a Higher Intensity of Algae Growth.

- **<u>Reservoir mixing and dissolved oxygen.</u>** The water column in the deepest portions of most large reservoirs has a characteristic thermal and chemical structure. With thermal stratification (in summer and early fall), the isolated deeper water is not exposed to the atmosphere and often completely loses its supply of dissolved oxygen over a period of weeks or months as organic matter in bottom sediments decays (anoxic) (Figure 3.2-2). Releases of this deeper, oxygen-depleted water from the bottom of the reservoir can cause serious problems for downstream fish and other aquatic biota. In late fall, thermal stratification typically breaks down as the surface water layer cools and wind mixing of the water column occurs. This process is called reservoir turnover (Figure 3.2-2).
- **<u>Phytoplankton in reservoirs.</u>** As large reservoirs have long retention times for water and thermally stratify in the summer months, they often provide ideal conditions for the growth of phytoplankton in the epilimnion. Phytoplankton are microscopic organisms, including algae, bacteria, protists, and other single-celled plants, that float in the water column of fresh and salt waters and obtain energy via photosynthesis. Depending upon available nutrients, extensive seasonal phytoplankton blooms can develop in these reservoirs (Figure 3.2-2). Phytoplankton photosynthesis during the day releases dissolved oxygen and consumes carbon dioxide. At night, phytoplankton respiration consumes dissolved oxygen and releases carbon dioxide. This can result in wide daily swings in dissolved oxygen and pH, which is stressful to aquatic biota. Under nutrient-rich conditions, harmful blooms of phytoplankton composed of blue-green algae (also referred as cyanobacteria) can occur. Blue-green algae can produce algal toxins, which are also referred to as cyanotoxins (e.g., cyclic peptide toxins such as microcystin that adversely affects liver function and alkaloid toxins such as anatoxin-a and saxitoxin that adversely affect the nervous system). Algal toxins can be harmful to a wide range of organisms including exposed fish, shellfish, livestock, and humans. Releases of reservoir impounded waters can transport phytoplankton and/or toxins to downstream waters (Figure 3.2-2) and phytoplankton blooms can die abruptly ("crash"), releasing algal toxins into the water column. The subsequent decomposition of organic matter associated with dead phytoplankton can create periods of low dissolved oxygen in reservoir bottom waters, along with peaks of algal toxins, which adversely impact environmental and human health conditions (Figure 3.2-2). Additional information on phytoplankton and its impacts on water quality (including nitrogen fixation) can be found in *Section 3.4 Phytoplankton and Periphyton*.
- **<u>Nutrient cycling in reservoirs and internal loading.</u>** Nutrients entering reservoirs can undergo many changes and be involved in many biochemical processes. On an annual basis, the majority of nutrients entering a reservoir from a watershed are eventually discharged downstream, with only a small fraction being retained in the reservoir sediments. Dissolved nutrients (e.g., ortho-phosphorus, nitrate, and ammonium) entering a reservoir can be used directly by phytoplankton (which includes blue-green algae) when growing conditions are conducive. When phytoplankton die, they settle to the bottom of reservoirs and contribute nutrients and organic matter to the sediments. Under low dissolved oxygen conditions, nutrients contained within bottom sediments can be released back into the water column, creating a source of nutrients internal to the reservoir itself, in addition to the nutrients entering the reservoir from upstream sources. This is particularly important for phosphorus and results in highly enriched reservoir bottom waters during periods of stratification. During reservoir turnover

when the stratification breaks down, these nutrient rich waters are mixed throughout the reservoir water column and the nutrients can be released downstream, resulting in a secondary (fall) phytoplankton bloom (which includes blue-green algae) (Figure 3.2-2).

- **Sediment deposition in reservoirs**. The characteristically slow-moving waters within large reservoirs result in the deposition of sediments that enter the reservoir from the surrounding watershed (Figure 3.2-2). While large reservoirs interrupt the natural transport of both coarse sediments (e.g., sand, gravel, cobble, boulders) and fine sediments (e.g., clay, silt), contaminants found in the bottom sediments of reservoirs are typically transported from the watershed with fine sediments, which include both inorganic material and organic particulate matter. Trace metals are mostly attached to inorganic material (e.g., clays and silts). Organic contaminants, such as pesticides and dioxin, are adsorbed to (i.e., attached to the surface of) organic particulate matter, such as dead vegetation and phytoplankton.
- **Periphyton growth downstream of reservoirs.** Slow transport of water downstream and modified timing and magnitude of river flows can affect the growth of periphyton downstream of hydroelectric dams. Periphyton are aquatic freshwater organisms, including algae and bacteria that live attached to underwater surfaces such as rocks on a riverbed. Periphyton are important base components of the food web in riverine systems. Periphyton can influence riverine water quality by affecting nutrient cycling and diel (i.e., 24-hour cycle) fluctuations in dissolved oxygen and pH. Natural scouring of periphyton populations can be diminished downstream of large dams due to altered flows and interception of coarse sediment movement by the dam, leading to seasonal occurrence of large periphyton mats that can cause water quality problems and provide abundant habitat for fish parasites (see also Section 3.3.4.5 *Fish Disease and Parasites* and Section 3.4.2.2 *Periphyton*).

The following sections summarize general existing water quality conditions in the water quality Area of Analysis. Existing conditions are generally defined as physical, chemical, and biological characteristics of water in the Area of Analysis at the time of the NOP (2016). Water quality parameters analyzed in this EIR are represented by data collected within the past 10 to 17 years (2000–2017). Additional detail, including data from multiple agency and tribal monitoring programs throughout the Klamath Basin, is presented in Appendix C.

3.2.2.2 Water Temperature

Water temperatures in the Klamath Basin vary seasonally and by location. The North Coast Regional Water Quality Control Board (North Coast Regional Board) has determined that existing receiving water temperatures in the Klamath River are already too warm to support several designated beneficial uses, including cold freshwater habitat (COLD), rare, threatened, or endangered species (RARE), and migration of aquatic organisms (MIGR) annually during late summer/early fall (North Coast Regional Board 2010). All reaches of the Klamath River from the Oregon-California state line to the mouth of the Klamath River are listed as impaired for elevated water temperature on the Clean Water Act (CWA) Section 303(d) list. As a result, the North Coast Regional Board has developed TMDLs for water temperature in the Klamath River. A quantitative Klamath River TMDL model was created to determine what natural water temperature conditions would be in the Klamath River, and then the model was used to determine how flow modifications, water withdrawals, and other human activities alter water temperatures, forming the basis of the TMDLs (see Appendix D). The Klamath River TMDL allocates specific water temperature loads for Copco No. 1 and Iron Gate reservoirs, as discussed below. Properly functioning thermal refugia[22] are necessary to meet the Basin Plan water temperature objectives, as these areas of colder water in the mainstem Klamath River moderate naturally high summer water temperature conditions by providing places where fish can escape warmer temperatures. These thermal refugia support beneficial uses such as migration of salmonids (North Coast Regional Board 2011).

In the Hydroelectric Reach, water temperatures are influenced by the presence of the Lower Klamath Project facilities. The relatively shallow depth and short hydraulic residence times do not support thermal stratification in J.C. Boyle Reservoir (FERC 2007; Raymond 2008a, 2009a, 2010a) and thus this reservoir does not directly alter summertime water temperatures in further downstream reaches (NRC 2004). However, current power-peaking operations at the J.C. Boyle Powerhouse affect water temperatures in the river immediately downstream from the dam. While natural diel (24-hour) water temperature variations occur in the river, daily peaking operations at J.C. Boyle Powerhouse (river mile [RM] 225.2) result in an increase in the daily water temperature range in the Bypass Reach because warmer reservoir discharges are diverted around this reach (see also Section 2.3.1 *J.C. Boyle Dam Development*) and cold groundwater springs enter the river and dominate remaining flows (PacifiCorp 2006a; Kirk et al. 2010). Water temperatures in the Bypass Reach can decrease by 9 to 27°F when bypass operations are underway due to the influence of the springs (Kirk et al. 2010). In the Peaking Reach, which is downstream of the Bypass Reach, the flow diverted around the Bypass Reach rejoins the Klamath River (see Figure 2.3-1). At the upstream end of the Peaking Reach, the natural, cold groundwater input into the Bypass Reach, combined with fluctuations in river flow due to hydroelectric power operations in the Peaking Reach also produces an observed increase in daily water temperature range above the natural diel water temperature fluctuations (Kirk et al. 2010).

Further downstream in the Peaking Reach, near the confluence of the Klamath River and Shovel Creek (Figure 2.2-3), there are natural hot springs that contribute flows to the mainstem river. The natural hot springs were not found to result in consistent substantial warming of the Klamath River based on two sets of measurements made in November and December 2017 (KRRC 2018). Water temperature data collected upstream and downstream of the confluence of the Klamath River and Shovel Creek showed a 1.4˚F increase in the downstream direction during the November 2017 measurement, but a 0.2˚F decrease during the December 2017 measurement (KRRC 2018).

Iron Gate and Copco No. 1 reservoirs are the two deepest reservoirs in the Hydroelectric Reach. These reservoirs thermally stratify each year beginning in April/May and the warmer surface and cooler bottom waters do not mix again until October/November (FERC 2007; Raymond 2008a, 2009a, 2010a; Asarian and Kann 2011). The large

[22] Thermal refugia are typically identified as areas of cool water created by inflowing tributaries, springs, seeps, upwelling hyporheic flow, and/or groundwater in an otherwise warm stream channel offering refuge habitat to cold-water fish and other cold water aquatic species (North Coast Regional Board 2011). Cold water fish utilize thermal refugia for cold water habitat when ambient river temperatures exceed their preferred temperature range.

thermal mass of the stored water in the reservoirs delays the natural warming and cooling of riverine water temperatures on a seasonal basis such that spring water temperatures in the Hydroelectric Reach are generally cooler than would be expected under natural conditions, and summer and fall water temperatures are generally warmer (Figure 3.2-3; North Coast Regional Board 2010, Asarian and Kann 2013). In the Hydroelectric Reach, maximum temperatures, generally occur in late July and regularly exceed the range of chronic effects temperature thresholds (approximately 55–68°F) for full salmonid support in California (North Coast Regional Board 2010).

The Klamath River TMDL specifies the allowable increase in daily average (and daily maximum) water temperatures is 0.9ºF (0.5ºC) for Copco No. 1 and Copco No. 2 reservoir tailraces and 0.18ºF (0.1ºC) for the Iron Gate Reservoir tailrace to alleviate the late summer/fall warming caused by Lower Klamath Project reservoirs downstream of Iron Gate Dam under existing conditions. On average the Lower Klamath Project reservoirs increase late summer/fall water temperatures below Iron Gate Dam by approximately 4ºF to 18ºF (approximately 2ºC to 10ºC). Additionally, the Klamath River TMDL specifies a portion of Copco No. 1 and Iron Gate reservoirs must provide suitable water temperature and dissolved oxygen conditions for cold water fish during the critical summer period—thus maintaining a “compliance lens” within the reservoir that can support cold water fish. In 2015, PacifiCorp installed a powerhouse intake barrier/thermal curtain in Iron Gate Reservoir under IM 11. One of the purposes of the curtain is to isolate warmer, less dense near-surface waters while withdrawing cooler, denser, and deeper waters from the reservoir for release to the Klamath River downstream (PacifiCorp 2018). The other purpose is to isolate surface waters that have high concentrations of blue-green algae (cyanobacteria) such that extensive summer and fall blooms are not readily released downstream to the Middle and Lower Klamath River (see further discussion in Potential Impact 4.2.2-4). Results from the intake barrier/thermal curtain indicate that modest 1–2°C (1.8–3.6°F) water temperature improvement is possible (PacifiCorp 2017), although data do not indicate that this measure could achieve compliance with the Thermal Plan or to meet the Klamath River TMDLs temperature requirement in the Middle Klamath River (North Coast Regional Board (2010).

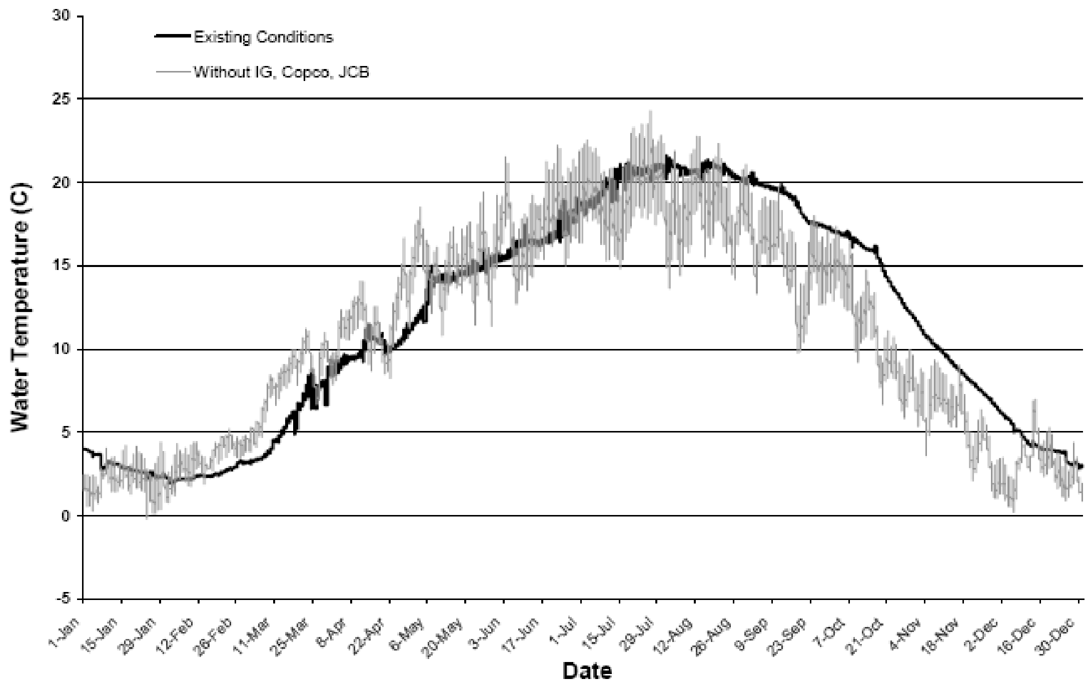

Figure 3.2-3. Simulated Hourly Water Temperature Downstream from Iron Gate Dam Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate Dams. Source: PacifiCorp 2005.

The seasonal water temperature pattern of the Hydroelectric Reach is similar in the Klamath River immediately downstream from Iron Gate Dam, where water released from Iron Gate Dam is 1.8–4.5°F cooler in the spring and approximately 4–18°F warmer in the summer and fall as compared to modeled conditions without the Lower Klamath Project dams (PacifiCorp 2004a; Dunsmoor and Huntington 2006; North Coast Regional Board 2010). In addition to this "thermal lag", immediately downstream from Iron Gate Dam water temperatures tend to exhibit relatively low variability due to the influence of the reservoir's water releases (Karuk Tribe of California 2009, 2010a, 2010b, 2011, 2012, 2013; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; Asarian and Kann 2013). Water temperature data collected since 2009 as part of KHSA Interim Measure 15 (see also Table 2.7-12) indicate that water temperature trends under the 2013 BiOp flows are consistent with those under the pre-2013 BiOp flows. For example, Asarian and Kann (2013) found that mean and maximum water temperature between 2001 and 2011 peaked each year between July and August with a maximum temperature of approximately 75°F. Although the 2013 BiOp increased minimum flows during July compared to pre-2013 BiOp flows, water temperature downstream of Iron Gate Dam peaked in July during 2013 to 2015 under 2013 BiOp flows, with a maximum temperature of approximately 75°F in mid/late July in all three years (Watercourse Engineering, Inc. 2014, 2015, 2016).

Farther downstream, the presence of the Lower Klamath Project exerts less influence on water temperatures, and the Klamath River is more influenced by solar energy, the natural heating and cooling regime of ambient air temperatures, and tributary inputs of surface water. Meteorological influences on water temperature result in increasing temperature with distance downstream from Iron Gate Dam in the summer and fall months (Basdekas and Deas 2007; Asarian and Kann 2013). For example, daily average temperatures between June and September are approximately 1.8–7.2°F higher near Seiad Valley (RM 132.7) than those just downstream from Iron Gate Dam (Karuk Tribe of California 2009, 2010a, 2010b, 2011, 2012, 2013) (see Appendix C for more detail). At the Salmon River confluence with the Klamath River (RM 66.3), the effects of the Lower Klamath Project on water temperature are significantly diminished. Downstream from the Salmon River, the influence of the Lower Klamath Project dams on water temperature in the Klamath River is not discernable from the modeled data (PacifiCorp 2005; Dunsmoor and Huntington 2006; North Coast Regional Board 2010; Perry et al. 2011; Risley et al. 2012).

Downstream from the Salmon River (RM 66), summer water temperatures begin to decrease slightly with distance as coastal weather influences (i.e., fog and lower air temperatures) decrease longitudinal warming (Scheiff and Zedonis 2011) and cool water tributary inputs increase the overall flow volume in the Klamath River (Asarian and Kann 2013). In general, however, water temperatures in this reach still regularly exceed salmonid thermal preferences (less than 68ºF) during summer months. Asarian and Kann (2013) reported that the average daily maximum water temperature[23] between 2001 and 2011 was 73.4ºF or higher between July through August from the Salmon River (RM 66) to Turwar Creek (RM 5.6). Daily maximum summer water temperatures have been measured at values greater than 78.8°F just upstream of the confluence with the Trinity River (Weitchpec [RM 43.6]), decreasing to 76.1°F near Turwar Creek (RM 5.6) (YTEP 2005, Sinnott 2010a). Maximum temperatures in the Klamath River downstream from Iron Gate Dam to the Klamath River Estuary regularly exceed the range of chronic (sublethal) effects temperature thresholds[24] (55.4–68°F) for full salmonid support in California (North Coast Regional Board 2010; Sinnott 2010a, 2011a, 2012a; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; Hanington 2013; Hanington and Ellien 2013) (see Appendix C for more detail).

Water temperatures in the Klamath River Estuary are linked to temperatures and flows entering the estuary, salinity of the estuary and resulting density stratification, and the timing and duration of sand berm formation across the estuary mouth. When the estuary mouth is open, denser salt water from the ocean sinks below the lighter fresh river water, resulting in a salt wedge that moves up and down the estuary with the daily tides (Horne and Goldman 1994; Wallace 1998; Hiner 2006). The salt water wedge results in thermal stratification of the estuary with cooler, high salinity ocean waters remaining near the estuary bottom, and warmer, low salinity river water near the surface. Under low-flow summertime conditions, when the mouth can close, surface water temperatures in the estuary have been observed at 64.4–76.5°F (Wallace 1998; Hiner 2006; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Input of cool ocean water and fog along the coast minimizes extreme water temperatures much of the time (Scheiff and Zedonis 2011).

[23] The average daily maximum water temperature is calculated by determining the daily maximum water temperature for each day with at least 80 percent complete data (38 out of 48 individual 30-minute measurements present), then averaging the daily maximum water temperature for each day from 2001 to 2011.
[24] Chronic (sub-lethal) effects temperature thresholds are detailed in Appendix 4 of North Coast Regional Board (2010).

3.2.2.3 Suspended Sediments

For the purposes of the Lower Klamath Project EIR, "suspended sediment" refers to settleable suspended material in the water column. Bed materials, such as gravels and larger substrates, are discussed in Section 3.11.2.4 *Sediment Load*. Two types of suspended material are important to water quality in the Klamath River: algal-derived (organic) suspended material and mineral (inorganic) suspended material. Sources of each type of suspended material differ, as do spatial and temporal trends for each, within the Upper, Middle, and Lower Klamath river reaches.

Suspended material concentrations tend to decrease through the Hydroelectric Reach (PacifiCorp 2004b), where interception, decomposition, and retention of organic suspended materials occur in the Lower Klamath Project reservoirs. Additionally, dilution from coldwater springs below J.C. Boyle assists in decreasing organic suspended material concentrations. However, seasonal increases in organic suspended material can occur in Copco No. 1 and Iron Gate reservoirs due to large summertime phytoplankton blooms, which can adversely affect water quality beneficial uses (PacifiCorp 2004b; Raymond 2008a, 2009a, 2010a; Watercourse Engineering, Inc. 2011b, 2012, 2013, 2014, 2015, 2016) (see Appendix C, Section C.2.1 for more detail).

In the winter months, suspended material in the Hydroelectric Reach is dominated by mineral sediment loads from several tributaries that join the river in this reach (primarily Shovel Creek, Spencer Creek, Jenny Creek, Fall Creek). Inorganic suspended materials (i.e., silts, clays with diameters less than 0.063 mm) are primarily transported during high flow events and generally settle out in the Lower Klamath Project reservoirs such that water column concentrations decrease with distance downstream in this reach (see also Appendix C, Section C.2.1). Likewise, the reservoirs trap bedload or fluvial sediment (coarse sand, gravels, and larger materials with diameters greater than 0.063 mm) from the tributaries. On the scale of the entire Klamath Basin, the trapping of fine sediments and suspended materials does not appear to be a critical function of the Lower Klamath Project reservoirs with respect to the overall cumulative sediment delivery including downstream tributaries (see also Section 3.11.2.4 Sediment Load), since a relatively small percentage (3.4 percent) of total sediment supplied to the Klamath River on an annual basis originates from the Upper and Middle Klamath River (i.e., from J.C. Boyle Dam to the confluence with the Shasta River). Beneficial uses in the Hydroelectric Reach are currently not impaired due to inorganic suspended material (North Coast Regional Board 2011).

Just downstream from Iron Gate Dam (RM 193.1), inorganic suspended material concentrations are generally low. However, in the summer months, organic suspended materials can increase in the Klamath River between Iron Gate Dam and Seiad Valley (RM 132.7) due to the transport of in-reservoir algal blooms to downstream reaches of Klamath River as well as resuspension of previously settled organic materials (YTEP 2005; Sinnott 2008; Armstrong and Ward 2008; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Further downstream, near the confluence with the Scott River (RM 145.1) concentrations of organic suspended materials tend to decrease with distance as phytoplankton gradually settle out of the water column farther downstream or are diluted by tributary inputs (see Appendix C for more detail).

Inorganic suspended sediments downstream of Iron Gate are mainly contributed by major tributaries to the mainstem during winter and spring (Armstrong and Ward 2008). The three tributaries that contribute the largest amount of suspended sediment to the Klamath River are located below Iron Gate Dam and include: the Scott River (RM 145.1) (607,300 tons per year or 10 percent of the cumulative average annual delivery from the basin); Salmon River (RM 66) (320,600 tons per year or 5.5 percent of the cumulative average annual delivery from the basin) (Stillwater Sciences 2010); and, the Trinity River (3,317,300 tons per year or 57 percent of the cumulative average annual delivery from the basin) (Stillwater Sciences 2010) (see Appendix C for more detail). Additionally, steep terrain and land use activities such as timber harvest and road construction near the Klamath River and its tributaries result in high sediment loads during high-flow periods.

3.2.2.4 Nutrients

Levels of nutrients, including nitrogen and phosphorus, are affected by the geology of the Klamath Basin, upland productivity and land uses, and a number of physical processes affecting aquatic productivity within reservoir and riverine reaches. The two major upstream sources of nutrients to the water quality Area of Analysis are Upper Klamath Lake, which inputs nitrogen and phosphorus (Kann and Walker 1999; ODEQ 2002; PacifiCorp 2004b; Deas and Vaughn 2006; FERC 2007; Sullivan et al. 2008; Asarian et al. 2010) and the Lost River Basin (via the Klamath Straits Drain and the Lost River Diversion Channel), which inputs nutrients and organic matter (Lytle 2000; Mayer 2005; Sullivan et al. 2009; Sullivan et al. 2011; Kirk et al. 2010).

On an *annual* basis, nutrients typically decrease slightly through the Hydroelectric Reach due to settling of particulate matter and associated nutrients in Copco No. 1 and Iron Gate reservoirs, and dilution by the coldwater springs located downstream of J.C. Boyle Reservoir (Asarian et al. 2010; North Coast Regional Board 2010; Oliver et al. 2014)[25]. However, on a *seasonal* basis, total phosphorus (TP), and to a lesser degree total nitrogen (TN), can increase in the Hydroelectric Reach due to the release (export) of dissolved forms of phosphorus (ortho-phosphorus) and nitrogen (ammonium) from reservoir sediments during summer and fall when reservoir bottom waters are anoxic (Kier Associates 2006; Kann and Asarian 2007; Stillwater Sciences 2009; Asarian et al. 2010; Oliver et al. 2014) (see Appendix C for additional details). Seasonal nutrient releases occur during periods of in-reservoir phytoplankton growth, and, in the case of TP, can also result in downstream transport of bioavailable nutrients to the Lower Klamath River where they can stimulate excessive growth of periphyton (aquatic freshwater organisms attached to river bottom surfaces). Additional information on effects of the Lower Klamath Project to phytoplankton and periphyton can be found in Section 3.4 *Phytoplankton and Periphyton*.

Seasonal variations in concentrations of TN and TP occur in the Klamath River downstream of Iron Gate Dam, due to a combination of nutrient storage and release from the water column and reservoir sediments, varying water concentrations at the elevation of the penstock intakes, residence times, and possible atmospheric losses through denitrification (for TN only) (Asarian and Kann 2011). In the summer and fall,

[25] The total nitrogen (TN) and total phosphorus (TP) nutrient concentrations in the natural coldwater springs are low, at approximately 0.22 mg/L TN (almost exclusively dissolved) and 0.06–0.08 mg/L TP (mostly dissolved) (Asarian et al. 2010).

TN and TP loads from Iron Gate Reservoir dominate nutrient loading to the Lower Klamath River compared to inputs from downstream tributaries, because tributary flows are relatively low during these seasons (Armstrong and Ward 2008). Downstream from the Lower Klamath Project, TP values typically range 0.1–0.25 milligrams per liter (mg/L) in the Klamath River between Iron Gate Dam and Seiad Valley, with the highest values occurring just downstream from the dam. TN concentrations in the river downstream from Iron Gate Dam generally range from less than 0.1 to over 2.0 mg/L and are generally lower than those in upstream reaches due to reservoir retention and dilution by springs in the Hydroelectric Reach (Asarian et al. 2009) (see Appendix C for additional details). TP and TN concentrations in the Klamath River vary with flow, with the highest concentrations tending to occur during low flow years (e.g., 2001-2004) and the lowest concentrations tending to occur during high flow years (e.g., 2006, 2010, 2011) (Asarian and Kann 2013). Dissolved nitrogen (nitrate) shows substantial variability among years (Asarian and Kann 2013).

Further variations in TN occur in the Middle and Lower Klamath river reaches due to a combination of tributary dilution and in-river nutrient spiraling processes by phytoplankton and periphyton. Nutrient concentrations are generally much lower in tributaries, with the exception of TP, TN, and soluble reactive phosphorus in the Shasta River and TN and nitrate in the Scott River at the outlet of Scott Valley (Asarian and Kann 2013). In-river nutrient spiraling processes by phytoplankton and periphyton involve cycling of nutrients by uptake during growth, storage in biomass, and release during biomass decay. These nutrient spiraling processes strongly affect nitrogen concentrations in flowing rivers. Removal processes such as denitrification and/or assimilation and storage related to biomass uptake decrease dissolved nitrogen concentrations in the river (Mulholland 1996; Butcher 2008; Asarian et al. 2010; Asarian and Kann 2013). Late-seasonal recycling of nutrients downstream occurs as active phytoplankton and periphyton growth wanes and may result in more bioavailable nutrients in the river. Ratios of nitrogen to phosphorus (TN:TP) measured in the Klamath River downstream from Iron Gate Dam suggest the potential for nitrogen-limitation of primary productivity[26] (i.e., phytoplankton and/or periphyton growth) with some periods of co-limitation by both nitrogen and phosphorus. However, concentrations of both nutrients are high enough that other factors (i.e., light, water velocity, or available substrate) may be more limiting to phytoplankton and periphyton growth than nutrients are, particularly in the vicinity of Iron Gate Dam (FERC 2007; HVTEPA 2008; Asarian et al. 2010) (see Appendix C and Section 3.4 *Phytoplankton and Periphyton* for additional details).

Downstream from the confluence with the Salmon River, nutrient concentrations continue to decrease in the Klamath River due to tributary dilution and nutrient retention. Contemporary data (2001–2015) indicate that TP concentrations in this portion of the river are generally 0.05–0.1 mg/L with peak values occurring in September and October. Contemporary data indicate that, on a seasonal basis, TN increases from May through November with peak concentrations (greater than 0.5 mg/L) typically observed between August and October (YTEP 2004a, 2005; Sinnott 2008, 2009a, 2009b, 2010b, 2011b, 2012b; Asarian et al. 2010; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; Asarian and Kann 2013; HVTEPA 2013; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014; Oliver et al.

[26] Primary productivity is the synthesis of organic compounds by organisms through either photosynthesis or chemosynthesis.

2014). Under these existing conditions, both TP and TN are at or above the Hoopa Valley Tribe numeric criterion of 0.2 mg/L TN and 0.035 mg/L TP (HVTEPA 2008).

Nutrient levels in the Klamath River Estuary experience inter-annual and seasonal variability. Measured levels of TP in the estuary are typically below 0.1 mg/L during summer and fall (June–October) and TN levels are consistently below 0.7 mg/L (June–October) (Sinnott 2008, 2009a, 2009b, 2010b, 2011b, 2012b; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014). While the Basin Plan water quality objective for biostimulatory substances is narrative rather than numeric (North Coast Regional Board 2011), as with upstream reaches, measured nutrient levels in the Klamath River Estuary may, at times, promote algal growth at levels that cause nuisance effects or adversely affect beneficial uses.

3.2.2.5 Dissolved Oxygen

Dissolved oxygen is the amount of oxygen gas dissolved in water. Oxygen enters water by direct incorporation from the atmosphere, through rapid mixing of water with air (e.g., turbulent mixing in fast flowing stream reaches), or as a waste product of photosynthesis by aquatic organisms. Water temperature and the volume of moving water can influence dissolved oxygen concentrations in water. Dissolved oxygen concentrations in the Klamath River depend on several factors, including water temperature (colder water absorbs more oxygen), water depth and volume, stream velocity (as related to mixing and re-aeration), atmospheric pressure, salinity, and the activity of organisms that depend upon dissolved oxygen for respiration. This last factor (respiratory consumption) is strongly influenced by the availability of nitrogen and phosphorus for supporting algal and aquatic plant growth.

During summer, the Lower Klamath Project reservoirs' surface waters exhibit varying levels of dissolved oxygen mainly driven by blue-green algae blooms in the reservoirs. During daylight hours, blue-green algae produce dissolved oxygen (through photosynthesis), resulting in super-saturation of dissolved oxygen. During nighttime hours, blue-green algae consume dissolved oxygen (through respiration) contributing to dissolved oxygen levels that can be below Basin Plan objectives.

The relatively long and shallow J.C. Boyle Reservoir (in Oregon) does not thermally stratify (see also Section 3.2.2.2 *Water Temperature*). While reaeration in the steep gradient of the Upper Klamath River between Keno Dam and J.C. Boyle Reservoir can increase dissolved oxygen in the Klamath River to near saturation levels, high biological oxygen demand in water entering J.C. Boyle during summer months can still reduce dissolved oxygen levels as the water slows in the relatively low gradient of the reservoir (Raymond 2008a, 2009a, 2010a). While J.C. Boyle Reservoir does not thermally stratify, there are still large summertime variations in dissolved oxygen with depth observed in J.C. Boyle Reservoir that result in bottom waters in the reservoir having lower dissolved oxygen concentrations than surface waters (Raymond 2009a, 2010a; see Appendix C, Figure C-29 for more detail). This variation can affect dissolved oxygen concentrations further downstream in the California portion of the Hydroelectric Reach.

Copco No. 1 and Iron Gate reservoirs thermally stratify beginning in April/May and do not mix again until October/November (FERC 2007). During summer months, dissolved oxygen in Copco No. 1 and Iron Gate in the layer of water at the surface (epilimnion) is generally at, or in some cases above, saturation, while levels in hypolimnetic waters (the layer at the bottom) reach minimum values near 0 mg/L by July (see Appendix C for more detail). While minimum surface dissolved oxygen concentrations generally co-occur with maximum water temperatures in July and August, the lowest surface dissolved oxygen concentrations tend to occur in October in Iron Gate Reservoir (see Appendix C, Figure C-32) (Raymond 2009a, 2010a; Asarian and Kann 2011). The low surface dissolved oxygen levels and their occurrence later in the season at Iron Gate Reservoir is believed to be associated with seasonal algal blooms, as dead algal cells are decomposed by aerobic organisms, exhausting dissolved oxygen in reservoir bottom waters and sediments (Asarian and Kann 2013).

In addition to the biological oxygen demand of the water column, there is also a sediment oxygen demand that influences dissolved oxygen levels in the water column of lakes, reservoirs, and rivers (Doyle and Lynch 2005). Sediment oxygen demand is the rate at which dissolved oxygen is removed from the water column by the decomposition of organic matter in streambed or lake/reservoir sediments. An analysis of oxygen demand in sediment cores sampled in 2002 from Copco No. 1 and Iron Gate reservoirs indicates that sediment oxygen demand in these waterbodies ranges from 1.0 to 2.0 grams of oxygen per square meter per day (g O_2/m^2/day) (FERC 2007), which is on the high end of values measured in other California reservoirs that typically range from approximately 0.1 g O_2/m^2/day to 1.4 g O_2/m^2/day (Beutel 2003).

Based upon measurements collected in the Middle Klamath River immediately downstream from Iron Gate Dam, dissolved oxygen concentrations in this location regularly fall below 8.0 mg/L[27] and the Basin Plan minimum dissolved oxygen criteria of 85 to 90 percent saturation (depending on season and location) (Karuk Tribe of California 2001, 2002, 2003, 2007, 2009, 2010a, 2010b, 2011, 2012, 2013; Asarian and Kann 2011, 2013; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Daily fluctuations in dissolved oxygen (ranging from 1 to 3 mg/L per day) measured in the Klamath River immediately downstream from Iron Gate Dam have been attributed to daytime algal photosynthesis and nighttime bacterial respiration in the upstream reservoirs (Karuk Tribe of California 2002, 2003; YTEP 2005; North Coast Regional Board 2010; Asarian and Kann 2011, 2013). Although PacifiCorp has operated a turbine venting system since 2010 that mechanically adds oxygen to water as it is passed through the powerhouse turbines and before it is discharged to the Middle Klamath River, low dissolved oxygen saturation values continue to occur immediately downstream of the dam during late summer through fall (August through November) every year (PacifiCorp 2013, 2014, 2014, 2015, 2016, 2017, Karuk Tribe of California 2012, 2013).

Farther downstream in the mainstem Klamath River, near Seiad Valley, dissolved oxygen concentrations tend to be higher but variable, with mean daily values ranging from approximately 6.5 mg/L to supersaturated concentrations of approximately 11.5 mg/L from June through November (Karuk Tribe of California 2001, 2002, 2003, 2007, 2009, 2010a, 2010b, 2011, 2012, 2013; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). At Seiad Valley, 31 percent of dissolved oxygen continuous data showed less than 8.0 mg/L between June and October during 2001 to 2011. During this period, the dissolved oxygen concentrations were less than 90 percent saturation in 25 percent of the continuous data and less than 85 percent

[27] The Hoopa Valley Tribe surface-water quality objective for dissolved oxygen for COLD beneficial use is 8.0 mg/L (see Table 3.2-7).

saturation in 9 percent of measurements (Asarian and Kann 2013). Longitudinal variations in dissolved oxygen from Iron Gate Dam to Seiad Valley are most pronounced in the fall when dissolved oxygen concentrations are low immediately downstream of Iron Gate Dam and increase to saturation (or supersaturation) by Seiad Valley (Karuk Tribe of California 2013).

Dissolved oxygen concentrations from Orleans to Turwar in the Klamath River are also variable, with typical daily values ranging from approximately 6.5 mg/L to supersaturated concentrations of 11.5 mg/L during summer through fall (Karuk Tribe of California 2001, 2002, 2003, 2007, 2009, 2010a, 2010b, 2011, 2012, 2013; Ward and Armstrong 2010; North Coast Regional Board 2010; Asarian and Kann 2011, 2013; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Near the confluence with the Trinity River and at Turwar, diel fluctuations in dissolved oxygen concentrations were observed resulting in dissolved oxygen greater than 8.0 mg/L during part of the day, but dissolved oxygen below 8.0 mg/L for several hours on multiple consecutive days to weeks during late summer/early fall (YTEP 2005; Sinnott 2010a, 2011a, 2012a; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015; Asarian and Kann 2013; Hanington 2013; Hanington and Ellien 2013) (see Appendix C for additional details).

Dissolved oxygen concentrations in the Klamath River Estuary vary both temporally and spatially; concentrations in the deeper main channel of the estuary are generally greater than 6 to 7 mg/L throughout the year (Hiner 2006, YTEP 2005). Low dissolved oxygen concentrations (less than 1 to 5 mg/L) have been observed during summer months in the relatively shallow, heavily vegetated south slough (Hiner 2006, Wallace 1998). The low levels of dissolved oxygen observed in the slough are likely due to high rates of growth and subsequent decomposition of algae and macrophytes, which are not abundant elsewhere in the estuary. Data during the period of 2009−2015 in the lower Klamath River Estuary (approximately RM 0.5) indicate that dissolved oxygen usually ranges from 7 mg/L to supersaturated concentrations of approximately 11 mg/L during summer and fall, with minimum levels near 5 mg/L (Sinnott 2010a, 2011a, 2012a; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015; Hanington 2013; Hanington and Ellien 2013; Hanington and Cooper-Carouseli 2014) (see Appendix C for additional details).

3.2.2.6 pH

The pH of surface water is controlled by atmospheric carbon dioxide as well as the photosynthetic and respiratory processes of organisms in the water. pH controls the form that some chemical compounds take and mediates the chemical speciation of other compounds in the water (e.g., ammonia/ammonium, minerals, metals). In addition, pH influences the concentration of un-ionized ammonia and the ammonium ion in the water column (North Coast Regional Board 2010). The ability of a system to buffer changes in pH from natural and anthropogenic sources is measured by the total alkalinity of the water. Typical alkalinity of freshwater ranges from 20 to 200 mg/L, with levels below 100 mg/L indicating limited buffering capacity and an increased susceptibility to changes in pH. Levels below 10 mg/L indicate that the system is poorly buffered and very susceptible to changes in pH (Stillwater Sciences 2009).

The Klamath River is a weakly buffered system (i.e., has typically low alkalinity less than 100 mg/L as calcium carbonate [$CaCO_3$]; PacifiCorp [2004a], Karuk Tribe of California

[2010a]), so it is susceptible to photosynthesis-driven daily and seasonal swings in pH. In the Hydroelectric Reach, pH varies with both depth in the reservoirs and season, as changes in rates of photosynthesis and respiration alter pH of the water. Vertical profile measurements of pH in Iron Gate and Copco No. 1 reservoirs between March and November 2000−2005 and June through November 2007 indicate that pH decreases with depth in both reservoirs (Figure 3.2-4; see Appendix C for additional details). The vertical distribution of pH values in both Lower Klamath Project reservoirs is attributed to photosynthesis of floating phytoplankton in surface waters (which increases pH) and respiration in bottom waters (which decreases pH) (Raymond 2008a; Asarian and Kann 2011). The dissolved oxygen vertical profiles in the Lower Klamath Project reservoirs further supports the role of phytoplankton in influencing pH with supersaturated dissolved oxygen concentrations in surface waters from photosynthesis and low dissolved oxygen in bottom waters from respiration (Figure 3.2-4).

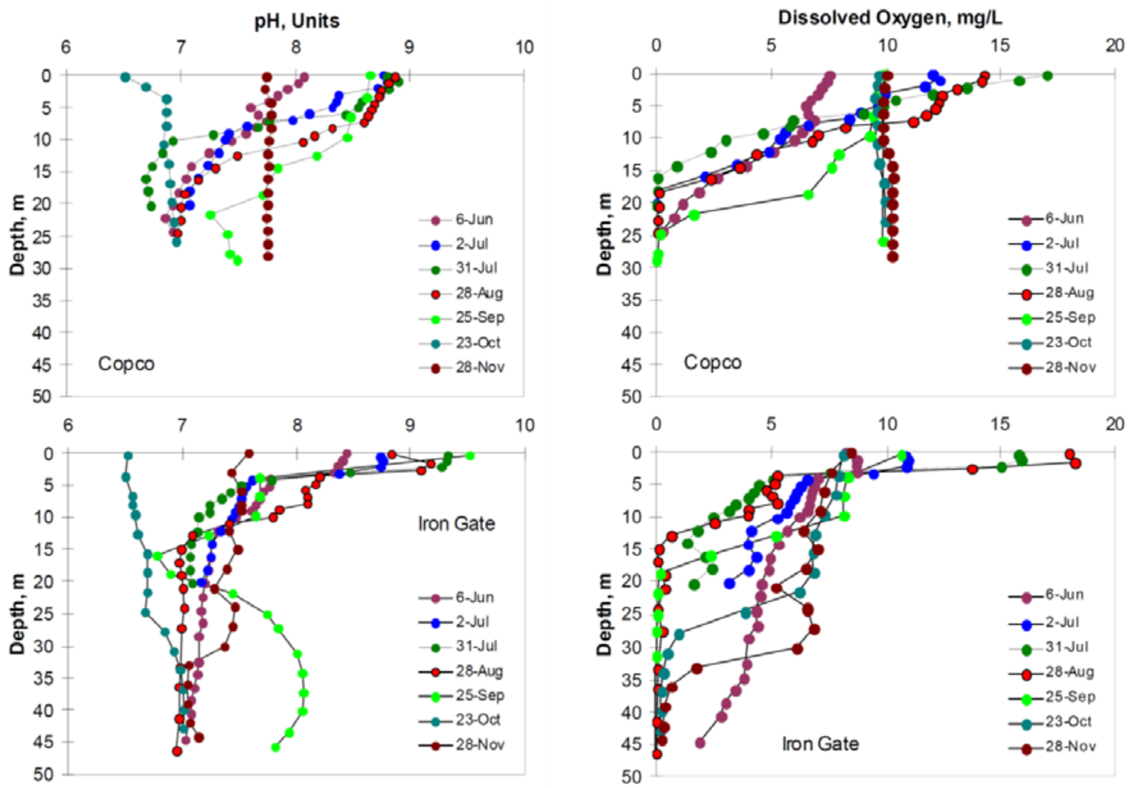

Figure 3.2-4. Vertical Profiles of pH and Dissolved Oxygen Measured During 2007 in Copco No 1. Reservoir at the Log Boom (top plot) and Iron Gate Reservoir at the Log Boom (bottom plot). Source: Adapted from Raymond 2008a.

Approximately 30 percent of samples collected in Copco No. 1 Reservoir and 5 to 20 percent of samples[28] collected in Iron Gate Reservoir surface waters (here, less than

[28] PacifiCorp (2008) Table 5.2-11 specifies the number of samples with pH greater than 8.5 as 25 of 485 total samples, equating to approximately 5 percent of samples. However, the table lists the percent of samples with pH greater than 8.5 as 19.6 percent. This appears to be a typographical error that cannot be resolved with the available information in PacifiCorp (2008).

eight meters deep) exhibited pH values greater than 8.5 standard units (s.u.) (PacifiCorp 2008), which is the Basin Plan instantaneous maximum pH objective (North Coast Regional Board 2011). In contrast, pH samples collected in bottom waters (here, greater than 20 meters) of both reservoirs tend to be lower, with approximately 17 percent of samples (68 of 391) collected in Copco No. 1 Reservoir and 22 percent of samples (135 of 613) collected in Iron Gate Reservoir exhibiting pH values less than 7.0 s.u. Other studies document peak pH values (8.5 to 9.2 s.u.) near the reservoir surfaces during summer months (Raymond 2010a; Watercourse Engineering, Inc. 2012, 2013, 2014, 2015, 2016), while lower values (5.4 to 8.0 s.u.) have been documented near reservoir bottoms, without a consistent temporal trend amongst the reservoirs. Longitudinally within the Hydroelectric Reach, the lowest pH values have been recorded downstream from J.C. Boyle Reservoir (in Oregon) and the highest values in Copco No. 1 and Iron Gate reservoirs (Raymond 2008a, 2009a, 2010a).

In the Middle Klamath River, there are seasonally high pH values , with the highest pH values generally occurring during late-summer and early-fall months. Daily cycles in pH also occur in these reaches, with pH usually peaking during later afternoon or early evening following the period of maximum photosynthesis (North Coast Regional Board 2010, Asarian and Kann 2013). The daily range of pH (i.e., daily maximum pH minus daily minimum pH) generally peaks between late July and early September, corresponding to daily cycles of photosynthesis and respiration, which also peak between late July and early September (Asarian and Kann 2013). The Basin Plan instantaneous maximum pH objective of 8.5 s.u. is regularly exceeded in the Middle and Lower Klamath River (FISHPRO 2000; Karuk Tribe of California 2002, 2003; YTEP 2005; FERC 2007; USFWS 2008; North Coast Regional Board 2010, 2011; Asarian and Kann 2013; Watercourse Engineering, Inc. 2012, 2013, 2014, 2015, 2016) (see Appendix C for more detail). The most extreme pH exceedances typically occur from Iron Gate Dam to approximately Seiad Valley, with pH values generally decreasing with distance downstream (FERC 2007; Karuk Tribe of California 2007, 2009, 2010a, 2010b, 2011, 2012, 2013; Asarian and Kann 2013) (see Appendix C for more detail). Analysis of data from 2001 to 2011 indicates that for June through October, 35 percent of pH measurements exceeded 8.5 s.u. between Iron Gate Dam and the confluence with the Shasta River, and 11 percent of pH measurements exceeded 8.5. s.u. at Orleans. pH greater than 9.0 s.u. was most frequently recorded at Iron Gate Dam (nine percent for September) and was rare (less than 0.1 percent) at mainstem locations below Seiad Valley (Asarian and Kann 2013).

During the summer months, pH values also are elevated in the Lower Klamath River from the confluence with the Trinity River downstream to approximately Turwar Creek (FISHPRO 2000; Karuk Tribe of California 2002, 2003, 2007, 2009, 2010a, 2010b, 2011, 2012, 2013; YTEP 2005; USFWS 2008; North Coast Regional Board 2010, 2011; Sinnott 2010a, 2011a, 2012a; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; Asarian and Kann 2013) (see Appendix C for more detail). In the Klamath River Estuary, pH ranges between approximately 6.9 and 9.0 s.u. with peak values also occurring during the summer months, though values below 6.9 s.u. have occasionally been measured (YTEP 2005; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Daily variations in pH are typically on the order of 0.5 s.u., and fluctuations tend to be somewhat larger in the late summer and early fall. When large daily fluctuations are observed, they are likely caused by algal blooms that are transported into the estuary (YTEP 2005).

3.2.2.7 Chlorophyll-*a* and Algal Toxins

As primary producers, phytoplankton and periphyton are critical components of river and lake ecosystems (see also Section 3.4 *Phytoplankton and Periphyton*). Their presence and abundance affect food web dynamics as well as physical water quality parameters (e.g., dissolved oxygen, pH, turbidity, and nutrients). Physical water quality parameters are affected by phytoplankton and periphyton through rates of photosynthesis, respiration, and decay of dead phytoplankton and periphyton cells (Horne and Goldman 1994). Phytoplankton and periphyton species in the water quality Area of Analysis include a number of different species that may have very different effects on water quality and water chemistry. With respect to phytoplankton, a 2007 field study from Upper Klamath Lake to the Klamath River at Turwar found that the major groups present include diatoms (70 percent of total biovolume), cyanobacteria [blue-green algae] (28 percent of total biovolume), and green algae (1 percent of total biovolume) (Raymond 2008b). Diatoms (i.e., unicellular, photosynthetic microalgae) typically dominate in spring then decrease due to zooplankton[29] grazing and the onset of water column stratification, which results in the diatoms settling out of the water column below the lake or reservoir surface layer (epilimnion). Cyanobacteria, also referred to as "blue-green algae," are photosynthetic bacteria and can often be a nuisance aquatic species, occurring as large seasonal blooms that alter surrounding water quality. Blue-green algae dominance increases during late summer and early fall because their ability to control their buoyancy which enables blue-green algae to remain near the surface during lake or reservoir stratification, thereby obtaining light for photosynthesis better than diatoms (Raymond 2008b, 2009b, 2010b; Asarian and Kann 2011; McDonald and Lehman 2013; Visser et al. 2016). Dense blooms of blue-green algae that can remain at the water surface also reduce the light available for photosynthesis and growth of other phytoplankton species, like diatoms and green algae, that cannot control their buoyancy (Miller et al. 2010).

Some blue-green algae species produce algal toxins, which are also referred to as cyanotoxins (e.g., cyclic peptide toxins such as microcystin that act on the liver, alkaloid toxins such as anatoxin-a and saxitoxin that act on the nervous system). Cyanotoxins can cause irritation, sickness, or, in extreme cases, death to exposed organisms, including humans (WHO 1999). Incidence of visual disturbance, nausea, vomiting, muscle weakness, and acute liver failure have been reported in humans exposed to algal toxins (OEHHA 2012). For example, four hours of recreational water exposure to 48.6 micrograms per liter (ug/L) of microcystin (one of the more common algal toxins found in Iron Gate and Copco reservoirs) is documented to cause abdominal pain, headache, sore throat, vomiting, nausea, dry cough, diarrhea, blistering around the mouth, and pneumonia (USEPA 2015). The California Cyanobacteria and Harmful Algal Bloom (CCHAB) Network, a multi-agency workgroup formerly called the Statewide Blue-Green Algae Working Group, has developed guidance for responding to harmful algal blooms (HABs), cyanotoxin (algal toxin) threshold levels for protection of human health, and cyanotoxin posting requirements for recreational waters (State Water Board et al. 2010, updated 2016). Species present in the Klamath River capable of producing microcystin include *Microcystis aeruginosa* and *Anabaena flos-aquae*[30], while species

[29] Heterotrophic plankton that prey on diatoms

[30] While *Anabaena flos-aquae* are capable of producing microcystin (Lopez et al. 2008), it is widely assumed that detected concentrations of microcystin are due to *Microcystis aeruginosa* rather than *Anabaena flos-aquae* due to the lower abundance of *Anabaena flos-aquae* compared

present in the Klamath River in the genus *Anabaena* can produce anatoxin-a and saxitoxin. More complete listings of specific toxins produced by genera of blue-green algae worldwide are provided in Lopez et al. (2008) and ODEQ (2011).

For microcystin specifically, thresholds in drinking water or recreational waters for the protection of human health have been developed primarily using the results of animal studies (USEPA 2015). The State Water Board, California Department of Public Health (CDPH), and California Environmental Protection Agency's (CalEPA) Office of Environmental Health and Hazard Assessment (OEHHA) "Caution Action" posting threshold for the protection of human health in recreational waters is 0.8 micrograms per liter (ug/L) of microcystin (State Water Board et al. 2010, updated 2016).

Additional discussion of algal species, including algae suspended in the water column (phytoplankton) and algae attached to bottom sediments or channel substrate (periphyton), is provided in Section 3.4 *Phytoplankton and Periphyton*.

Chlorophyll-*a*, a pigment produced by photosynthetic organisms, is often used as a surrogate measure of algal biomass. Historically, seasonal algal blooms and elevated chlorophyll-*a* concentrations have been observed in the Hydroelectric Reach, including a 1975 survey in Iron Gate Reservoir documenting algal blooms in March, July, and October, including diatoms and blue green algae (USEPA 1978). More contemporary data indicate that chlorophyll-*a* levels in Copco No. 1 and Iron Gate reservoirs can be two to ten times greater than those in the mainstem Klamath River (Flint et al. 2005; Kann and Corum 2009; North Coast Regional Board 2010; Asarian and Kann 2011; Watercourse Engineering, Inc. 2016) (Figure 3.2-25; see Appendix C for more detail).

to *Microcystis aeruginosa*. The relative proportion of microcystin contributions from *Anabaena flos-aquae* versus *Microcystis aeruginosa* has not been documented for the Klamath Basin.

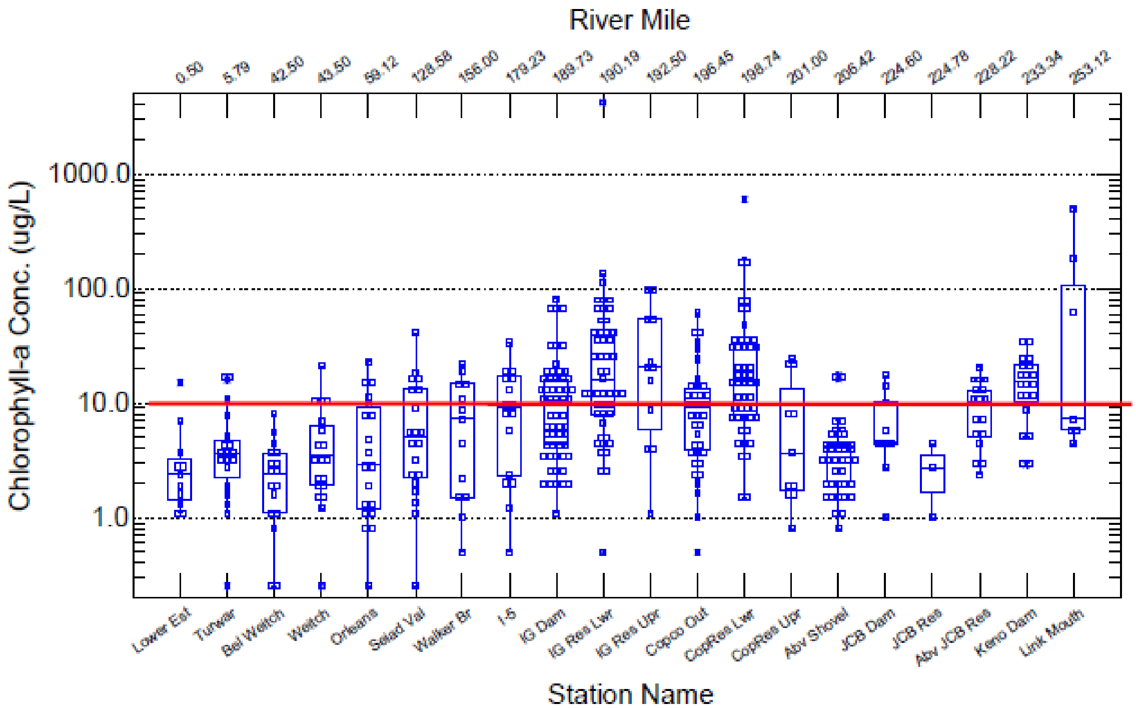

Figure 3.2-5. Longitudinal Analysis of Summer (May through September) Chlorophyll-*a* Concentrations from 2005–2007 Along the Klamath River. Note the Logarithmic Scale. Data from the Yurok Tribe, Karuk Tribe, North Coast Regional Water Quality Control Board, and PacifiCorp. Source: North Coast Regional Board 2010.

Summer and early fall chlorophyll-*a* measurements for the period 2005−2010 show higher concentrations in Copco No. 1 and Iron Gate reservoirs compared to the Hydroelectric Reach upstream of Copco No. 1, between the reservoirs, or below Iron Gate Dam. Chlorophyll-*a* concentrations are generally higher at the reservoir surface and decrease with depth in the reservoir. Peak chlorophyll-*a* concentrations during algal blooms are generally higher in Copco No. 1 Reservoir than in Iron Gate Reservoir, with some exceptions (Asarian and Kann 2011). Overall, chlorophyll-*a* in the Klamath River tends to decrease downstream of Iron Gate Dam, but concentrations can occasionally remain approximately the same or increase during intense algal blooms in Iron Gate and Copco No. 1 reservoirs (Ward and Armstrong 2010; Asarian and Kann 2013; Watercourse Engineering, Inc. 2013, 2014, 2015, 2016). Chlorophyll-*a* concentrations downstream of Iron Gate Dam also exhibit seasonal variation, with concentrations increasing in summer months and decreasing in fall and winter (Asarian and Kann 2013) (see Appendix C for additional details). Chlorophyll-*a* concentrations downstream of Iron Gate Dam tend to be low during winter months (Asarian and Kann 2011). Phycocyanin, a pigment produced by blue-green algae, has been collected between May and November at some monitoring sites in the Klamath River downstream of Iron Gate Dam since 2007. At Seiad Valley (RM 132.7), phycocyanin is typically low from May through early August, increases to a peak in early September, and decreases until reaching low levels again by the end of October (Asarian and Kann 2013). Phycocyanin concentrations generally coincide with chlorophyll-a concentrations for the portion of the Klamath River at Seiad Valley.

High levels of the cyanotoxin microcystin occur during summer months in Copco No. 1 and Iron Gate reservoirs (Kann and Corum 2009; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; Otten et al. 2015). In Copco No. 1 Reservoir, peak microcystin concentrations between 2006 and 2015 exceeded the CCHAB (2010, updated 2016) 0.8 ug/L threshold for the protection of human health in recreational waters by over 10,000 times. Watercourse Engineering (2011a) found extremely high concentrations (1,000–73,000 ug/L) during summer algal blooms in both Copco No. 1 and Iron Gate reservoirs during 2009 (see Appendix C for more detail). Consistent with previous findings, public health sampling data from 2015 show microcystin peaking between 12,000 and 16,000 ug/L in Copco No. 1 Reservoir during algal blooms in the summer and microcystin peaking from 64 to 770 ug/L in Iron Gate Reservoir (Watercourse Engineering, Inc. 2016). Microcystin concentrations are generally low from J.C. Boyle Reservoir to Copco No. 1 Reservoir, higher between Copco No. 1 Reservoir and Iron Gate Reservoir, and then generally decrease with distance downstream from Iron Gate Reservoir (Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016).

Microcystin concentrations downstream of Iron Gate Dam to the Klamath River Estuary are spatially and temporally variable (see Appendix C for more detail). The longitudinal and temporal variations in microcystin concentrations from upstream of Copco No. 1 Reservoir to Turwar indicate that Iron Gate Reservoir is the principal source of *Microcystis aeruginosa* cells to the Middle and Lower Klamath River (Otten et al. 2015). The timing of peak microcystin concentrations in Iron Gate Reservoir corresponds to peak concentrations in the Klamath River downstream of Iron Gate Dam, consistent with the reservoir as the source (Otten et al. 2015).

Baseline monitoring for potential risk to public health from microcystin toxins was established in 2008. Public health monitoring within the Copco No. 1 and Iron Gate reservoirs and along the mainstem of the Klamath River is conducted collaboratively by PacifiCorp, Karuk Tribe, and Yurok Tribe. Monitoring occurs at various intervals from May through November. If river conditions exceed public health standards for toxic algae the area is posted with a health advisory sign.

Guidelines for posting health advisories have varied since 2008 and currently are provided by the State Water Board et al. (2010, updated 2016) for water in California. SWRCB posting levels are listed as Caution, Warning, and Danger at microcystin concentrations of 0.8, 6, and 20 ug/L, respectively, with toxin producing cells densities greater than 4,000 cells/mL, or "blooms, scums, or mats", resulting in posting at the Caution level.

The Karuk Tribe (Kann 2014) and Yurok Tribe (YTEP 2016) each adopted public health guidelines for recreational waters at levels equal to or more stringent than those adopted by the State Water Board. Annual results from baseline monitoring programs along used to determine postings of public health advisories are compiled by Klamath Basin Monitoring Program (KBMP) and used to inform the Blue Green Algae Tracker available on the KBMP website (www.kbmp.net).

Microcystin can also bioaccumulate in aquatic biota. During July through September 2007, 85 percent of fish and mussel tissue samples collected from the Klamath River, including samples from Iron Gate and Copco No. 1 reservoirs, exhibited microcystin bioaccumulation, with the total microcystin congeners ranging from less than detection levels to 2,803 ng/g (Kann 2008a). The levels of microcystin bioaccumulation measured in 2007 exceeded the public health guidelines defined by Ibelings and Chorus (2007), indicating ingestion of the fish or mussels would potentially pose a health hazard to humans (Kann 2008a). In 2010, algal toxins were found in salmonid tissues collected from the Middle Klamath River near Happy Camp (Kann et al. 2013). In contrast, data from 2008 and 2009 did not show microcystin bioaccumulation in the tissue and liver samples from fish collected from Copco No. 1 and Iron Gate reservoirs (CH2M Hill 2009; PacifiCorp 2010). Estuarine and marine nearshore effects (e.g., sea otter deaths) from blue-green algae exposure have been reported in other California waters; however, none have been documented to date for the Klamath River Estuary or marine nearshore (Miller et al. 2010). Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project − Algal Toxins* presents a discussion of algal toxins as related to fish health.

Anatoxin-a produced by the genus *Anabaena* of blue-green algae species was detected in Iron Gate Reservoir on September 3, 2005, in testing by the California Department of Health Services (Kann 2007a; Kann 2008b). In additional, monitoring conducted for the Karuk Tribe during 2005, 2006, 2007, 2008 in Copco No. 1 or Iron Gate reservoirs found no anatoxin-a detected (Kann and Corum 2006, 2007, 2009; Kann 2007b). At Lower Klamath River monitoring sites, anatoxin-a was not detected above the reporting limit in water samples collected during 2008 and 2009 (Fetcho 2009, 2011). In recent years, anatoxin-a has been measured in the Klamath River downstream of Iron Gate Reservoir on several occasions, typically in the lower reaches including at monitoring sites near Weitchpec and Orleans (Otten 2017). While concentrations of *Anabaena flos-aquae* cells have continued to be monitored, anatoxin-a concentrations are not available for Lower Klamath Project reservoir and Klamath River sites in recent years.

3.2.2.8 Inorganic and Organic Contaminants

Water Column Contaminants

Data collected under the California Surface Water Ambient Monitoring Program (SWAMP) for the period 2001−2005 indicate that at eight monitoring sites from the Oregon-California state line to Turwar, the majority of inorganic constituents (i.e., arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, and zinc) detected in the Hydroelectric Reach, Middle Klamath River, and Lower Klamath River were in compliance with water quality objectives. Aluminum concentrations ranged from 50.7 to 99.2 ug/L, so all samples were less than California primary drinking water standards[31] (1,000 ug/L), but some samples were slightly elevated above USEPA freshwater aquatic life standards (87 ug/L) along with USEPA and California secondary drinking water standards[32] (50 ug/L) (North Coast Regional Board 2008). Grab samples were analyzed for 100 pesticides, pesticide constituents, isomers, or metabolites; 50 polychlorinated biphenyl (PCB) congeners; and six phenolic compounds. Results indicated no PCBs and only occasional detections of pesticides (North Coast Regional Board 2008) (see Appendix C for more detail). The results of water quality studies during 2002 and 2003 at four USGS gage stations downstream of Iron Gate Dam

[31] Primary drinking water standards are limits for inorganic and organic contaminants to protect public health.
[32] Secondary drinking water standards are guidelines to prevent aesthetic effects (e.g., taste, odor, or color) or cosmetic effects (skin or tooth discoloration).

indicate that, with the exception of nickel, magnesium, and calcium, the concentration of trace elements decreased as water flowed downstream, most likely because of binding to other particles and settling out of the water column (Flint et al. 2005) (see Appendix C for more detail).

Sediment Contaminants

To investigate the potential for toxicity of sediments in J.C. Boyle, Copco No. 1, and Iron Gate reservoirs, Shannon & Wilson, Inc. (2006) collected 25 sediment cores in J.C. Boyle, Copco No. 1, and Iron Gate reservoirs and analyzed them for a suite of potential contaminants. The sediment cores were collected as part of a larger study sponsored by the California State Coastal Conservancy (GEC 2006). The locations of the sediment cores were distributed throughout each reservoir, including locations on the historical Klamath River channel (on-thalweg) and surrounding submerged terraces or near tributary mouths (off-thalweg) along the edge of the historical Klamath River. Four locations (4 on-thalweg, 0 off-thalweg) were sampled in J.C. Boyle Reservoir, with maximum core depths ranging from 0.3 feet at the upstream end of the reservoir to 13.2 feet near the dam. Twelve locations (7 on-thalweg, 5 off-thalweg) were sampled in Copco No. 1 Reservoir with maximum core depths ranging from 1.5 feet at the upstream end of the reservoir to 12.1 feet near the middle of the reservoir. Nine locations (5 on-thalweg, 4 off-thalweg) were sampled in Iron Gate Reservoir with maximum core depths ranging from 0.7 feet at the upstream end of the reservoir to 7.8 feet within the Slide Creek/Camp Creek arm of the reservoir. During sediment core drilling, the sediments were evaluated to distinguish recent reservoir-deposited sediment from pre-reservoir sediment, with drilling logs noting the depth of different sediment horizons. Shannon & Wilson, Inc. (2006) used a composite sampling[33] technique to represent field conditions for reservoir sediment deposits. Interval composite/depth interval sediment samples were generated from the sediment cores, including both the reservoir-deposited and pre-reservoir sediments, with the number of interval samples depending on the total depth of the sediment core. The sediment samples were analyzed for contaminants, including acid volatile sulfides, metals, pesticides, chlorinated acid herbicides, PCBs, volatile organic compounds (VOCs), semi-volatile organic compounds (SVOCs), cyanide, and dioxins. No herbicides or PCBs were found above U.S. Army Corps of Engineers (USACE) Puget Sound Dredged Disposal Analysis Program (PSDDA) screening levels and only one sample exceeded applicable PSDDA screening levels for VOCs ethyl benzenes and total xylenes (Shannon & Wilson, Inc. 2006). While cyanide was detected in multiple sediment cores, it was not found in the bioavailable toxic free cyanide form (HCN or CN^-).

Dioxin, a known carcinogen, was also measured in the Shannon & Wilson, Inc. (2006) study. Long-term exposure to dioxin in humans is linked to impairment of the immune system, the developing nervous system, the endocrine system, and reproductive functions. In the 2006 J.C. Boyle, Copco No. 1 and Iron Gate reservoir samples, measured levels were 2.48–4.83 pg/g (picograms per gram or parts per trillion [ppt] expressed as Toxic Equivalent Concentrations) and did not exceed USACE (1,000 pg/g), International Joint Commission for Great Lakes Science Advisory Board (10 pg/g), PSDDA (15 pg/g), or Washington State Department of Ecology (8.8 pg/g) (Shannon & Wilson, Inc. 2006, Dillon 2008, USEPA 2010) and the measured dioxin concentrations

[33] Composite samples are created by combining and thoroughly mixing individual samples from different locations and treating the combined sample as a single sample for analysis. Composite samples are a standard method for determining average conditions.

were within the estimated background dioxin concentrations (2–5 ppt) for non-source-impacted sediments throughout the U.S. and specifically in the western U.S. (USEPA 2010). However, the range of measured dioxin concentrations was slightly above the minimum for the U.S. Environmental Protection Agency fish and wildlife guidelines (2.5–210 pg/g) screening levels for human health and ecological receptors (Shannon & Wilson, Inc. 2006, Dillon 2008, USEPA 2010) (see Appendix C for more detail).

As part of the Klamath Dam Removal Secretarial Determination studies, a sediment evaluation was undertaken during 2009–2011 to evaluate potential environmental and human health impacts of the downstream release of sediment deposits currently stored behind the Lower Klamath Project dams[34]. Sediment cores were collected during 2009–2010 at 37[35] sites on the historical Klamath River channel (on-thalweg) and surrounding submerged terraces or near tributary mouths along the edge of the historical Klamath River (off-thalweg), distributed throughout J.C. Boyle Reservoir (Figure 2.6-4), Copco No. 1 Reservoir (Figure 2.6-5), Iron Gate Reservoir (Figure 2.6-6), and the Klamath River Estuary (Figure 3.2-6) (USBR 2010, 2011). Twelve sites (7 on-thalweg, 5 off-thalweg) were sampled in J.C. Boyle Reservoir with maximum core depths ranging from 0.3 feet near the middle of the reservoir to 18.7 feet near the dam. Twelve sites (7 on-thalweg, 5 off-thalweg) were sampled in Copco No. 1 Reservoir with maximum core depths ranging from 1.2 feet on an off-thalweg site downstream of the Beaver Creek arm of the reservoir to 9.7 feet on an off-thalweg location upstream of the Beaver Creek arm of the reservoir. Thirteen sites (8 on-thalweg, 5 off-thalweg) were sampled in Iron Gate Reservoir with maximum core depths ranging from 0.5 feet at the upstream end of the reservoir to 7.7 feet within the Jenny Creek arm of the reservoir. At each site, cores were inspected by on-site geologists to verify that the reservoir-deposited/pre-reservoir sediment contact had been reached for each core. Sediment cores were used to either create whole core composite[33] sediment samples or interval composite/depth interval composite sediment samples for laboratory analysis of potential contaminants with samples representing both the reservoir-deposited and pre-reservoir sediments. Area composite samples were also generated from sediment cores for the Klamath River Estuary. A total of 501 analytes were quantified in the sediment samples, including metals, poly-cyclic aromatic hydrocarbons (PAHs), PCBs, pesticides/herbicides, phthalates, VOCs, SVOCs, dioxins, furans, and polybrominated diphenyl ethers (PBDEs) (i.e., flame retardants). The chemical composition of sediment and elutriate[36] sediment samples were analyzed, and bioassays were conducted on the sediment and elutriate sediment samples using fish and invertebrate national benchmark toxicity species (see below for discussion of the bioaccumulation component of this study).

[34] There are currently 13.1 million cubic yards of sediment deposits stored within J.C. Boyle, Copco No. 1 and 2, and Iron Gate reservoirs (Table 2.7-7). Prior estimates of the sediment deposits were 14.5 million cubic yards (Eilers and Gubala 2003) and 20.4 million cubic yards (GEC 2006).

[35] Of the 37 sampling sites, two sites in J.C. Boyle, two in Copco No. 1, and three in Iron Gate Reservoir were analyzed for dioxins/furans, PCBs, and PBDEs.

[36] Elutriate sediment samples were created from reservoir composite sediment samples mixed with reservoir water (e.g., one part sediment to four parts water). In general, elutriate tests are a standard approach that analyzes the chemical composition of the overlying water of the elutriate sediment sample in order to estimate potential chemical concentrations in the water between the grains of sediment (pore water). Standard elutriate tests do not reflect the full dilution of re-suspended sediments that would occur during dam removal.

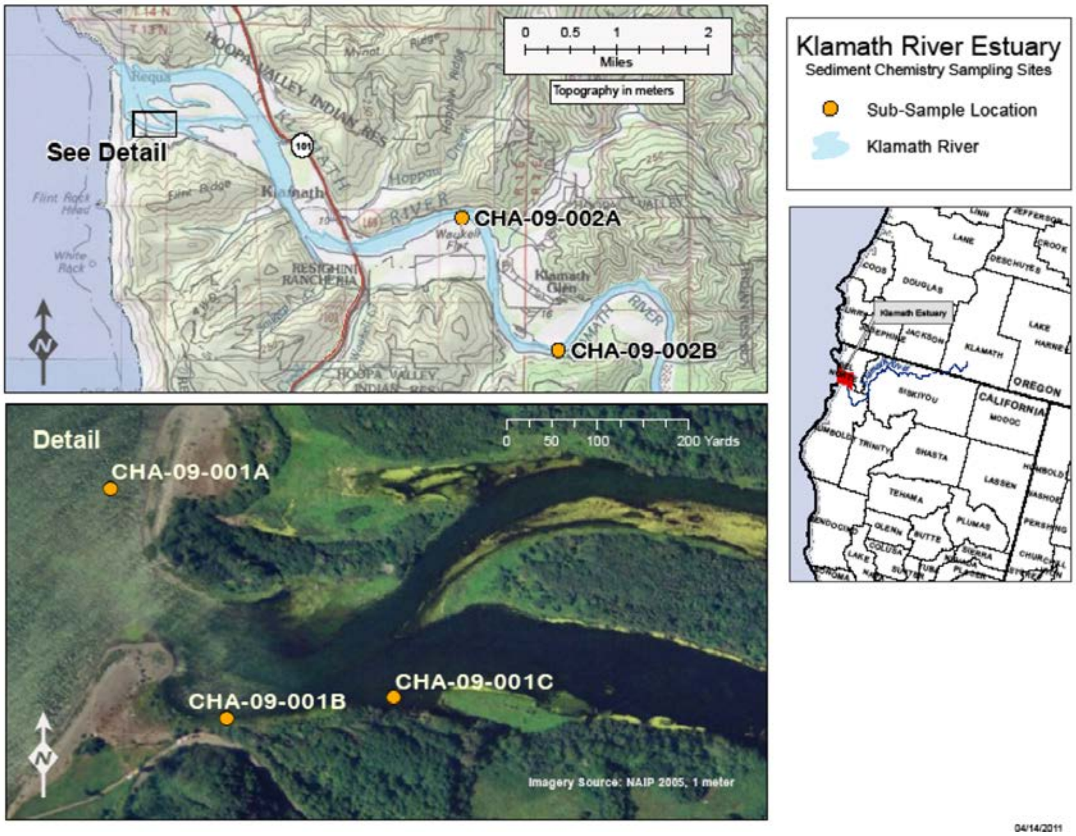

Figure 3.2-6. Klamath River Estuary Sediment Sampling Site Locations. Source: USBR 2011.

A relatively small number of chemicals of potential concern (COPCs) were identified in Lower Klamath Project reservoir sediment samples. Nickel, iron, and 2,3,4,7,8-pentachlordibenzofuran (PECDF) were detected in sediment in all three Lower Klamath Project reservoirs, while 4,4'-dichlorodiphenyltrichloroethane (DDT), 4,4'-dichlorodiphenyldichloroethane (DDD), 4,4'-dichlorodiphenyldichloroethylene (DDE), dieldrin, and 2,3,7,8-tetrachlorodibenzodioxin (TCDD) were detected only in J.C. Boyle sediments. No consistent pattern of elevated chemical composition was observed across discrete sampling locations within a reservoir, but sediment in J.C. Boyle Reservoir does have marginally higher iron concentrations and more detected COPCs in sediment when compared to Copco No. 1 and Iron Gate reservoirs and the Klamath River Estuary. Also, J.C. Boyle Reservoir exhibited more COPCs based on comparison to CalEPA, National Oceanic and Atmospheric Administration (NOAA), U.S. Fish and Wildlife Service (USFWS), USEPA, and ODEQ freshwater ecological and human health screening levels (SLs). However, in the case of J.C. Boyle Reservoir, and in other instances where elevated concentrations of chemicals in sediment were found, the degree of exceedance based on comparisons of measured detected chemical concentrations to SLs was small, and in several cases (i.e., arsenic, mercury, 2,3,7, 8-TCDD, total PCBs) may reflect regional background conditions (see Appendix C, Section C.7.1.1 for more detail). Toxicity tests generally indicated low potential for sediment toxicity to benchmark benthic indicator species; the exception to this occurred in a single sample from J.C. Boyle Reservoir, where survival of the benthic amphipod *Hyalella azteca* indicated a moderate potential for sediment toxicity.

Lastly, analysis of the 2009–2010 USBR collected sediment core results (USBR 2010, 2011) from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs and the Klamath River Estuary indicate that total chromium and total nickel concentrations are higher in estuary sediments than in Lower Klamath Project reservoir sediments, but total arsenic, total copper, and total lead concentrations are higher in reservoir sediments than estuary sediments (Eagles-Smith and Johnson 2012). Total arsenic concentrations in the reservoir sediments samples range from 4.3 milligrams per kilogram, dry weight (mg/kg) to 15 mg/kg in J.C. Boyle Reservoir, 6.3 mg/kg to 13 mg/kg in Copco No. 1 Reservoir, and 7.4 mg/kg to 10 mg/kg in Iron Gate Reservoir, which exceed USEPA total carcinogen residential screening levels (0.39 mg/kg) and CalEPA California Human Health residential (0.07 mg/kg) and commercial (0.24 mg/kg) screening levels. Peak total copper concentrations in Lower Klamath Project reservoir sediments (9.8−38 mg/kg) are greater than total copper concentrations in Klamath River Estuary sediments (19−26 mg/kg) (Eagles-Smith and Johnson 2012). Total copper concentrations in Lower Klamath Project reservoir and Klamath River Estuary sediments only exceeded lower NOAA Screen Quick References Table (SQuiRT) freshwater and marine screening levels for copper in sediment (**freshwater**: Threshold Effect Concentrations [31.6 mg/kg], Threshold Effects Level [37.3 mg/kg], Lowest Effect Level [16 mg/kg]; **marine**: T20 [chemical concentration corresponding to 20 percent probability of observing toxicity] [32 mg/kg], Threshold Effects Level [18.7 mg/kg], Effects Range-Low [34 mg/kg]) with no measured total copper concentrations in reservoir or estuary sediments above freshwater or marine probable effects concentrations (freshwater: Probable Effect Concentrations [149 mg/kg], Probable Effect Level [197 mg/kg]; marine: T50 [chemical concentration corresponding to 50 percent probability of observing toxicity] [94 mg/kg], Probable Effect Level [108 mg/kg]). Total lead concentrations in reservoir sediments range from 2.8 mg/kg to 25 mg/kg in J.C. Boyle Reservoir, 6.4 mg/kg to 10 mg/kg in Copco No. 1 Reservoir, and 5.1 mg/kg to 11 mg/kg in Iron Gate Reservoir, which are consistently below USEPA total non-carcinogen residential screening levels (400 mg/kg) and CalEPA California Human Health residential (80 mg/kg) and commercial (320 mg/kg) screening levels (CDM 2011).

Note that while total metal concentrations were measured in the existing sediment cores, metals are typically bound to fine sediments and exhibit limited bioavailability or aquatic toxicity. The amount of bioavailable metals released by sediments may vary significantly depending on the sediment (surface area, availability of sorption sites, organic material, and clay content) and water properties (temperature, dissolved organic compounds, suspended particles, pH, various inorganic cations and anions like those composing hardness and alkalinity) (USEPA 2007).

Contaminants in Aquatic Biota

Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project−Algal Toxins* presents a discussion of algal toxins (i.e., microcystin) in fish tissue. Assessments of other contaminants in fish tissue for the Hydroelectric Reach have been undertaken by SWAMP and PacifiCorp. SWAMP data include sport fish tissue samples collected during 2007 and 2008 to evaluate accumulated contaminants in nearly 300 lakes throughout California. Sport fish were sampled to provide information on potential human exposure to selected contaminants and to represent the higher aquatic trophic levels (i.e., the top of the aquatic food web).

In a screening-level study of potential chemical contaminants in fish tissue in J.C. Boyle, Copco No. 1, and Iron Gate reservoirs, PacifiCorp analyzed metals (i.e., arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, and zinc), organochlorine (pesticide) compounds, and PCBs in largemouth bass (*Micropterus salmoides*) and black bullhead catfish (*Ameiurus melas*) (PacifiCorp 2004c, FERC 2007). PacifiCorp reported that, in general, contaminant levels in fish tissue were below screening level values for protection of human health (USEPA 2000) and recommended guidance values for the protection of wildlife (MacDonald 1994). Exceptions to this include some tissue samples for total mercury, arsenic, total DDTs and total PCBs when compared to screening levels for wildlife and subsistence fishers (individual comparisons are shown in Appendix C for more detail). Dioxins were not tested.

Fish tissue samples also were collected in Copco No. 1 and Iron Gate reservoirs and analyzed for total mercury, selenium, and PCBs (Iron Gate Reservoir only) as part of a larger SWAMP study of contaminants in sport fish in California lakes and reservoirs (Davis et al. 2010). SWAMP data for Iron Gate and Copco No. 1 reservoirs indicate mercury tissue concentrations above the USEPA criterion of 300 nanograms per gram (ng/g) methylmercury (for consumers of noncommercial freshwater fish); and greater than OEHHA public health guideline levels advisory tissue levels (Klasing and Brodberg 2008) for consumption for 3 and 2 servings per week (70 and 150 ng/g wet weight, respectively) and the fish contaminant goal (220 ng/g wet weight). Measured selenium concentrations were 3–4 orders of magnitude lower than OEHHA thresholds of concern (2,500–15,000 ng/g wet weight) and PCB concentrations were below the lowest OEHHA threshold (i.e., fish contaminant goal of 3.6 ng/g wet weight) (Davis et al. 2010).

To supplement existing fish tissue data and provide additional lines of evidence in the Klamath Dam Removal Secretarial Determination sediment evaluation (see *Sediment Contaminants* above and Appendix C – *Section C.7.1.1*), two species of field-caught fish (perch and bullhead) were collected during late September 2010 from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs and analyzed for contaminant levels in fish tissue (CDM 2011; see Appendix C – *Section C.7.1.1* for more detail). Results indicate that multiple chemicals were present in fish tissue (e.g., arsenic, DDE/DDT, dieldrin, mercury, mirex, selenium, and total PCBs; see Appendix C for a complete list of chemicals detected) (CDM 2011). Mercury exceeded tissue-based toxicity reference values for perch in Iron Gate Reservoir and bullhead samples in all three reservoirs (CDM 2011). Toxicity reference values are not available for several chemicals detected in invertebrate and fish tissue (CDM 2011, see Appendix C – *Section C.7.1.1* for more detail). Toxicity equivalent quotients (TEQs) for dioxin, furan, and dioxin-like PCBs in reservoir and estuary sediment samples were within the range of local background values and suggest a potential to cause minor or limited adverse effects for fish exposed to reservoir sediments (CDM 2011).

Lastly, Copco No. 1 and Iron Gate reservoirs are included on the 303(d) list of impaired waterbodies for mercury based on elevated methylmercury concentrations in fish tissue for trophic level 4 fish (USEPA 2001; PacifiCorp 2004b; Davis et al. 2010; CDM 2011; State Water Board 2017). A mercury TMDL for Copco No. 1 and Iron Gate reservoirs has not been completed.

3.2.3 Significance Criteria

Significance criteria used for the evaluation of impacts on water quality are listed below. Designated beneficial uses and associated water quality objectives for the Klamath River in California are defined in the Basin Plan (North Coast Regional Board 2018), the

Hoopa Valley Tribe Water Quality Control Plan (HVTEPA 2008), and the Yurok Tribe Water Quality Control Plan for the Yurok Indian Reservation[37] (YTEP 2004) (see Table 3.2-2).

Effects on water quality are considered significant if the Proposed Project would:

- Cause an exceedance of water quality standards as identified in the above documents in the areas addressed by the relevant plans;
- Substantially exacerbate an existing exceedance of water quality standards as identified in the above documents in the areas addressed by the relevant plans;
- Cause water quality changes that would result in a failure to maintain existing beneficial uses at the levels currently supported, or result in a failure to maintain high quality waters at the highest level of water quality consistent with the maximum benefit to the people of the State, meaning:
    - The action degrades high quality waters to an extent inconsistent with recent beneficial uses or in a manner that would result in water quality below that required by an applicable water quality control plan; or
    - The action involves a discharge that either does not comply with best practicable treatment or does not employ controls that avoid nuisance or pollution and are consistent with the maximum benefit to the people of the State.
- Result in substantial adverse impacts on human health or environmental receptors.

Unless otherwise indicated in Section 3.2.3.1 *Thresholds of Significance*, for purposes of determining the significance of any potential water quality impacts, "substantial," as used in the significance criteria, means the effect on water quality and the support of beneficial uses (or human health or environmental receptors, as specified) is of considerable importance.

For the Lower Klamath Project water quality analysis, short-term is defined as the period during pre-dam removal activities, reservoir drawdown, dam removal, and associated sediment flushing events, which corresponds to pre-dam removal activities that would occur in the one to three years before dam removal, dam removal year 1, dam removal year 2, and post-dam removal year 1 (Table 2.7-1). Long-term is defined as occurring after post-dam removal year 1 (i.e., greater than three years after dam removal).

Significance criteria related to groundwater and flood hydrology (i.e., subsurface drainage, flooding, inundation) are addressed in Section 3.6 *Flood Hydrology* and/or Section 3.7 *Groundwater*.

[37] USEPA approval for treatment of the Yurok Tribe as a State for purposes of operating a water quality standard program has not yet occurred (CWA §§ 303(c)/401).

Notes:
[1] Beneficial Uses listed (existing and potential) apply to one or more Basin Plan specified hydrologic areas, sub-areas, or waterbodies within the Water Quality Area of Analysis, but they do not necessary apply all reaches within the Water Quality Area of Analysis.
[2] Basin Plan designated Beneficial Uses apply to the entire Water Quality Area of Analysis, including the territorial marine waters of the State of California.
[3] Tribal designated Beneficial Uses apply to the sections of the Water Quality Area of Analysis within the tribal boundaries.
[4] These Beneficial Uses come from the Basin Plan's incorporation of the State Water Board's 2015 Ocean Plan, which applies to the territorial marine waters of the State of California.
Key:
N/A: Not applicable
* = Proposed Beneficial Use
** = Historical Beneficial Use

Table 3.2-3. Water Bodies Included on the 303(d) List within the Water Quality Area of Analysis.[1]

Water Body/Reach	Water Temperature	Sediment	Organic Enrichment/Low Dissolved Oxygen	Nutrients	Microcystin	Mercury	Aluminum
Hydroelectric Reach of the Upper Klamath River – Oregon-California state line to the upstream end of Copco No. 1 Reservoir	X		X	X			
Hydroelectric Reach of the Upper Klamath River – upstream end of Copco No. 1 Reservoir to Iron Gate Dam (excluding Copco No.1 and No. 2 and Iron Gate Reservoir)	X		X	X	X		
Copco No. 1 Reservoir	X				X	X	
Copco No. 2 Reservoir	X				X		
Iron Gate Reservoir	X				X	X	
Middle Klamath River – Iron Gate Dam to Scott River	X	X	X	X	X		X
Middle and Lower Klamath River – Scott River to Trinity River	X	X	X	X	X		
Lower Klamath River – Trinity River to Mouth	X	X	X	X			

1 While there are additional water quality impaired waterbodies in the Klamath Basin, the waterbodies listed in this table are the ones that are directly relevant to the water quality analysis for the Proposed Project.

3.2.3.1 Thresholds of Significance

Thresholds of significance for this EIR are identified for water temperature, suspended sediment, nutrients, dissolved oxygen, pH, chlorophyll-*a* and algal toxins, and inorganic and organic contaminants. All of these are a water quality concern due to their potential to influence multiple designated beneficial uses and because hydroelectric project operations can affect these constituents (see Section 3.2.2.1 *Overview of Water Quality Processes in the Klamath Basin*). Table 3.2-4 through Table 3.2-10 provide the existing water quality objectives for: (1) the Basin Plan (North Coast Regional Board 2018), which incorporates the provisions of the Water Quality Control Plan for Ocean Waters of California (Ocean Plan) and the Water Quality Control Plan for Control of Temperature in the Coastal and Interstate Waters and Enclosed Bays and Estuaries of California (Thermal Plan); (2) the Hoopa Valley Tribe Water Quality Control Plan (HVTEPA 2008); and (3) the Yurok Tribe Water Quality Control Plan for the Yurok Indian Reservation[37] (YTEP 2004). The water quality objectives are interpreted in this water quality analysis to determine the applicable thresholds of significance for this EIR since there are multiple overlapping water quality objectives, quantitative objectives are not available for some water quality parameters when objectives are narrative, and there is a lack of background information available to apply objectives that are relative background conditions. Applicable numeric values used as thresholds of significance for the Lower Klamath Project analysis include water temperature, dissolved oxygen, and pH. There are multiple numeric standards for algal toxins potentially applicable for the Klamath River, so these various numeric standards are evaluated in the sub-section titled *Chlorophyll-a and Algal Toxins* (after Table 3.2-4, Table 3.2-9, and Table 3.2-10) to identify the appropriate threshold of significance for algal toxins in this EIR. Numeric and narrative water quality objectives for various inorganic and organic contaminant were combined into a broad set of thresholds of significance as described below in the sub-section titled *Inorganic and Organic* (after Table 3.2-4, Table 3.2-9, and Table 3.2-10).

Other numeric values presented in Table 3.2-4 through Table 3.2-10, including California turbidity standards, California nitrate and nitrite standards for the support of municipal beneficial uses, the Hoopa Valley Tribe criterion for chlorophyll-*a* as periphyton, and the Hoopa Valley Tribe and Yurok Tribe ammonia and nitrate standards for the support of cold freshwater habitat and municipal beneficial uses, are not used as thresholds of significance. The California surface water quality objective for turbidity could not be used as a threshold of significance for suspended sediment since it is based on a comparison to naturally occurring background levels, but there is not readily available data on turbidity in the Klamath River. The threshold of significance for suspended sediment in this EIR is discussed below in the sub-section titled *Suspended Sediments* (after Table 3.2-4, Table 3.2-9, and Table 3.2-10).

The California surface water quality objectives for nitrate (NO_3) and nitrate and nitrite (NO_3 + NO_2), along with the Hoopa Valley Tribe and Yurok Tribe nitrate water quality objective, are not appropriate thresholds of significance for nutrients in this EIR since they are based on supporting municipal beneficial uses (i.e., drinking water). These objectives are much higher than concentrations that have been measured in the Klamath Basin, such that there is no indication that the municipal beneficial use is not being met or would not be met in the future under the Proposed Project. Thus, other water quality objectives are evaluated to determine the threshold of significance for nutrients in this EIR, as discussed below in the sub-section titled *Nutrients* (after Table 3.2-4, Table 3.2-9, and Table 3.2-10).

The Hoopa Valley Tribe criterion for chlorophyll-*a* as periphyton is not an appropriate threshold of significance for chlorophyll-*a* since it is based on periphyton growth rather than phytoplankton growth; periphyton growth is assessed in detail in Section 3.4 *Phytoplankton and Periphyton*, and it is only applicable to a short reach (at approximately RM 45) of the Klamath River upstream of the Trinity River. Thus, criteria are evaluated to determine the threshold of significance for chlorophyll-a in this EIR, as discussed below in the sub-section titled *Chlorophyll-a and Algal Toxins* (after Table 3.2-4, Table 3.2-9, and Table 3.2-10).

The Hoopa Valley Tribe and Yurok Tribe have an ammonia toxicity objective based on pH and temperature (Table 3.2-7 and Table 3.2-8, respectively), but these objectives are not used as a threshold of significance for toxicity since available data suggests there are no actual ammonia toxicity events associated with the operation of the Lower Klamath Project (North Coast Regional Board 2010). Similarly, the Yurok Tribe has a nitrite water quality objective (Table 3.2-8), but available data does not suggest operation of the Lower Klamath Project influences nitrite concentrations in the Klamath River. Turbulent mixing and dissolved oxygen conditions in the Klamath River under the Proposed Project would promote the conversion of ammonia to nitrate or nitrite to nitrate and minimize the potential for ammonia or nitrite toxicity. The potential for short-term toxicity to aquatic organisms during reservoir drawdown, including consideration of ammonia toxicity, is addressed using bioassay results (see Section 3.2.4.7 *Inorganic and Organic Contaminants*).

Table 3.2-4. California Surface-Water Quality Objectives Relevant to the Proposed Project.

Parameter	Description[1]
Suspended Material	Waters shall not contain suspended material in concentrations that cause nuisance or adversely affect beneficial uses.
Settleable Material	Waters shall not contain substances in concentrations that result in deposition of material that causes nuisance or adversely affect beneficial uses.
Sediment	The suspended sediment load and suspended sediment discharge rate of surface waters shall not be altered in such a manner as to cause nuisance or adversely affect beneficial uses.
Turbidity	Turbidity shall not be increased more than 20% above naturally occurring background levels. Allowable zones of dilution within which higher percentages can be tolerated may be defined for specific discharges upon the issuance of discharge permits or waiver thereof.
Temperature	Intrastate waters (Basin Plan) • No alteration of natural receiving water temperature of intrastate waters that adversely affects beneficial uses. • At no time or place shall the temperature of any **COLD** water be increased by more than 5°F above natural receiving water temperature. • At no time or place shall the temperature of **WARM** intrastate waters be increased more than 5°F above natural receiving water temperature. Interstate waters (Thermal Plan) • Elevated temperature waste discharges into **COLD** interstate waters are prohibited. • Thermal waste discharges having a maximum temperature greater than 2.8ºC (5ºF) above natural receiving water temperature are prohibited for **WARM** interstate waters. • Elevated temperature wastes shall not cause the temperature of **WARM** interstate waters to increase by more than 5°F above natural temperature at any time or place.
Dissolved Oxygen	**WARM, MAR, Inland Saline Water Habitat (SAL), COLD, SPWN** Klamath River Mainstem Specific Water Quality Objectives based on natural receiving water temperatures (see Table 3.1a for minimum dissolved oxygen concentrations in mg/L) • From Oregon-California state line (RM 214.1) to the Scott River (RM 145.1), 90% saturation October 1-March 31 and 85% saturation April 1-September 30. • From Scott River (RM 145.1) to Hoopa Valley Tribe boundary (≈RM 45), 90% saturation year-round. • From Hoopa Valley Tribe boundary to Turwar (RM 5.6), 85% saturation June 1-August 31 and 90% saturation September 1-May 31. • For upper and middle Klamath River Estuary (RM 0-3.9), 80% saturation August 1-August 31, 85% saturation September 1-October 31 and June 1-July 31, and 90% saturation November 1-May 31. • **EST** for Lower Klamath River Estuary (RM 0), dissolved oxygen content shall not be depressed to levels adversely affecting beneficial uses as a result of controllable water quality factors.

Parameter	Description[1]
Biostimulatory Substances	Waters shall not contain biostimulatory substances in concentrations that promote aquatic growths to the extent that such growths cause nuisance or adversely affect beneficial uses.
Nitrate	**MUN** 45 mg/L as NO_3 (equivalent to 10 mg/L for nitrate as N)[2]
Nitrate + Nitrite	**MUN** 10 mg/L as N [3]
pH	The pH shall not be depressed below 6.5 units nor raised above 8.5 units, unless otherwise state below
	COLD, WARM Changes in normal ambient pH levels in fresh waters shall not exceed 0.5 units within the range specified above. **MAR, SAL** Changes in normal ambient pH levels shall not exceed 0.2 units
	The pH shall not be depressed below 7 units nor raised above 8.5 units for the Klamath River upstream of Iron Gate Dam, including Iron Gate and Copco No.1 reservoirs, the Klamath River in the Middle Klamath River Hydrologic Area downstream from Iron Gate Dam, and the Klamath River in the Lower Klamath River Hydrologic Area.
Toxicity	All waters shall be maintained free of toxic substances in concentrations that are toxic to, or that produce detrimental physiological responses in human, plant, animal, or aquatic life.
Pesticides	No individual pesticide or combination of pesticides shall be present in concentrations that adversely affect beneficial uses. There shall be no bioaccumulation of pesticide concentrations found in bottom sediments or aquatic life. Waters designated for use as domestic or municipal supply shall not contain concentrations of pesticides in excess of the limiting concentrations set forth in California Code of Regulations, title 22, section 64444 (Table 64444-A), and listed in Table 3-1 of the Basin Plan.
Chemical Constituents	Waters designated for use as domestic or municipal supply (MUN) shall not contain concentrations of chemical constituents in excess of the limits specified in California Code of Regulations, title 22, section 64431 (Table 64431-A) and section 64444 (Table 64444-A) and listed in Table 3-1 of the Basin Plan. Waters designated for use as agricultural supply (AGR) shall not contain concentrations of chemical constituents in amounts which adversely affect such beneficial use.

Source: North Coast Regional Board (2018) unless otherwise noted.

[1] Relevant beneficial uses are shown in bold and all caps. If no beneficial use is specified, the objective or criteria applies to all beneficial uses.

[2] Maximum contaminant level for domestic or municipal supply.

[3] Maximum contaminant level (shall not be exceeded in water supplied to the public) as specified in Table 64431-A (Inorganic Chemicals) of Section 64431, Title 22 of the California Code of Regulations, as of December 20, 2018.

Table 3.2-6. California Marine Water Quality Objectives Relevant to the Proposed Project.

Water Quality Objective[1]	Description
Physical Characteristics	• Floating particulates and grease and oil shall not be visible. • The discharge of waste shall not cause aesthetically undesirable discoloration of the ocean surface. • Natural light shall not be significantly reduced at any point outside the initial dilution zone as the result of the discharge of waste. • The rate of deposition of inert solids and the characteristics of inert solids in ocean sediments shall not be changed such that benthic communities are degraded.
Chemical Characteristics	• The dissolved oxygen concentration shall not at any time be depressed more than 10% from that which occurs naturally, as the result of the discharge of oxygen demanding waste materials. • The pH shall not be changed at any time more than 0.2 units from that which occurs naturally. • The dissolved sulfide concentration of waters in and near sediments shall not be significantly increased above that present under natural conditions. • The concentration of substances set forth in Chapter II, Table 1 (State Water Board 2015), in marine sediments shall not be increased to levels which would degrade indigenous biota. • The concentration of organic materials in marine sediments shall not be increased to levels that would degrade marine life. • Nutrient materials shall not cause objectionable aquatic growths or degrade indigenous biota. • Numerical Water Quality Objectives for discharges are listed in Chapter II, Table 1 (State Water Board 2015), including objectives for the protection of marine aquatic life (i.e., metals, inorganics, organics, chronic and acute toxicity, pesticides and PCBs, radioactivity) and objectives for the protection of human health (noncarcinogenic and carcinogenic compounds).

Source: State Water Board (2015) unless otherwise noted.

[1] Water quality objectives for bacterial characteristics, radioactivity, and elevated temperature (thermal) wastes are not included, as these water quality parameters are not anticipated to be affected by the Proposed Project.

Table 3.2-7. Hoopa Valley Tribe Surface-Water Quality Objectives.

Parameter	Criteria/Description[1]
Ammonia (NH3, as mg/L N)	**COLD** Because ammonia toxicity to fish is influenced by pH, waters designated for the purpose of protection of threatened and endangered fish species in cold freshwater habitat shall meet conditions for ammonia based on maximum one-hour (acute) and 30-day average (chronic) concentrations linked to pH by the following formulas (HVTEPA 2008): Specific use numerical criteria: The one-hour average concentration of total ammonia nitrogen (in [milligrams nitrogen per liter] mg N/L) shall not exceed, more than once every three years on average, the CMC (acute criterion) calculated using the following equation. Where salmonid fish are present: $CMC = \frac{0.275}{1 + 10^{7.204-pH}} + \frac{39.0}{1 + 10^{pH-7.204}}$ The thirty-day average concentration of total ammonia nitrogen (in mg N/L) should not exceed, more than once every three years on average, the CCC (chronic criterion) calculated using the following equation. When fish early life stages are present: $CCC = \left(\frac{0.0577}{1 + 10^{7.688-pH}} + \frac{2.487}{1 + 10^{pH-7.688}}\right) x\ MIN\left(2.85, 1.45\ x\ 10^{0.028\ x\ (25-T)}\right)$ where T is the water temperature in Celsius.
Periphyton	150 mg chlorophyll-*a* /m^2
Dissolved oxygen[2]	**COLD** 8.0 mg/L minimum
	SPWN 11.0 mg/L minimum
	SPWN 8.0 mg/L minimum in inter-gravel water
Total Nitrogen (TN)[3,4]	0.2 mg/L
Total Phosphorous (TP)	0.035 mg/L
pH	The pH in the Klamath River shall be between 7.0 and 8.5 at all times
Microcystis aeruginosa cell density	**MUN, REC-1** Less than 5,000 cells/mL for drinking water Less than 40,000 cells/mL for recreational water
Microcystin toxin Concentration	**MUN, REC-1** Less than 1 ug/L total microcystins[5] for drinking water Less than 8 ug/L total microcystins[5] for recreational water
Total potentially toxigenic cyanobacteria [blue-green algae] species [6]	**MUN, REC-1** Less than 100,000 cells/mL for recreational water

Parameter	Criteria/Description[1]
Cyanobacterial [blue-green algae] scums	**MUN, REC-1** There shall be no presence of cyanobacterial [blue-green algae] scums
Nitrate	**MUN** 10 mg/L

Source: HVTEPA (2008)

[1] Relevant beneficial uses are shown in bold and all caps. If no beneficial use is specified, the objective or criteria applies to all beneficial uses.

[2] HVTEPA (2008) includes a natural conditions clause which states, "If dissolved oxygen standards are not achievable due to natural conditions, then the COLD and SPAWN standard shall instead be dissolved oxygen concentrations equivalent to 90% saturation under natural receiving water temperatures." USEPA has approved the Hoopa Valley Tribe definition of natural conditions; the provision that site-specific criteria can be set equal to natural conditions and the procedure for defining natural conditions have not been finalized as of December 2018.

[3] HVTEPA (2008) includes a natural conditions clause which states, "If total nitrogen and total phosphorus standards are not achievable due to natural conditions, then the standards shall instead be the natural conditions for total nitrogen and total phosphorus." USEPA has approved the Hoopa definition of natural conditions; the provision that site-specific criteria can be set equal to natural conditions and the procedure for defining natural conditions have not been finalized as of December 2018.

[4] 30-day mean of at least two sample per 30-day period.

[5] Total microcystins, as defined in the Hoopa Valley Tribe Surface-Water Objectives, is assumed to be equivalent to total microcystin for this EIR.

[6] Includes: *Anabaena*, *Microcystis*, *Planktothrix*, *Nostoc*, *Coelosphaerium*, *Anabaenopsis*, *Aphanizomenon*, *Gloeotrichia*, and *Oscillatoria*.

Table 3.2-8. Yurok Tribe Surface-Water Quality Objectives Relevant to the Proposed Project.

Parameter[1]	Description
Ammonia	Levels of ammonia shall not be increased, in any body of water, by human related activity that could cause a nuisance or adversely affect the water to support specified beneficial uses. Specific use[2] numerical criteria[3]: The one-hour average concentration of total ammonia nitrogen (in [milligrams nitrogen per liter] mg N/L) shall not exceed, more than once every three years on average, the CMC[4] (acute criterion) calculated using the following equation. Where salmonid fish are present: $$CMC = \frac{0.275}{1+10^{7.204-pH}} + \frac{39.0}{1+10^{pH-7.204}}$$ The thirty-day average concentration of total ammonia nitrogen (in mg N/L) should not exceed, more than once every three years on average, the CCC[5] (chronic criterion) calculated using the following equation. When fish early life stages are present: $$CCC = \left(\frac{0.0577}{1+10^{7.688-pH}} + \frac{2.487}{1+10^{pH-7.688}}\right) x\ MIN\left(2.85, 1.45\ x\ 10^{0.028\ x\ (25-T)}\right)$$ where T is the water temperature in Celsius. In addition, the highest four-day average within the 30-day period should not exceed 2.5 times the CCC.

Parameter[1]	Description
Biostimulatory Substances	Waters shall not contain biostimulatory substances in concentrations that promote aquatic growths to the extent that such growths could cause a nuisance or adversely affect the water to support specified beneficial uses.
Dioxins	No dioxin compounds will be discharged to any water within the YIR[6] boundaries.
Dissolved Oxygen	Dissolved oxygen concentrations shall not be altered by human caused activities that could cause a barrier to salmonid fish migration or adversely affect the water to support specified beneficial uses. Specific use[1] numerical criteria[3]: **Year-round objective in the water column** 7-day moving average of the daily minimum concentrations ≥ 8 mg/L **Intergravel objective during the incubation and emergence life stage** 7-day moving average of the daily minimum concentrations ≥ 8 mg/L **Water column objective during the incubation and emergence life stage** 7-day moving average of the daily minimum concentrations ≥ 11 mg/L.
Oil and Grease	Waters shall not contain oils, greases, waxes or other materials in concentrations that result in a visible film or coating on the surface of the water or on objects in the water that could cause a nuisance, or adversely affect the water to support specified beneficial uses.
Nitrate	Levels of nitrates in waters with municipal or domestic supply use shall not exceed 10 mg/L. In other bodies of water, the levels of nitrate shall not be increased by human related activity that could cause a nuisance, or adversely affect the water to support specified beneficial uses.
Nitrite	Levels of nitrites shall not be increased, in any body of water, by human related activity that could cause a nuisance, or adversely affect the water to support specified beneficial uses.
Pentachlorophenol (PCP)	No discharge of Pentachlorophenol will be allowed to any water body within the boundaries of the YIR. Any existing point or non-point source resulting in the presence of PCP shall be addressed as a non–compliance condition under the antidegradation plan.
Petroleum Hydrocarbons	No increase above background levels of petroleum hydrocarbons will be allowed due to human related activity in any water body within the YIR boundaries. Background levels shall be considered to be non-detect if baseline levels have not been established.
Pesticides	Pesticide concentrations, individually or collectively, shall not be detected by using the most recent detection procedures available. There shall be no detectable amount of pesticide concentrations found in bottom sediments. There shall be no detectable increase in bioaccumulation of pesticides in aquatic life.

Parameter[1]	Description
pH	Changes related to human caused activities in normal pH levels shall not exceed 0.5 pH units [s.u.]. pH levels shall not be below 6.5 [s.u.] and not exceed 8.5 [s.u.] due to human caused activities.[2]
Phosphates	Levels of phosphorous in any water body shall not be increased by human related activity above the levels that could cause a nuisance, or adversely affect the water to support specified beneficial uses.
Sediment	The suspended sediment load and suspended sediment discharge rate of surface waters shall not be altered in such a manner as to cause a nuisance, or adversely affect the water to support specified beneficial uses. In addition, the placing or disposal of soil and silt from any operation where such material could cause a nuisance or adversely affect the water to support specified beneficial uses is prohibited.
Settleable Materials	Waters shall not contain substances caused by human activities in concentrations that result in deposition of material that could cause a nuisance, or adversely affect the water to support specified beneficial uses.
Suspended Materials	Waters shall not contain suspended materials caused by human activities in concentrations that could cause a nuisance, or adversely affect the water to support specified beneficial uses.
Temperature	The natural receiving water temperature shall not be altered unless it is shown to the YTEP[7], and the YTEP concurs, that it does not affect beneficial uses. See Table 3.2-9 for water temperature specific use[2] numerical criteria[3].
Toxicity	All waters shall be maintained free of toxic substances in concentrations that are toxic to, or that produce detrimental physiological responses in human, plant, animal, or aquatic life. Compliance with this objective will be determined by use of indicator organisms, analysis of species diversity, population density, growth anomalies, bioassays of appropriate duration and/or other appropriate methods as specified by USEPA's toxicity test guidance.
Turbidity	Waters shall be free of human caused changes in turbidity that could cause a nuisance, or adversely affect the water to support specified beneficial uses. Allowable zones of dilution within which higher percentages can be tolerated may be defined for specific discharges upon the issuance of discharge permits or waiver thereof. Turbidity shall not exceed 5 Nephelometric Turbidity Units (NTU) over background turbidity when the background turbidity is 50 NTU or less or have more than a 10 percent increase in turbidity when the background is greater than 50 NTU.[8]

Parameter[1]	Description
Other Chemical Constituents	Waters used for domestic or municipal supply shall not contain concentrations of chemical constituents in amounts which adversely affect such beneficial use.

[1] Water quality objectives for bacteria, boron, floating materials, hardness, radioactivity, and elevated temperature (thermal) wastes are not included, as these water quality parameters are not anticipated to be affected by the Proposed Project. Analysis of potential impacts to riverbed substrate composition is discussed in Section 3.11 Geology, Soils, and Mineral Resources. Analysis of potential impacts to the ability of tribes to use water for ceremonial and other purposes is discussed in Section 3.12 Historical Resources and Tribal Cultural Resources. Analysis of potential impacts to color is discussed in Section 3.19 Aesthetics. Consideration of hydrology under the Proposed Project is discussed in Section 3.1.6 Summary of Available Hydrology Information for the Proposed Project. Specific hydrologic conditions for the alternatives are discussed in Section 4 Alternatives.

[2] Waters listed with the designated uses of preservation of biological habitat with special significance (BIO), cold freshwater habitat (COL), commercial and sport fishing (COM), cultural and ceremonial activities (CUL), migration of aquatic organisms (MGR), municipal and domestic supply (MUN), navigation (NAV), contact recreation (REC-1), rare, threatened, or endangered species habitat (RARE), spawning, reproduction, and development habitat (SPN) shall meet the criteria over the entire length of the stream including connecting tributaries and the Pacific Ocean where applicable within Yurok Tribal jurisdiction.

[3] Specific use numerical criteria for ammonia adopted from USEPA's 1999 update of ambient water quality criteria for ammonia (USEPA 1999) and Hoopa Valley Tribe's 2001 WQCP (HVTEPA 2008).

[4] CMC = Criteria Maximum Concentrations

[5] CCC = Criterion Continuous Concentration

[1] Waters listed with the designated uses of preservation of biological habitat with special significance (BIO), cold freshwater habitat (COL), commercial and sport fishing (COM), cultural and ceremonial activities (CUL), migration of aquatic organisms (MGR), municipal and domestic supply (MUN), navigation (NAV), contact recreation (REC-1), rare, threatened, or endangered species habitat (RARE), spawning, reproduction, and development habitat (SPN) shall meet the criteria over the entire length of the stream including connecting tributaries and the Pacific Ocean where applicable within Yurok Tribal jurisdiction.

[2] Mean Weekly Average Temperature

[3] Mean Weekly Maximum Temperature

Suspended Sediments

California has established separate water quality objectives for the two closely-related water quality parameters: suspended sediment (the amount of silt, clay, and other small particles in the water column) and turbidity (the clarity or murkiness of the water causes by small particles). California objectives for turbidity are based on comparing the clarity of the water currently to the clarity of the water under natural conditions (Table 3.2-4). However, there are not readily-available data on what turbidity levels are in the Klamath River under natural conditions, so increases in turbidity above natural conditions cannot be calculated for the Proposed Project in the manner anticipated by the Basin Plan (i.e. relative to natural conditions). While measurements of suspended sediments and turbidity are related such that a relationship can be determined to estimate turbidity from suspended sediments, or vice versa, the relationship between suspended sediments and turbidity varies between watersheds due to changes in sediment properties. Both suspended sediment and turbidity data must be collected at one or more locations in a river over a sufficiently long time period to characterize the range of suspended sediment and turbidity conditions and determine the relationship between the two parameters in the river near those locations; there currently is not sufficient data to develop this relationship in the Klamath River, either for natural conditions or for existing background conditions (Stillwater Sciences 2009). Thus, it is not possible to use the turbidity water quality objective directly, and accordingly the CEQA water quality impacts analysis uses the narrative sediment water quality objectives, rather than the numeric turbidity standards.

Basin Plan water quality objectives for suspended material, settleable material, and sediment are narrative and require that waters not contain concentrations that cause nuisance or adversely affect beneficial uses (Table 3.2-4). While the Klamath River has multiple designated beneficial uses, the use most sensitive to water quality is the cold freshwater habitat (COLD) associated with salmonids (North Coast Regional Board 2011). In order to adequately analyze short-term and long-term impacts[38] of the Proposed Project on this beneficial use, the water quality impact analysis assesses the narrative suspended material water quality objective using the predicted suspended sediment concentrations (SSCs)[39] for two to 50 years beginning with the initiation of drawdown in the Lower Klamath Project reservoirs. Predictions of SSCs during dam removal were determined as part of the extensive sediment transport modeling conducted for the Klamath Dam Removal Secretarial Determination process (USBR 2012). The narrative suspended material water quality objective was interpreted into a numeric SSC value for assessing potential impacts to the most sensitive beneficial use (COLD) by analyzing the magnitude and duration of SSCs that produce negligible, behavioral, sub-lethal, and lethal impacts to salmonids (Newcombe and Jenson 1996).

[38] For the Lower Klamath Project water quality analysis, short term is defined as the period during pre-dam removal activities, reservoir drawdown, dam removal, and associated sediment flushing events, which corresponds to pre-dam removal activities that would occur in the one to three years before dam removal, dam removal year 1, dam removal year 2, and post-dam removal year 1 (Table 2.7-1). Long-term is defined as occurring after post-dam removal year 1 (i.e., greater than three years after dam removal.

[39] For the purposes of this report, SSC is considered equivalent to Total Suspended Solids (TSS). SSC and TSS are generally similar, but there are potential differences in the numeric values reported by each method (Gray et al. 2000). As needed, data from multiple sources reported as either TSS or SSC are used interchangeably. SSC is more commonly used in riverine systems while TSS is used for wastewater treatment plants.

Using a generalized "dose-response"[40] approach, the numeric SSCs threshold of significance for potential short-term impacts is 100 mg/L over a continuous two-week exposure period, as this exposure for the duration of two weeks would be a significant adverse impact to salmonids (see Appendix D, Section D.2 for detail).

A more detailed analysis of suspended sediment effects on key fish species, including consideration of specific life history stages, SSCs, and exposure period, is required for a comprehensive assessment of the impacts of the Proposed Project on fisheries-related beneficial uses. This level of analysis is presented in Section 3.3 *Aquatic Resources* and appendices to the section. Further discussion of the particular impacts of suspended sediment on shellfish and estuarine and marine organisms is also presented in Section 3.3.5.1 *Suspended Sediment*.

In the Pacific Ocean nearshore environment, the narrative California marine water quality objectives (Table 3.2-6) are applied as the threshold of significance rather than the freshwater numeric SSCs threshold of significance of 100 mg/L over a continuous two-week exposure period. The freshwater numeric SSCs threshold of significance is not applied to the Pacific Ocean nearshore environment since mixing conditions would potentially result in rapid variations in SSCs and salmonids within the Pacific Ocean nearshore environment would have more of an opportunity to avoid elevated SSCs conditions compared to opportunities within the Klamath River. Due to the fact that turbulent mixing in the Pacific Ocean nearshore environment could result in rapid variations in physical characteristics, including SSCs, the threshold of significance in the marine environment for this EIR is whether the changes in the physical characteristics of the Pacific Ocean nearshore environment would be greater than occurring under natural (i.e., storm) conditions. Variations in the physical characteristics of the Pacific Ocean nearshore environment within the range occurring under natural (i.e., storm) conditions would be similar to existing conditions, so there would be no significant impact. Variations in the physical characteristics of the Pacific Ocean nearshore environment greater than the range occurring under natural (i.e., storm) conditions would potentially cause water quality changes that would result in a failure to maintain existing beneficial uses at the levels currently supported, resulting in a significant impact.

Nutrients

California has a narrative water quality objective for biostimulatory substances and does not stipulate numeric nutrient water quality standards for the COLD beneficial use (Table 3.2-4). California does have numeric nitrate and nitrite standards for the support of municipal beneficial uses (i.e., drinking water). However, these standards are much higher than concentrations that have been measured in the Klamath Basin, such that there is no indication that the municipal beneficial use is not being met or would not be met in the future under the Proposed Project. The Hoopa Valley Tribe and Yurok Tribe also have nitrate standards for municipal beneficial uses (Table 3.2-7) that are similarly high. The Yurok Tribe nitrite water quality objective is discussed under the sub-section *Inorganic and Organic Contaminants* below.

The narrative objective for biostimulatory substances in the Basin Plan applies to all North Coast waters. The California Klamath River TMDLs interpret the narrative

[40] A "dose-response" approach analyzes how exposure to different concentrations over a range of time periods (i.e., hours, days, weeks, months) produces various impacts (i.e., negligible, behavioral, sub-lethal, and lethal) on the organism being evaluated.

biostimulatory substances objective for the Klamath River with numeric targets for nutrients, organic matter, chlorophyll-*a*, *Microcystis aeruginosa*, and microcystin. The numeric TMDL targets for nutrients (TP and TN) and organic matter vary by month and are established for the tailraces of Copco No. 2 and Iron Gate dams. The numeric TP targets range from 0.023–0.029 mg/L for May–October and 0.024–0.030 mg/L for November–April. The numeric TN targets range from 0.252–0.372 mg/L for May–October and 0.304–0.395 mg/L for November–April (North Coast Regional Board 2010). These are established as the monthly mean concentrations that allow achievement of in-reservoir water quality targets to attain the chlorophyll-*a* summer mean target of 10 ug/L, the *Microcystis aeruginosa* cell density target of 20,000 cells/mL, and the microcystin target of 4 ug/L (i.e., avoid nuisance algae blooms in Iron Gate and Copco No. 1 reservoirs) (North Coast Regional Board 2010; see also Appendix D, Section D.1 for a discussion of the "TMDL dams-in" modeling scenario [T4BSRN], which is the basis of these targets).

At multiple locations in the Klamath River, the Klamath River TMDL model results indicate large daily variability in TP and TN in excess of the small range in the monthly TMDL targets, particularly during summer and early fall (generally June–October) (Tetra Tech 2009). As a result, the nutrient impact analysis for this EIR considers whether a general downward (or upward) trend in TP and TN toward (or away from) the numeric targets would occur and, qualitatively, the impact analysis interprets whether such a trend would support or alleviate the growth of nuisance and/or noxious phytoplankton or nuisance periphyton. In the Pacific Ocean nearshore environment, the applicable narrative water quality objective for nutrients would be from the California Ocean Plan that states that nutrient materials shall not cause objectionable aquatic growths or degrade indigenous biota (see Table 3.2-6). Thus, the threshold of significance for nutrients is the combination of a qualitative evaluation of potential changes in nutrients under the Proposed Project and an evaluation of whether potential responses in nuisance and/or noxious phytoplankton or nuisance periphyton would impact designated beneficial uses.

Chlorophyll-*a* and Algal Toxins

The Klamath River TMDLs establish a Lower Klamath Project phytoplankton chlorophyll-*a* target of 10 ug/L during the May to October growth season (North Coast Regional Board 2010). The Hoopa Valley Tribe chlorophyll-*a* criterion[41] (150 mg/m^2) relates to periphyton growth rather than phytoplankton growth or algae blooms and it is not discussed further in this section since periphyton growth under the Proposed Project is addressed in Section 3.4 *Phytoplankton and Periphyton*.

The California TMDL target (10 ug/L) is used as the chlorophyll-*a* threshold of significance for Copco No. 1 and Iron Gate reservoirs. Anticipated regular exceedances of these thresholds greater than would occur under existing conditions would constitute a significant impact for this analysis.

For algal toxins, the North Coast Regional Board Basin Plan has narrative water quality objectives for general toxicity that all waters shall be maintained free of toxic substances in concentrations that are toxic to, or that produce detrimental physiological responses in human, plant, animal, or aquatic life (North Coast Regional Board 2018). The World

[41] Applicable to the short reach (approximately RM 45) of the Klamath River upstream of the Trinity River.

Health Organization (WHO) has set numeric thresholds for recreational exposures of microcystin toxin at 4 ug/L for a low probability of adverse health effects, and 20 ug/L for a moderate probability of adverse health effects (Falconer et al. 1999; Chorus and Cavalieri 2000). The WHO thresholds are general levels representing a variety of toxigenic cyanobacteria [blue-green algae]. To avoid conditions that lead to water quality impairments, the California Klamath River TMDLs use the WHO low probability of adverse health effects thresholds as targets specific to the California reaches of the Lower Klamath Project for *Microcystis aeruginosa* (less than 20,000 cells/mL) and microcystin toxin (less than 4 ug/L). In addition to the WHO and California Klamath River TMDLs numeric objectives for microcystin toxin thresholds, the CCHAB Network, comprised of the State Water Board, CDPH, and CalEPA OEHHA with participation by multiple federal, state, and local stakeholders, details primary and secondary cyanotoxin [algal toxin] trigger threshold levels for protection of human health in recreational waters in the *Draft Voluntary Statewide Guidance for Blue-Green Algae Blooms* (Table 3.2-10; State Water Board et al. 2010, updated 2016). The minimum primary cyanotoxin [algal toxin] trigger thresholds that would result in a waterbody being posted include 0.8 ug/L total microcystin toxins, detection of anatoxin-a (using an analytical method that detects less than or equal to 1 ug/L), or 1 ug/L cylindrospermopsin. The secondary trigger thresholds are 4,000 cells/mL of all toxin producing species- or site-specific indicators of cyanobacteria [blue-green algae] like blooms, scums, or mats (State Water Board et al. 2010, updated 2016). Additionally, the Hoopa Valley Tribe and Yurok Tribe have numeric objectives for algal toxins. The Hoopa Valley Tribe numeric objectives for algal toxins are less than 1 ug/L total microcystins[42] for drinking water and less than 8 ug/L total microcystins[42] for recreational water (see Table 3.2-7; HVTEPA 2008). The Yurok Tribe has multiple numeric objectives for algal toxins (i.e., microcystin) with the lowest threshold for posting being detection of microcystin (see Table 3.2-11; YTEP 2016).

Table 3.2-10. California Cyanobacteria Harmful Algal Bloom (CCHAB) Trigger Levels for Human Health.

Trigger Level	Primary Triggers[1]			Secondary Triggers	
	Total Microcystins (ug/L)	**Anatoxin-a (ug/L)**	**Cylindrospermopsin (ug/L)**	**Total potentially toxigenic cyanobacteria [blue-green algae] species (cells/mL)**	**Site specific indicators of cyanobacteria [blue-green algae]**
Caution Action	0.8	Detection[2]	1	4,000	Blooms, scums, mats, etc.
Warning TIER I	6	20	4	-	-
Danger TIER II	20	90	17	-	-

Source: (State Water Board et al. 2010, updated 2016)
[1] Primary triggers are met when ANY toxin exceeds criteria
[2] Must use an analytical method that detects less than or equal to 1 ug/L Anatoxin-a

[42] "Total microcystins", as defined in the Hoopa Valley Tribe Surface-Water Objectives, is assumed to be equivalent to "total microcystin" for this EIR.

Table 3.2-11. Yurok Tribe Posting Guidelines for Blue-Green Algae Public Health Advisories

Public Health Advisory Level	*Microcystis aeruginosa* (cells/mL)	Total potentially toxigenic blue-green algae species (cells/mL)	Microcystin toxin Concentration (ug/L)
Caution	Detection	Detection	Detection
Level I Health Advisory Warning	≥ 1,000	≥ 100,000	≥ 0.8
Level II Health Danger Advisory	≥ 5,000	≥ 500,000	≥ 4.0

Source: YTEP (2016)

Since the less than 4 ug/L criterion for microcystin in recreational waters is common to the California Klamath River TMDL, WHO, and Yurok Tribe criteria, and it is less than the Hoopa Valley Tribe recreational criterion, 4 ug/L microcystin is used as the threshold of significance for the Lower Klamath Project EIR water quality analysis. The current lowest CCHAB and Yurok Tribe posting limit for microcystin (0.8 ug/L) is also considered in the analysis although application of the lower threshold would in no case change the significance determinations in this EIR.

While the threshold of significance for microcystin (i.e., algal toxins) is a numeric value, quantitative predictive tools for algal toxins are not available for assessment of the Proposed Project. Therefore, the algal toxin impact analysis is based on a qualitative assessment of whether the Proposed Project would result in exceedances of the criterion and adversely affect human health and recreational beneficial uses. Growth conditions for toxigenic suspended blue-green algae (e.g., nutrient availability, stable, slow-moving water) are considered as part of the qualitative analysis, where predicted changes in nutrient availability, water temperatures, and the availability of stable, slow-moving water (e.g., reservoir) conditions would correspondingly affect algal toxin concentrations.

Inorganic and Organic Contaminants

California has water quality objectives related to inorganic and organic contaminants, with numeric objectives for California's chemical constituents (listed in the Basin Plan [North Coast Regional Board 2018]), and chemical-specific water-column criteria for freshwater and marine aquatic life and human health, including bioaccumulative chemicals such as PCBs, methylmercury, dioxins, and furans (North Coast Regional Board 2018). The most stringent criteria are applied when more than one would be applicable (e.g., freshwater or marine in estuaries with brackish water). California's toxicity and pesticides objectives are narrative (Table 3.2-4).

Thresholds of significance for the California narrative water quality objectives focus on designated beneficial uses and are applicable for contaminants in either the water column or the sediments. For this EIR analysis, establishment of toxicity and/or bioaccumulation potential for sediment contaminants relies upon thresholds developed through regional and state efforts in the Sediment Evaluation Framework for the Pacific Northwest (SEF) (Appendix D – *Section D.3*). The SEF is a regional guidance document that provides a framework for the assessment and characterization of freshwater and marine sediments in Idaho, Oregon, and Washington (RSET 2018). The SEF includes bulk sediment screening levels for standard chemicals of concern and chemicals of special occurrence in marine and freshwater sediments for Idaho, Oregon, and

Washington (RSET 2018). Numeric chemical guidelines for the assessment and characterization of freshwater and marine sediments do not exist for California. Exposures to suspended sediment with elevated concentrations of potentially toxic chemicals are of lower concern for marine receptors than exposures to elevated concentrations of dissolved chemicals since dissolved chemicals are more bioavailable (i.e., able to interact with biological processes) and likely to cause toxicity than chemicals that are bound to sediments and less bioavailable (USEPA 2007). As part of the SEF approach used for the Klamath Dam Removal Secretarial Determination process, bioassays and sediment bioaccumulation tests were conducted to provide additional empirical evidence about the biological effects of inorganic and organic contaminants in reservoir sediment deposits. Bioassays and sediment bioaccumulation test results represent direct exposure to the undiluted reservoir sediments samples, so those results are interpreted based on the expected dilution of reservoir sediments once they are transported from the reservoir footprints under the Proposed Project and potential toxicity from bioassays and sediment bioaccumulation tests are only applied as thresholds of significance after consideration of dilution. Additional information regarding applicable sediment screening levels used for the Klamath Dam Removal Secretarial Determination sediment evaluation process is presented in CDM (2011).

With respect to inorganic and organic contaminants, impacts on water quality are considered significant if the Proposed Project would result in substantive adverse impacts on human health or environmental receptors (e.g., aquatic organisms) due to dam removal. Substantive adverse impacts on human health or environmental receptors is defined as exceedance of applicable chemical screening levels and/or laboratory toxicity results that indicate one or more chemicals are present at levels with potential to cause toxicity after consideration of dilution that would be representative of conditions in the Klamath River, Klamath River Estuary, and the Pacific Ocean nearshore environment during and following dam removal. The detection of one or more chemicals at concentrations with potential to cause only minor or limited adverse effects based on exceedances of applicable screening levels and/or laboratory toxicity results after consideration of dilution under the Proposed Project would be below the threshold of significance, thus constitute a less than significant impact. This evaluation is not intended to be equivalent to the SEF process.

Lastly, the Hoopa Valley Tribe and the Yurok Tribe have ammonia toxicity objective based on pH and temperature (Table 3.2-7). Available data suggests no actual ammonia toxicity events associated with the operation of the Lower Klamath Project (North Coast Regional Board 2010), and the turbulent mixing, increased river velocity and expected dissolved oxygen conditions in the river under the Proposed Project would promote an increase in nitrification (i.e., biological oxidation of ammonia and ammonium to nitrate) minimizing the potential for ammonia toxicity. Similarly, the Yurok Tribe has a nitrite water quality objective (Table 3.2-8), but available data does not suggest operation of the Lower Klamath Project influences nitrite concentrations in the Klamath River. Additionally, the rapid oxidation of nitrite to nitrate in the environment combined with the dissolved oxygen and turbulent mixing conditions in the Klamath River would result in any potential nitrite becoming nitrate under the Proposed Project. As a result, these specific objectives are not considered further. Potential short-term toxicity to aquatic organisms during reservoir drawdown, including consideration of ammonia and nitrite toxicity, is addressed using bioassay results (see Section 3.2.4.7 *Inorganic and Organic Contaminants*).

3.2.4 Impact Analysis Approach

Water quality impact analysis considers the Proposed Project's anticipated short-term and long-term water quality effects. For the Lower Klamath Project water quality analysis, short-term is defined as the period during pre-dam removal activities, reservoir drawdown, dam removal, and associated sediment flushing events, which corresponds to pre-dam removal activities that would occur in the one to three years before dam removal, dam removal year 1, dam removal year 2, and post-dam removal year 1 (Table 2.7-1). Long-term is defined as occurring after post-dam removal year 1 (i.e., greater than three years after dam removal).

As these are the areas of greatest potential impact and of most heightened public concern, the water quality analysis in this EIR focuses on the potential impacts of the Proposed Project on water temperature, suspended sediments, nutrients (TN, TP, nitrate, ammonium, ortho-phosphorus), dissolved oxygen, pH and alkalinity, chlorophyll-*a* and algal toxins, and inorganic and organic contaminants in water and reservoir sediments.

While the timing of reservoir drawdown under the Proposed Project was selected to minimize environmental effects, significant short-term impacts are anticipated. In the short term, the water quality impacts are expected to be heavily driven by the release of fine sediment deposits currently stored behind the dams to the downstream river reaches, the Klamath River Estuary, and the Pacific Ocean nearshore environment. Mobilization of reservoir sediment deposits would be most intense during reservoir drawdown and the year following dam removal, when the majority of sediments would be eroded and transported by river flows (Stillwater Sciences 2008; USBR 2012, 2016) (see also Section 2.7.3 *Reservoir Sediment Deposits and Erosion During Drawdown*). Additionally, there is the potential for short-term water-quality impacts as a result of construction and restoration activities.

Long-term changes in water quality are primarily characterized by the shift from reservoir to river environments in the Hydroelectric Reach and the associated alterations in physical and chemical processes on water quality in this reach and downstream river reaches. Additionally, potential long-term water quality impacts associated with future land use and the transfer of Parcel B lands under the Proposed Project are considered qualitatively.

Multiple numeric models[43] are used for the water quality impact analyses because no one individual existing numeric model captures all of the water quality conditions anticipated for and encompassed by the Proposed Project (Appendix D, Section D.1). Numeric models include those developed by PacifiCorp for the FERC relicensing process for water temperature and dissolved oxygen, North Coast Regional Board models for development of the Klamath River TMDLs, and models used in the course of the Klamath Dam Removal Secretarial Determination studies. While modeling conducted as part of the Klamath Dam Removal Secretarial Determination studies used Water Year (WY) 2012 as the start of the period of analysis for hydrology (i.e., river flows), water temperature, and suspended sediment, the overall range of river flows remains generally consistent between WY 2012 and current conditions (see Section

[43] Here numeric models refers to mathematical models that are developed to represent the physical, chemical, and biological conditions in waterbodies such as rivers, lakes, reservoirs, wetlands, estuaries, and the ocean.

3.1.6 *Summary of Available Hydrology Information for the Proposed Project*) and other modeling assumptions for water temperature and suspended sediment have not changed in the interim. The California Klamath River TMDL models stemmed from a significant five-year effort by the North Coast Regional Board in collaboration with PacifiCorp and working jointly with USEPA Regions 9 and 10 and ODEQ. That work was subject to extensive peer review and public comment before adoption by the North Coast Regional Board. It was further reviewed and subject to additional public comment before being approved unanimously by the State Water Board. It was then subsequently reviewed and approved by the USEPA in December 2010.

The following documents were assessed to determine if the Proposed Project has the potential to conflict with any local policies or ordinances protecting water quality or conflict with provisions of any adopted conservation plans:

- Del Norte County General Plan (Mintier & Associates et al. 2003):
  - Section 1 *Natural Resources/Conservation, Water Resources*, including Policies 1.B.1, 1.B.3, 1.B.6, 1.B.7, and 1.B.12.
- Humboldt County General Plan for Areas Outside of the Coastal Zone (Humboldt County 2017):
  - Water Resources Element, including Policies WR-P1, WR-P2, WR-P3, WR-P4, WR-P5, WR-P12, WR-P18, WR-P22, WR-P23, WR-P24, WR-P25, WR-P29, WR-P33, WR-P34, WR-P35, WR-P36, WR-P37, WR-P39, WR-P42, WR-P43, and WR-P45; Standards WR-S2, WR-S6, WR-S7, and WR-S9; and Implementation Measures WR-IM9, WR-IM14, WR-IM17, WR-IM19, WR-IM20, WR-P28 [sic], WR-IM29, WR-IM30, and WR-IM32.
- Siskiyou County General Plan:
  - Conservation Element (Siskiyou County 1973), including Section 4.H *Watershed and Water Recharge Lands*, Objective and Recommendations 2, 3, and 4; Section 4.I *The [Conservation] Plan*, 1, 4, 8, and Objectives 1, 3, and 5; and Section 5.C.3 *Environmental Impacts*, 1, 3, 5, and 7.
  - Land Use and Circulation Element (Siskiyou County 1980) and Land Use Update (Siskiyou County 1997).

The aforementioned policies, standards, implementation measures, and objectives are stated in general terms, consistent with their overall intent to protect water quality, water resources, and general watershed conditions. In evaluating the potential impacts to specific water quality parameters within the water quality Area of Analysis, including water temperature, suspended sediments, nutrients, dissolved oxygen, pH, chlorophyll-a and algal toxins, and inorganic and organic contaminants, the more general local policies listed above are inherently considered and addressed by the water quality parameter specific analyses in Section 3.2.5 *[Water Quality] Potential Impacts and Mitigation*.

Parameter-specific analysis methods are discussed below.

3.2.4.1 Water Temperature

The analysis of the Proposed Project's potential short-term and long-term impacts on water temperatures is informed by three quantitative models: the Klamath River Water Quality Model (KRWQM), the Klamath River TMDL model, and the RBM10 model. Each of these models includes a scenario that is similar to existing conditions (i.e., with the Lower Klamath Project dams in place) and scenarios with one or more dams removed that are similar to the Proposed Project and/or alternatives analyzed in Section 4 *Alternatives*. The KRWQM was developed for FERC relicensing of the Klamath Hydroelectric Project (PacifiCorp 2004a), and it was later used to inform development of the Klamath River TMDL model. The Klamath River TMDL model was developed to inform the Oregon and California TMDLs. The Klamath River TMDL model includes a "TMDL dams-in" scenario (T4BSRN), which approximates the condition where the Lower Klamath Project dams remain in place, as well as the TOD2RN (Oregon reaches) and TCD2RN (California reaches) scenarios (together the "TMDL dams-out" scenario) that assume the removal of the Lower Klamath Project (see Appendix D for more detail). The Klamath River TMDL model assumes full TMDL implementation for both the dams-in and dams-out scenarios (Tetra Tech 2009); however, the mechanisms for implementation and the timing required to achieve future TMDL compliance are currently speculative. Despite this assumption, the Klamath River TMDL model results are still informative with respect to the analysis of potential water temperature impacts under the Proposed Project, particularly for reaches where the KRWQM was not run for the FERC relicensing process (see Section 3.2.5 *Potential Impacts and Mitigation* for additional discussion). Further, the Klamath "TMDL natural conditions scenario" (T1BSR) is useful for contextualizing water temperature background or natural levels as compared with existing conditions, the Proposed Project, and/or the alternatives. The Klamath River TMDL model assumes that the upstream Keno Dam is replaced by the historical natural Keno Reef in the "TMDL natural conditions" scenario (T1BSR), and the "TMDL dams-out" scenario (TOD2RN and TCD2RN), but not in the "TMDL dams-in" scenario (T4BSRN). Where this assumption applies, the Keno Reach is still partially impounded even though the reef's elevation is two feet lower than the current full pool elevation of Keno Impoundment/Lake Ewauna, which does not materially influence model applicability to inform impact determinations for the Proposed Project and alternatives identified in this EIR.

Since the KRWQM and the Klamath River TMDL model do not include climate change projections or KBRA hydrology[44], one additional set of water temperature modeling results is used for this EIR. The RBM10 model was developed as part of the Klamath Dam Removal Secretarial Determination studies and includes the effects of climate change and KBRA hydrology on water temperatures (Perry et al. 2011). RBM10 model results use climate change predictions from five Global Circulation Models (GCMs) (see Appendix D for more detail). The climate change predictions are used to give additional context to the temperature discussion, but they are not relied on for significance determinations. Future climate changes are not part of the existing condition against which this EIR compares potential impacts under the Proposed Project.

Additional details regarding available numeric models for analysis of long-term water temperature are presented in Appendix D. Table D-1 shows the reaches where KRWQM, Klamath River TMDL, and RBM10 model results are used for the water quality analysis under the Proposed Project and each alternative and Table D-2 presents a

[44] A quantitative comparison between KBRA and the NMFS and USFWS 2013 Joint Biological Opinion for the Klamath Irrigation Project (2013 BiOp Flows) indicates that KBRA Flows sufficiently bracket the range of 2013 BiOp Flows (see also Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*), and so RBM10 model results still generally represent the expected trends under the Proposed Project

comparison of assumptions and parameters for the available numeric models, including flow assumptions. Since no single existing model captures all of the elements analyzed for water temperature in this EIR, model outputs are used in combination to assess similar spatial and temporal trends in predicted water temperature where possible.

3.2.4.2 Suspended Sediments

Reservoir drawdown under the Proposed Project is anticipated to mobilize a large amount of sediment in the short term (USBR 2012). In light of this, the Proposed Project schedules reservoir drawdown during winter months when precipitation, river flows, suspended sediments, and turbidity are naturally highest (see Section 2.7 *Proposed Project*). This EIR uses quantitative modeling and analyses of drawdown to inform the analysis of drawdown's suspended sediment effects, as further described in this section. Additionally, this EIR evaluates the potential for the Proposed Project to affect suspended sediment concentrations over the long-term, using existing data sources and analyses.

Results from the sediment mobility analysis conducted by USBR (2012) for the Klamath Dam Removal Secretarial Determination process are used to provide estimates of short-term SSCs downstream of Iron Gate Dam under the Proposed Project. The sediment mobility analysis used existing suspended sediment data collected by the USGS at the Shasta River near the City of Yreka (USGS gage no. 11517500), Klamath River near Orleans (USGS gage no.11523000), and Klamath River near Klamath (USGS gage no. 11530500) gages to estimate daily total SSCs (measured in mg/L) as a function of flow (measured in cfs) using the SRH-1D sediment transport model (Sedimentation and River Hydraulics–One Dimension Version 2.4) (Huang and Greimann 2010) and the SRH-2D sediment transport model (Sedimentation and River Hydraulics–Two Dimension Version 2.4) (USBR 2012, 2016). Daily total SSCs were modeled for existing conditions representing WY 1961–2008 ("background") and for short-term conditions following dam removal (WY 2020–2021). SRH-1D model output representing total settleable suspended material in the water column, including both inorganic (e.g., silt, clay, and sand) and organic (e.g., algae and plant) suspended material, is applied herein to the suspended sediment analysis. "Suspended sediments" and "suspended material" are used interchangeably to refer to the combined inorganic and organic suspended material. Sources of each type of suspended material differ, as do spatial and temporal trends for each, within the Upper, Middle, and Lower Klamath River reaches (Section 3.2.2.3 *Suspended Sediments*). Bed materials, such as gravels and larger substrates, are discussed in Geology and Soils Section 3.11.5 *Potential Impacts and Mitigation*.

The SRH-1D model assumes drawdown for Copco No. 1 Reservoir begins on November 1 and drawdown for J.C. Boyle, and Iron Gate reservoirs begins on January 1, consistent with the Proposed Project. Copco No. 2 was not explicitly considered in the SRH-1D model, since: 1) construction of Copco No. 2 dam was completed seven years after the substantially larger, upstream Copco No. 1 dam was completed, where the larger dam effectively cut off the source of sediments that would have been transported into Copco No. 2 Reservoir and potentially stored over many years, and 2) Copco No. 2 Reservoir storage volume (70 ac-ft) is negligible compared with that of the upstream Copco No.1 (33,724 ac-ft) and J.C. Boyle (2,267 ac-ft) reservoirs, such that even if sediment deposits were to occur in Copco No. 2 Reservoir during drawdown of upstream Copco No. 1 and J.C. Boyle reservoirs, the smaller Copco No. 2 Reservoir would not meaningfully increase downstream SSCs during designated reservoir drawdown periods (see also Section 2.7.3 *Reservoir Sediment Deposits and Erosion During Drawdown*).

The Klamath River hydrology for the SRH-1D model was generated using the Index Sequential method, where historical flow data is used to generate a set of flows under future operational conditions (USBR 2012). Historical flows from 1961 to 2009 (i.e., 49 years of data) were used to estimate potential inflows to the Upper Klamath Lake and Klamath River in the future, then these inflows were routed down the Klamath River based on KBRA flow operations and requirements. In SRH-1D modeling that continued for more than one year (i.e., two years or more), the hydrology in the start year was followed by the hydrology in subsequent years. If there were no subsequent hydrology data (i.e., 2009), the period of record was looped (i.e., 2009 hydrology would be followed by 1961 hydrology) to obtain hydrology for Klamath River inflows for the desired modeling period. For example, if a start year of 2001 was chosen for a two-year modeling period, the hydrology from 2001 and 2002 was used to generate the inflows in the Klamath River that then were routed through the Hydroelectric Reach and further downstream. If a start year of 2001 was chosen for a 51-year modeling period, the hydrology from 2001 to 2009 followed by the hydrology from 1961 to 2002 would be used to generate the inflows in the Klamath River that then were routed through the Hydroelectric Reach and further downstream (USBR 2012).

In addition to modeling the sediment transport during drawdown of the Lower Klamath Project reservoirs, sediment transport in the Klamath River from Iron Gate Dam to the Pacific Ocean for all years between WY 1961 and 2008 was modeled with SRH-1D to estimate the background SSCs in the Klamath River under existing conditions (USBR 2012). Incoming sediment concentrations supplied by tributaries downstream of Iron Gate Dam in the SRH-1D modeling of background SSCs were estimated from existing data on sediment transport and estimates of the sediment delivery rates from portions of the Klamath Basin were used to (Stillwater Sciences 2010; USBR 2012). Additionally, the SRH-1D modeled SSCs were compared with suspended sediment data collected by the USGS on the Shasta River near Yreka, California (USGS 11517500) from 1957 to 1960, on the Klamath River at Orleans, California (USGS 11523000) from 1957 to 1979 and on the Klamath River at Klamath, California (USGS 11530500) from 1974 to 1995 to verify the SRH-1D modeled SSCs sufficiently characterized the background SSCs in the Klamath River at Orleans and Klamath (USBR 2012).

With respect to the assumed reservoir drawdown rate, the USBR (2012) SSC modeling assumes a maximum drawdown rate of 2.25 to 3 feet per day (USBR 2012b) whereas the Proposed Project uses a maximum drawdown rate of 5 feet per day (Appendix B: *Definite Plan*). Stillwater Sciences (2008) modeled a range of drawdown rates (3, 6, and 9 feet per day) for removal of the Lower Klamath Project dams, which spans the aforementioned USBR (2012) and Proposed Project maximum drawdown rates. In Stillwater Sciences (2008), as the drawdown rate increases from 3 to 6 feet per day, the peak concentration of suspended sediments approximately doubles from 10,000 ppm [mg/L] to 20,000 ppm [mg/L], the concentration of suspended sediments decreases more rapidly over the course of days and weeks, and the duration of elevated concentrations decreases by several weeks. A similar response in estimated SSCs is expected for the USBR (2012) model output when increasing the maximum drawdown rate from 2.25 to 3 feet per day to 5 feet per day and accordingly, this response pattern is applied to the analysis of potential impacts due to SSCs, such that no new SSC modeling is required for the Proposed Project. While peak SSCs under the Proposed

Project may be somewhat underestimated by the USBR (2012) modeled SSC results, the SSCs under the Proposed Project would still be within the inherent uncertainty of the USBR (2012) model (i.e., approximately a factor of two). Additionally, a more rapid decrease in suspended sediments and shorter duration of elevated SSCs under the faster drawdown in the Proposed Project would result in the USBR (2012) modeled SSC results underestimating the rate SSCs decrease and overestimate the duration of elevated concentrations in the river, thus the overall UBSR (2012) model results would provide a conservative estimate of the short-term impacts of dam removal on suspended sediments in the Klamath River.

The analysis of short-term suspended sediment-related impacts also considers results from previous studies (e.g., Stillwater Sciences 2010) regarding anticipated sediment release from Klamath River Dam removal within the context of sediment delivery at the broader scale of the Klamath Basin.

The long-term impact analysis of suspended materials uses existing data sources for TSS and turbidity sources to the Hydroelectric Reach and the Middle and Lower Klamath River (e.g., PacifiCorp 2004a, 2004b; YTEP 2005; Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Existing analyses of the potential effects of dam removal on long-term sediment supply (Stillwater Sciences 2010) are also considered.

3.2.4.3 Nutrients

Under the Proposed Project, short-term nutrient loads associated with high SSCs are assessed in a qualitative manner, considering the likelihood of sediment deposition in the Lower Klamath River, seasonal rates of primary productivity and microbially mediated nutrient cycling, and potential light limitation of primary producers given the high sediment concentrations in the river.

Additionally, the analysis uses Klamath River TMDL model runs to evaluate the general long-term trends (both spatial and temporal) for nutrients in the Hydroelectric Reach and the Middle and Lower Klamath River. The Klamath River TMDL model includes a “TMDL dams-in” scenario (T4BSRN), which approximates the condition where the Lower Klamath Project dams remain in place, as well as the TOD2RN (Oregon reaches) and TCD2RN (California reaches) scenarios (together the “TMDL dams-out” scenario) that assume the removal of the Lower Klamath Project (see Appendix D for more detail). The Klamath River TMDL model assumes full TMDL implementation for both the dams-in and dams-out scenarios (Tetra Tech 2009); however, the mechanisms for implementation and the timing required to achieve future TMDL compliance are currently speculative. Despite this assumption, the Klamath River TMDL model results are still informative with respect to the analysis of potential nutrient impacts under the Proposed Project, particularly since nutrient models were not developed for the FERC relicensing process. To place the Proposed Project analysis in context, results of the “TMDL dams-out” Oregon scenario (TOD2RN) and “TMDL dams-out” California scenario (TCD2RN) are generally interpreted with respect to starting assumptions (i.e., model boundary conditions) about nutrient concentrations. The Klamath River TMDL provides modeling results for all mainstem Klamath River reaches associated with the water quality nutrient analysis for this EIR (see Appendix D, Table D-1).

Long-term trends for nutrients under the Proposed Project are also assessed in this EIR using a prior study of potential nutrient dynamics under a “dams-out” scenario (Asarian et al. 2010). The prior study used nutrient measurements and hydrologic data for the Klamath River, to develop nutrient budgets for June through October of 2005–2008 for the free-flowing reaches of the Klamath River. The prior study included longitudinal trends in absolute and relative retention of TP and TN, and it also compared nutrient retention rates between free-flowing river reaches and reservoir reaches and developed a range of estimates for the degree to which seasonal TP and TN concentrations downstream from Iron Gate Dam might be altered by dam removal. The 2005–2008 study used hydrologic and nutrient data collected by a variety of tribal, federal, and state agencies, and PacifiCorp. The nutrient budget estimates for 2005–2008 improve upon estimates made for the earlier period 1998–2002 (Asarian and Kann 2006a) by using flow- and season-based multiple regression models for predicting daily nutrient concentrations and loads and quantification of uncertainty, relatively lower laboratory reporting limits, higher sampling frequency, and nutrient speciation (not just TN and TP). As compared to the 1998–2002 period, the nutrient budget estimates for 2005–2008 also used improved accounting for peaking flows in the J.C. Boyle Bypass Reach. The effects of dam removal were quantified using calculated relative retention rates in river reaches and comparing them to results from a retention study of Copco No. 1 and Iron Gate reservoirs by Asarian et al. (2009).

3.2.4.4 Dissolved Oxygen

Both short-term and long-term effects on dissolved oxygen levels due to the Proposed Project are analyzed in this EIR. For short-term effects, results of numerical modeling conducted as part of the Klamath Dam Removal Secretarial Determination studies are used to describe predicted short-term dissolved oxygen levels in the Hydroelectric Reach and downstream from Iron Gate Dam due to oxygen demand from mobilized reservoir sediments during dam removal. The one-dimensional, steady-state spreadsheet model uses an approach similar in concept to the Streeter and Phelps (1925) dissolved oxygen-sag equation to incorporate the oxygen-demand offsets of tributary dilution and re-aeration in evaluating the different short-term oxygen demand parameters (e.g., BOD, immediate oxygen demand [IOD], and SOD). The BOD/IOD spreadsheet model also includes chemical oxygen demand generated from the conversion of ammonium and other nitrogenous compounds in reservoir sediments to nitrate under oxic conditions (i.e., when dissolved oxygen levels are 0 mg/L or greater). This is termed nitrogenous oxygen demand and is inherently included in the oxygen demand rate constants used in the BOD/IOD spreadsheet model (Stillwater Sciences 2011).

BOD and IOD are predicted in the spreadsheet model using empirically derived oxygen depletion rates for a particular SSC based on laboratory incubations conducted under the Klamath Dam Removal Secretarial Determination oxygen demand study (Stillwater Sciences 2011). Oxygen depletion rates are scaled to the level of suspended sediments expected under each of the three water year types (typical dry, median, and typical wet water years) considered for the USBR hydrology and sediment transport modeling assessment (see Section 3.2.4.2 *Suspended Sediments*).

The BOD/IOD spreadsheet model assumes drawdown for Copco No. 1 Reservoir begins on November 1 and drawdown for J.C. Boyle and Iron Gate reservoirs begins on January 1, consistent with the Proposed Project (USBR 2012). This would allow maximum SSCs to occur during winter months when flows are naturally high in the mainstem river (Stillwater Sciences 2008, USBR 2012). While Copco No. 1 and Iron

Gate reservoirs exhibit varying degrees of thermal stratification and hypolimnetic anoxia during summer months (see Section 3.2.2.2 *Water Temperature*), all of the reservoirs tend to experience fully-mixed conditions by November/December and remain mixed through April/May. Thus, drawdown beginning in November or January is expected to involve a well-oxygenated water column and inflowing water and, potentially, an oxic sediment top layer. This is important because the spreadsheet model is highly sensitive to background concentrations of dissolved oxygen (Stillwater Sciences 2011), which are generally highest in the Lower Klamath Project reservoirs during winter months (see Section 3.2.2.2 *Water Temperature* and Appendix C). The BOD/IOD spreadsheet model results encompass a six-month period following drawdown in order to estimate potential dissolved oxygen minimum concentrations corresponding to the period of greatest sediment transport in the river under the Proposed Project.

For long-term effects, existing information on water quality dynamics and physical, chemical, and biological drivers for dissolved oxygen concentrations in the Klamath River are used to inform the impacts analysis. Additionally, the analysis of the Proposed Project's potential short-term and long-term impacts on dissolved oxygen is informed by two quantitative models: the Klamath River Water Quality Model (KRWQM) and the Klamath River TMDL model. Both of these models include a scenario that is similar to existing conditions (i.e., with the Lower Klamath Project dams in place) and scenarios with one or more dams removed that are similar to the Proposed Project and/or alternatives analyzed in Section 4 *Alternatives*. The KRWQM was developed for FERC relicensing of the Klamath Hydroelectric Project (PacifiCorp 2004a), and it was later used to inform development of the Klamath River TMDL model. The Klamath River TMDL model was developed to inform the Oregon and California Klamath River TMDLs. The Klamath River TMDL model includes a "TMDL dams-in" scenario (T4BSRN), which approximates the condition where the Lower Klamath Project dams remain in place, as well as the TOD2RN (Oregon reaches) and TCD2RN (California reaches) scenarios (together the "TMDL dams-out" scenario) that assume the removal of the Lower Klamath Project (see Appendix D for more detail). The Klamath River TMDL model assumes full TMDL implementation for both the dams-in and dams-out scenarios (Tetra Tech 2009); however, the mechanisms for implementation and the timing required to achieve future TMDL compliance are currently speculative. Despite this assumption, the Klamath River TMDL model results are still informative with respect to the analysis of potential long-term dissolved oxygen impacts under the Proposed Project, particularly for reaches where the KRWQM was not run for the FERC relicensing process (see Section 3.2.5 *Potential Impacts and Mitigation* for additional discussion).

Additional details regarding available numeric models for analysis of long-term dissolved oxygen are presented in Appendix D. Table D-1 shows the reaches where KRWQM and Klamath River TMDL model results are used for the water quality analysis under the Proposed Project and each alternative and Table D-2 presents a comparison of assumptions and parameters for the available numeric models, including flow assumptions. Since no single existing model captures all of the elements analyzed for dissolved oxygen in this EIR, model outputs are used in combination to assess similar spatial and temporal trends in predicted dissolved oxygen where possible.

3.2.4.5 pH

Short-term effects of the Proposed Project on pH are assessed based on the current understanding of seasonal effects of the Lower Klamath Project reservoirs on pH within the Hydroelectric Reach and the Middle and Lower Klamath River downstream from Iron Gate Dam.

For long-term effects, existing data characterizing pH in the Hydroelectric Reach and the Middle and Lower Klamath River are used to inform the impacts analysis. Additionally, the analysis uses Klamath River TMDL model runs to evaluate the general long-term trends (both spatial and temporal) for pH in the Hydroelectric Reach and the Middle and Lower Klamath River. The Klamath River TMDL model includes a "TMDL dams-in" scenario (T4BSRN), which approximates the condition where the Lower Klamath Project dams remain in place, as well as the TOD2RN (Oregon reaches) and TCD2RN (California reaches) scenarios (together the "TMDL dams-out" scenario) that assume the removal of the Lower Klamath Project (see Appendix D for more detail). The Klamath River TMDL model assumes full TMDL implementation for both the dams-in and dams-out scenarios (Tetra Tech 2009); however, the mechanisms for implementation and the timing required to achieve future TMDL compliance are currently speculative. Despite this assumption, the Klamath River TMDL model results are still informative with respect to the analysis of potential pH impacts under the Proposed Project, particularly since pH models were not developed for the FERC relicensing process. To place the Proposed Project analysis in context, results of the "TMDL dams-in" Oregon scenario (TOD2RN) and "TMDL dams-in" California scenario (TCD2RN) are generally interpreted with respect to starting assumptions (i.e., model boundary conditions) about pH. The Klamath River TMDL provides modeling results for all mainstem reaches associated with the water quality pH analysis for this EIR (see Appendix D, Table D-1).

3.2.4.6 Chlorophyll-a and Algal Toxins

Potential impacts of the Proposed Project on the algal community (phytoplankton, aquatic macrophytes, and periphyton) in the Klamath River are discussed in Section 3.4 *Phytoplankton and Periphyton*. Chlorophyll-*a* is analyzed as a separate water quality parameter in the Lower Klamath Project EIR because it is a surrogate measure of algal biomass and it is a target specific to the Lower Klamath Project reservoirs in the California Klamath River TMDLs (North Coast Regional Board 2010). The Hoopa Valley Tribe water quality objective for chlorophyll-*a* is a measure of attached (benthic) algal growth rather than phytoplankton growth, so it is not discussed further in this section.

Sufficiently accurate quantitative predictive tools for chlorophyll-*a* are not available for the Lower Klamath Project EIR impact analysis. While the California Klamath River TMDLs model includes a chlorophyll-*a* component covering both periphyton and phytoplankton, the model appears to over-predict chlorophyll-*a* under the "dams-out" scenario (Tetra Tech 2008) and is therefore not used for the Lower Klamath Project EIR analysis. The chlorophyll-*a* target (10 ug/L) developed for the Lower Klamath Project reservoirs in the California Klamath River TMDLs is based on a Nutrient Numeric Endpoints (NNE) analysis. The chlorophyll-*a* target of 10 ug/l (i.e. reduction to) is a conservative estimate of mean summer chlorophyll-*a* concentrations required to move the system toward support of beneficial uses (Creager et al. 2006, Tetra Tech 2008).

Instead, this EIR's chlorophyll-*a* impact analysis is based on a qualitative assessment of whether the Proposed Project would result in exceedances of the California 10 ug/L target for the Lower Klamath Project reservoirs and adversely affect beneficial uses with respect to water column concentrations of chlorophyll-*a*. Growth conditions for suspended algae (e.g., nutrient availability, impounded water) are considered as part of the qualitative analysis, where predicted changes in nutrient availability, water temperatures, and the availability of lake or reservoir conditions would correspondingly affect chlorophyll-*a* concentrations.

Since algal toxins are a water quality concern and have the potential to affect designated beneficial uses of water, an analysis of the potential impacts of the Proposed Project on algal toxins as related to water quality standards and beneficial uses is also included in the water quality impacts analysis. There are no quantitative models predicting algal toxin trends under a dam removal scenario, thus the impact analysis is based upon trends in the density of toxin-producing blue-green algae, including *Microcystis aeruginosa,* to algal toxin concentrations (see Section 3.2.2.7 and Appendix C) discerned from data collected in the Hydroelectric Reach and the Middle and Lower Klamath River. This information is considered along with the potential for changes in habitat availability for *Microcystis aeruginosa* (or other toxin-producing blue-green algae) under the Proposed Project.

3.2.4.7 Inorganic and Organic Contaminants

The determination of potential toxicity and bioaccumulation with respect to aquatic species and humans under the Proposed Project is based on the evaluation of existing data characterizing inorganic and organic contaminants associated with both reservoir water quality and sediment deposits, with comparison to thresholds for human and aquatic species exposure.

In particular, the Klamath Dam Removal Secretarial Determination sediment evaluation process followed screening protocols of the Sediment Evaluation Framework (SEF), issued by the interagency Regional Sediment Evaluation Team (RSET) in 2009 and updated in 2018 (Appendix C – *Section C.7*). The RSET is comprised of the USACE (Northwestern Division and Portland, Seattle, and Walla Walla Districts), the USEPA (Region 10), NOAA Fisheries (West Coast Region), USFWS (Pacific Region), ODEQ, Idaho Department of Environmental Quality, Washington Department of Ecology, and Washington Department of Natural Resources. The RSET developed the SEF to provide an approach for evaluating the suitability of sediments for placement in aquatic environments. The SEF involves a data screening assessment to compare reservoir sediment data to available and appropriate sediment maximum levels, screening levels, and bioaccumulation triggers established by the RSET. It also provides guidance for conducting elutriate chemistry (the chemistry of the water between grains of sediment, which can also be referred to as pore water), toxicity bioassays, and bioaccumulation tests, and special evaluations such as tissue analysis and risk assessments (the latter not utilized for this evaluation). The results of the SEF-based evaluation for the 2009–2010 Klamath River sediment samples are used to inform the water quality impacts analysis related to inorganic and organic contaminants under the Proposed Project.

In the Klamath Dam Removal Secretarial Determination process, sediment data were compared to established sediment screening values in a step-wise manner to systematically consider potential impact pathways. Elutriate[45] sample data were also

[45] Elutriate sediment samples were created from reservoir composite sediment samples mixed with reservoir water (e.g., one part sediment to four parts water). In general, elutriate tests are a standard approach that analyzes the chemical composition of the overlying water of the elutriate

evaluated through comparison with a suite of regional, state and federal standards for water quality (CDM 2011). In this EIR, elutriate test results are considered in light of the dilution that would occur under actual conditions during reservoir drawdown.

Biological testing was also conducted during the Klamath Dam Removal Secretarial Determination process using the SEF approach, and the testing consisted of sediment and elutriate toxicity testing and tissue analyses, or other evaluations designed to provide more empirical evidence regarding the potential for sediment contaminant loads to have adverse impacts on receptors (RSET 2009, 2018). While whole sediment toxicity tests identify potential contamination that may affect bottom-dwelling (benthic) organisms, toxicity tests using suspension/elutriates of dredged material assess potential water column toxicity. Bioaccumulation evaluation is undertaken when bioaccumulative chemicals of concern exceed or may exceed sediment screening levels, and thus further evaluation is needed to determine whether they pose a potential risk to human health or ecological health in the aquatic environment (RSET 2009, 2018).

Results from sediment and elutriate sample toxicity bioassays and sediment bioaccumulation tests carried out for the Klamath Dam Removal Secretarial Determination studies are used to provide additional information beyond simple comparisons of sediment contaminant levels to individual-contaminant regional or national screening levels. The results of sediment and elutriate sample toxicity bioassays provide a direct assessment of potential toxicity that takes into account possible interactive effects of mixtures of multiple contaminants, and of potential contaminants that may be present but were not individually measured.

3.2.5 Potential Impacts and Mitigation

Unless otherwise noted, the potential impacts for each water quality parameter are presented in terms of the physical or chemical process that would potentially cause a change in the existing condition. This potential change is then described and analyzed against the applicable significance criteria in Section 3.2.3 *Significance Criteria*, including application of applicable thresholds described in Section 3.2.3.1 *Thresholds of Significance*.

3.2.5.1 Water Temperature

Potential Impact 3.2-1 Short-term and long-term alterations in water temperatures due to conversion of the reservoir areas to a free-flowing river.

Reservoirs and free-flowing rivers have different effects on water temperatures, and these can vary on a seasonal and annual basis with the size (surface area, depth) and shape of the waterbody (see discussion of general effects on water quality from hydroelectric project reservoirs in Section 3.2.2.1 *Overview of Water Quality Processes in the Klamath Basin*). This potential impact evaluates the changes in the water temperature regime that are expected under the Proposed Project against the significance criteria for temperature.

sediment sample in order to estimate potential chemical concentrations in the water between the grains of sediment (pore water). Standard elutriate tests do not reflect the full dilution of re-suspended sediments that would occur during dam removal.

Hydroelectric Reach

The KRWQM did not model water temperatures within the Hydroelectric Reach. Klamath River TMDL model (see Appendix D) results indicate that if the Lower Klamath Project dams were to be removed ("TMDL dams-out, Oregon" [TOD2RN] scenario), water temperatures in the J.C. Boyle Peaking Reach at the Oregon-California state line (RM 214.1) would exhibit slightly lower daily maximum values (0.0–3.6°F) as compared to those predicted under the scenario where the dams remain in place ("TMDL dams-in" [T4BSRN] scenario) (Figure 3.2-7). Temperatures at these locations would also exhibit lower diel (i.e., 24-hour period) water temperature variation during June through September (Figure 3.2-7), and a general trend moving toward a more natural thermal regime (North Coast Regional Board 2010, data from electronic appendices of Asarian and Kann 2006b). The relative difference in diel water temperature variation between these two scenarios would be due to the elimination of peaking operations at J.C. Boyle Powerhouse and the associated large artificial temperature swings that occur in the Klamath River downstream.

Overall, the Klamath River TMDL model results indicate that in the short term and long term, the Proposed Project would decrease maximum summer/fall water temperatures. The Proposed Project would also result in less artificial diel water temperature swings in the J.C. Boyle Peaking Reach from the Oregon-California state line to Copco No. 1 Reservoir, returning the Klamath River to a more natural thermal regime compared with existing conditions. Elimination of both of these artificial temperature increases would better conform with the California Thermal Plan's prohibition on elevated temperature discharges (Table 3.2-4).

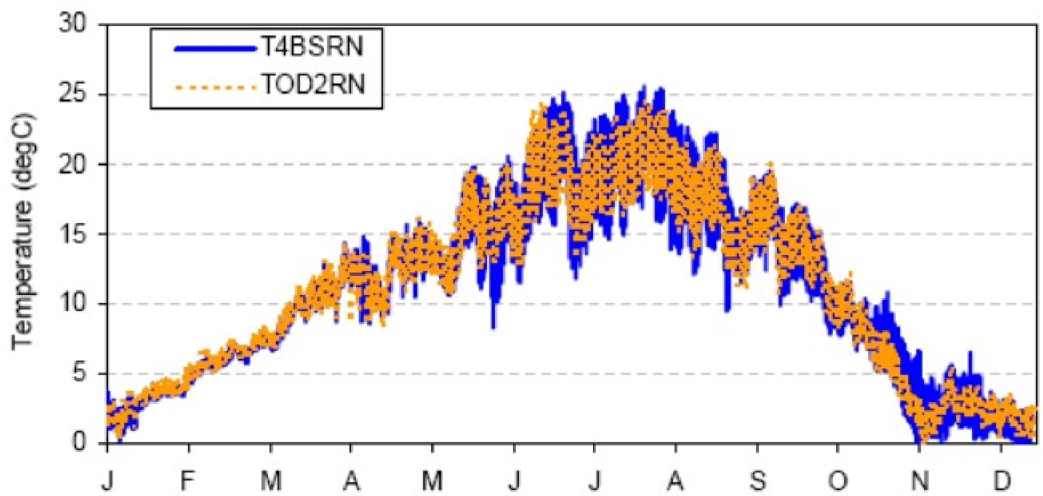

Figure 3.2-7. Predicted Water Temperature at the Oregon-California State Line (RM 214.1) for the Klamath River TMDL Scenarios Similar to the Proposed Project ("TMDL dams-out, Oregon" [TOD2RN] Scenario) and Existing Conditions ("TMDL dams-in" [T4BSRN] Scenario). Source: North Coast Regional Board 2010.

Farther downstream of the J.C. Boyle Peaking Reach (i.e., from Copco No. 1 Reservoir to Iron Gate Dam), the presence of the Lower Klamath Project reservoirs currently decreases spring water temperatures as compared to modeled natural conditions by up to 7°C (13°F) and increases water temperatures as compared to modeled natural conditions by up to roughly 4°C (7°F) (Figure 3.2-3). The Klamath River TMDL model indicates that removal of the Lower Klamath Project under the Proposed Project would eliminate the seasonal temperature shift caused by the Lower Klamath Project reservoirs, returning the Klamath River to a more natural thermal regime. More specifically, the Klamath River TMDL model indicates that just downstream from Copco No. 1 and Copco No. 2 reservoirs (approximately RM 201), removal of the Lower Klamath Project dams would increase daily maximum temperatures to a more natural regime for a period in spring (May and June) and decrease daily maximum temperatures to a more natural regime in late summer/fall (August through October).

Note that the Klamath River TMDL model scenarios are useful for informing impacts associated with the Proposed Project and alternatives identified in Section 4 *Alternatives*, but they include as a starting assumption that there will be full implementation of the TMDLs. For example, the "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios for California both assume that water entering into California from Oregon meets California water quality standards for water temperature, organic enrichment/low dissolved oxygen, nutrients, pH, and microcystin. In other words, the starting point for the California models is that all necessary reductions in pollution to address the current impaired conditions at the Oregon-California state line for these constituents would already have been implemented upstream. The full TMDL compliance modeling assumption does not reflect the existing condition, and it would be speculative at this point to identify either the mechanisms necessary to implement the TMDLs or the timing required to achieve full compliance. However, besides the Lower Klamath Project facilities themselves, the temperature point sources (e.g., industrial discharges, sewage treatment plant discharges) located along the Klamath River between Lake Ewauna (approximately RM 257) to upstream of the Shasta River confluence (RM 179.5) have a negligible impact on water temperatures represented in the TMDL model (North Coast Regional Board 2010). Thus, removal of J.C. Boyle Reservoir and its associated hydropower peaking operations, as well as Copco No. 1, Copco No. 2, and Iron Gate reservoirs, dominates the model response. The Klamath River TMDL model illustrates that dam removal would rapidly and substantially move the Hydroelectric Reach towards achieving California TMDL compliance.

Water temperature modeling conducted for the Klamath Dam Removal Secretarial Determination Studies (RBM10) provides generally similar results as the Klamath River TMDL model but includes consideration of future climate change and a KBRA flow regime (see Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project* for an assessment of the KBRA and 2013 BiOp flow regimes). Expected increases in summer and fall water temperatures in the Klamath Basin associated with climate change considerations are on the order of 1.8–5.4°F between 2012 and 2061 (Bartholow 2005; Perry et al. 2011). RBM10 model results show a projected shift in the annual temperature cycle that would slightly increase river temperatures in the spring and decrease river temperatures in the late summer/fall in the Hydroelectric Reach under the Proposed Project (Perry et al. 2011; USBR 2016), consistent with the general trend demonstrated by the Klamath River TMDL model results. Further discussion of RBM10 results is presented below for the Middle and Lower Klamath River.

Overall, dam removal under the Proposed Project would cause water temperatures in the Hydroelectric Reach[46] to align with historical anadromous migration and spawning periods for the Klamath River, warming earlier in the spring, and cooling earlier in the fall compared to existing conditions (see also Section 3.3.5.4 *Aquatic Resources – Water Temperature*). The return to a more natural thermal regime compared with existing conditions would align better with the California Thermal Plan's prohibition on increased temperature discharges above natural temperatures and would be beneficial.

Because drawdown of the reservoirs would begin in winter and would be largely complete by spring prior to thermal stratification in the reservoirs, water temperature alterations caused by the Proposed Project in the Hydroelectric Reach as a whole would be beneficial in the short term. As noted above, dam removal would rapidly and substantially move the Hydroelectric Reach towards achieving California TMDL compliance.

In the long term, the Proposed Project would help to decrease temperatures in the late summer/fall in the Hydroelectric Reach as a whole when climate change is expected to increase summer and fall water temperatures in the Klamath Basin on the order of 1.8–5.4°F between 2012 and 2061 (Bartholow 2005; Perry et al. 2011).

In summary, under the Proposed Project, the anticipated increases in springtime water temperatures in the Hydroelectric Reach as a whole and decreases in diel temperature variation in the J.C. Boyle Peaking Reach from the Oregon-California state line to Copco No. 1 Reservoir, would return the Klamath River to a more natural thermal regime compared with existing conditions. The projected decreases in late summer/fall water temperatures in the Hydroelectric Reach as a whole also would return the Hydroelectric Reach to a more natural thermal regime compared with existing conditions and would align better with the California Thermal Plan's prohibition on increased temperature discharges above natural temperatures. These effects would be beneficial in the short term and would rapidly move the Hydroelectric Reach towards achieving California TMDL compliance. In the long term, the beneficial effects would also help to offset the impacts of climate change on late summer/fall water temperatures.

Middle and Lower Klamath River, Klamath River Estuary, and Pacific Ocean Nearshore Environment

Water temperature modeling results are available for the Middle and Lower Klamath River downstream of Iron Gate Dam from three separate modeling efforts: the PacifiCorp relicensing efforts (KRWQM); development of the California Klamath River TMDLs; and water temperature modeling conducted for the Klamath Dam Removal Secretarial Determination studies (RBM10). For more information on these models, please see Section 3.2.4.1 *Water Temperature* (overview) and Appendix D (detailed). KRWQM results comparing existing conditions (all Lower Klamath Project dams in place) to four without-project scenarios[47] for 2001–2004 indicate that the reservoirs create a temporal

[46] Under existing conditions, anadromous fish do not migrate into or spawn in the Hydroelectric Reach due to the fish passage barriers caused by the Lower Klamath Project dams. Under the Proposed Project, these barriers would be removed.

[47] The four without-project scenarios are: 1) without Lower Klamath Project dams and Keno Dam; 2) without Iron Gate Dam; 3) without Copco No. 1, Copco No. 2, and Iron Gate dams; and 4) without J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams (most similar to the Proposed Project).

shift by releasing generally cooler water from mid-January to April, variably cooler or warmer water from April through early August, and warmer water from August through November (PacifiCorp 2004a, Dunsmoor and Huntington 2006). Just downstream from Iron Gate Dam, this translates to an approximately 2°F to 5°F cooling during spring and an approximately 4°F to 18°F warming during summer and fall (Figure 3.2-8). Immediately upstream of the confluence with the Scott River (RM 145.1), the difference between existing conditions and the dam removal scenario modeled using the KRWQM indicates a lesser, albeit still measurable, warming of approximately 4°F to 9°F for most of October and November (Figure 3.2-9). Because patterns in reservoir thermal structure for Iron Gate and Copco No. 1 reservoirs indicate that stratification generally starts in April and ends in November, the effect of reservoir thermal regime on downstream water temperatures appears to be cooling during non-stratified periods and warming during stratified periods.

The KRWQM model results also indicate that reservoir thermal regimes under existing conditions act to reduce the magnitude of diel temperature variation compared with natural conditions in the river reaches immediately downstream from Iron Gate Reservoir (RM 193.1; see Figure 3.2-8) (Deas and Orlob 1999, PacifiCorp 2005). As with the seasonal temperature effect, the dampening influence on diel temperature variation is considerably diminished farther downstream, at the confluence with the Scott River (RM 145.1; see Figure 3.2-9). The KRWQM indicates that the overall water temperature influence of the Hydroelectric Reach is mostly attenuated by RM 66.3 at the confluence with the Salmon River (see Figure 3.2-10).

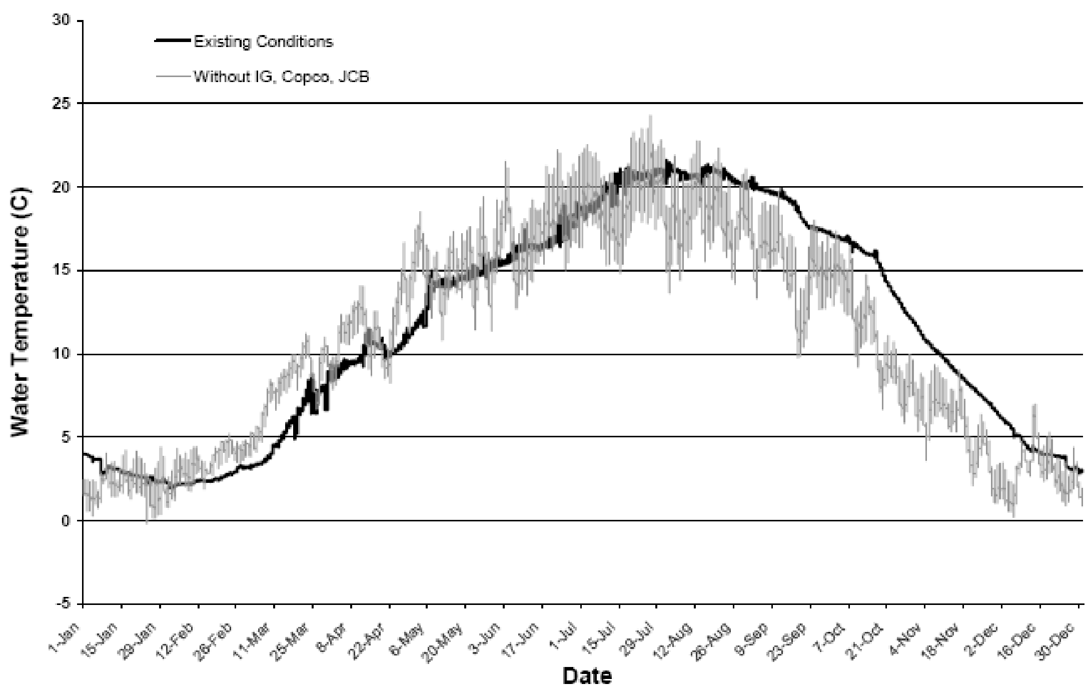

Figure 3.2-8. Simulated Hourly Water Temperature Downstream from Iron Gate Dam Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco No. 1, Copco No. 2, and Iron Gate (IG) Dams. Source: PacifiCorp 2005.

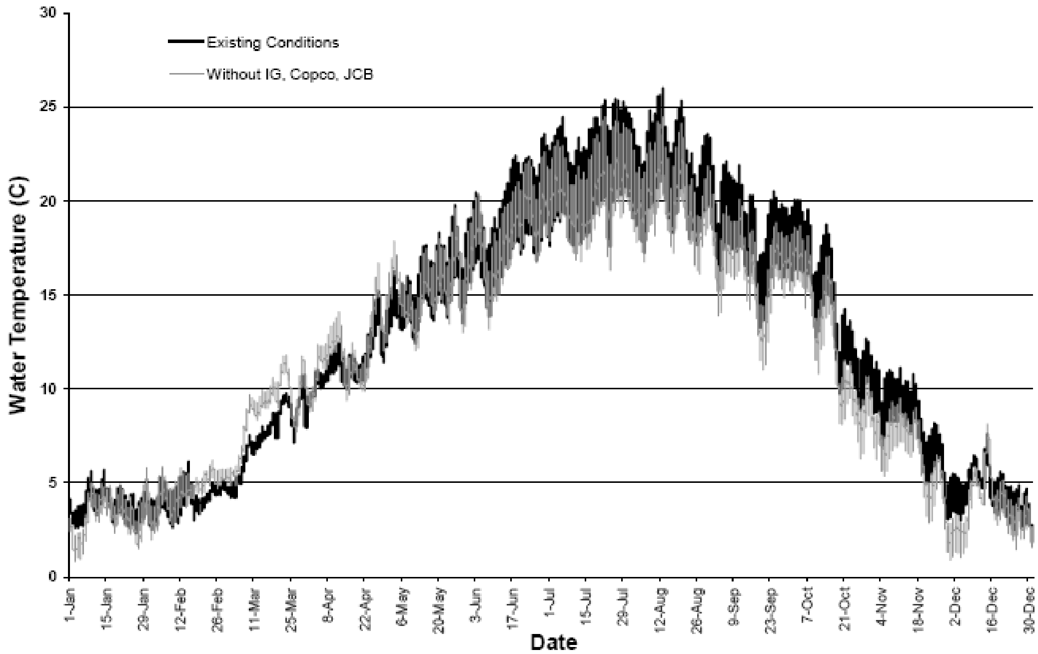

Figure 3.2-9. Simulated Hourly Water Temperature Immediately Upstream of the Scott River Confluence (RM 145.1) Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco No. 1, Copco No. 2, and Iron Gate (IG) Dams. Source: PacifiCorp 2005.

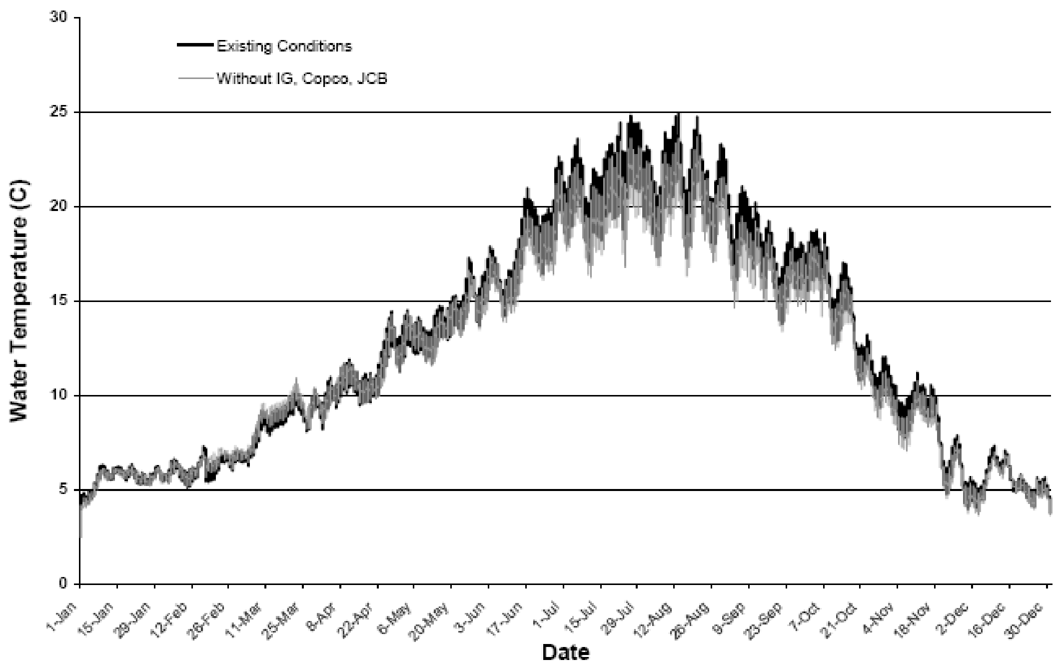

Figure 3.2-10. Simulated Hourly Water Temperature Downstream from the Salmon River Confluence (≈RM 66.3) Based on Year 2004 for Existing Conditions Compared to Hypothetical Conditions without J.C. Boyle (JCB), Copco No. 1, Copco No. 2, and Iron Gate (IG) Dams. Source: PacifiCorp 2005.

In agreement with KRWQM results, Klamath River TMDL model results also indicate that if the Lower Klamath Project dams were to be removed ("TMDL dams-out, California" [TCD2RN] scenario), then water temperature in the Klamath River downstream from Iron Gate Dam would be lower (by 4°F to 18°F) during August through November and higher (by 4°F to 9°F) during January through March (dams remaining in place would be the "TMDL dams-in" [T4BSRN] scenario) (North Coast Regional Board 2010). The Klamath River TMDL model also predicts that diel variation in water temperature downstream from Iron Gate Dam during these same periods would be greater for a dam removal scenario ("TMDL dams-out, California" [TCD2RN]) than a dams in-place scenario ("TMDL dams-in" [T4BSRN]) because river water temperatures would be in equilibrium with, and would reflect, diel variation in ambient air temperatures rather than being dominated by the large thermal mass of, and stratification patterns in, the reservoirs. Note that the Klamath River TMDL model for both "dams-in" and "dams-out" scenarios assumes full implementation of the TMDLs, a condition that is currently highly speculative with respect to the mechanisms and timing required to achieve future compliance. However, besides the Lower Klamath Project facilities themselves, because the temperature point sources (e.g., industrial discharges, sewage treatment plant discharges) located along the Klamath River between Lake Ewauna (approximately RM 257) to upstream of the Shasta River confluence (RM 179.5) have a negligible impact on water temperatures represented in the Klamath River TMDL model (North Coast Regional Board 2010), removal of the Lower Klamath Project reservoirs dominates model response for the referenced point downstream of Iron Gate Dam. Further, although the Klamath River TMDL model assumes full implementation of the Scott River TMDL (North Coast Regional Board 2005) and the Shasta River TMDL (North Coast Regional Board 2006) for the "dams-out" scenario, it also assumes full implementation of these major tributary TMDLs for the "dams-in" scenario, such that in the reach downstream of Iron Gate Dam, the only difference between the two model scenarios is the removal of the Lower Klamath Project. Thus, even under the assumption of full TMDL compliance, the model illustrates that dam removal would rapidly and substantially move the Klamath River downstream of Iron Gate Dam towards achieving TMDL compliance.

As with KRWQM, the Klamath River TMDL model indicates that the temperature effects of removing the Lower Klamath Project would decrease in magnitude with distance downstream from Iron Gate Dam, and they would not be evident in the reach downstream from the Salmon River confluence (approximately RM 66.3) (North Coast Regional Board 2010; Dunsmoor and Huntington 2006). Therefore, under a dam removal scenario that also assumes full TMDL implementation ("TMDL dams-out, California" [TCD2RN] scenario), water temperatures would not be directly affected in the Middle Klamath River downstream from the confluence with the Salmon River and would not affect temperatures farther downstream in the Lower Klamath River, the Klamath River Estuary, or the Pacific Ocean nearshore environment.

As part of the Klamath Dam Removal Secretarial Determination studies, the effects of climate change and of KBRA flows (which, as discussed in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project* sufficiently bracket the range of flows under the existing condition*)* were included in projections for future water temperatures under the Proposed Project using the RBM10 model. RBM10 model results using climate change predictions from five GCMs indicate that future water temperatures under the Proposed Project and climate change would be 1.8–4.1°F warmer than historical temperatures (Perry et al. 2011). This temperature range is slightly lower than that suggested by projecting Bartholow (2005) historical (1962–2001) estimates of 0.09°F per year, or approximately 4°F to 5°F over 50 years. However, within the general uncertainty of climate change projections, results from the two models correspond reasonably well and indicate that water temperatures in the Upper Klamath Basin are expected to increase on the order of 2°F to 5°F between 2012 and 2061.

RBM10 results also indicate that, even with warming of water temperatures under climate change, the primary long-term effect of dam removal downstream of Iron Gate Dam is still anticipated to be the return of approximately 126 miles of the Middle Klamath River, from Iron Gate Dam (RM 193.1) to the Salmon River (RM 66), to a more natural thermal regime (Perry et al. 2011). Model results indicate that the annual temperature cycle downstream from Iron Gate Dam would shift forward in time by approximately 18 days under the Proposed Project, with warmer temperatures in spring and early summer and cooler temperatures in late summer and fall immediately downstream from the dam. Just downstream from Iron Gate Dam, water temperatures under the Proposed Project, including climate change, would average approximately 4°F greater in May, while during October water temperatures would average approximately 7°F cooler. At the confluence with the Scott River, the differences would be diminished, but there would still be a slight warming in the spring (May) with average water temperatures approximately 2°F greater and a slight cooling in the fall (October) with average water temperatures approximately 4°F less. Water temperature changes from the Proposed Project would be less than 1°F at the confluence with the Salmon River (RM 66) in agreement with the Klamath River TMDL model results (Perry et al. 2011). Thus, despite the anticipated warming under climate change, long-term water temperature improvements under the Proposed Project would support continued achievement of the California temperature TMDLs for the mainstem Klamath River.

All of the existing water temperature model projections (KRWQM, TMDL, RBM10) indicate that dam removal under the Proposed Project would cause water temperatures in the Middle Klamath River to align better with historical anadromous migration and spawning periods for the Klamath River, warming earlier in the spring, and cooling earlier in the fall compared to existing conditions. Warmer springtime temperatures would result in fry emerging earlier, encountering favorable temperatures for growth sooner than under existing conditions, which could support higher growth rates and encourage earlier outmigration downstream, similar to what likely occurred under historical conditions, and reduce stress and disease (Bartholow et al. 2005, FERC 2007). In addition, fall-run Chinook salmon spawning in the mainstem Klamath River during fall would no longer be delayed (reducing pre-spawn mortality), and adult migration would occur in more favorable water temperatures than under existing conditions. Overall, these changes would result in water temperatures more favorable for salmonids in the mainstem Klamath River downstream from Iron Gate Dam (see also Section 3.3.5.4 *Aquatic Resources – Water Temperature*). The return to a more natural thermal regime compared with existing conditions would align better with the California Thermal Plan's prohibition on increased temperature discharges above natural temperatures and would be beneficial.

As drawdown of the Lower Klamath Project reservoirs would begin in winter and would be largely complete by spring prior to thermal stratification in the reservoirs, the water temperature alterations resulting from dam removal under the Proposed Project in the Klamath River downstream from Iron Gate Dam would occur, either partially or fully, within the first one to two years following dam removal and would be considered short-term benefits. As noted above, removal of the Lower Klamath Project Reservoirs would rapidly and substantially move the Klamath River downstream of Iron Gate Dam towards achieving TMDL compliance. Additionally, water temperature alterations due to the Proposed Project would continue beyond three years following dam removal so they would also be long-term benefits. The Proposed Project's temperature benefits on late summer/fall water temperatures may be of additional assistance in helping to offset the impacts of climate change on late summer/fall Klamath River water temperatures.

In summary, under the Proposed Project, the short-term and long-term increases in spring water temperatures, increased diel temperature variation, and decreases in late summer/fall water temperatures in the Middle Klamath River for the reach from Iron Gate Dam to the confluence with the Salmon River would be beneficial. There would be no impact for water temperatures in the Middle Klamath River downstream from the Salmon River, Lower Klamath River, Klamath River Estuary, or Pacific Ocean nearshore environment.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes temperature monitoring. The State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section 401. The State Water Board has issued a draft water quality certification which sets forth monitoring and adaptive management requirements for any Water Quality Monitoring Plan to meet, as Condition 1[48]. Additionally, the Oregon Department of Environmental Quality has issued a final water quality certification[49] that sets forth water quality monitoring and adaptive management conditions for points upstream of California. The effect of the Proposed Project on water temperature is anticipated to be beneficial in both the short and long term, and this analysis of Potential Impact 3.2-1 does not further discuss the water quality monitoring and adaptive management conditions.

Significance

Beneficial for the Hydroelectric Reach and the Middle Klamath River to the confluence with the Salmon River, in the short term and in the long term

No significant impact for the Middle Klamath River downstream from the Salmon River, Lower Klamath River, Klamath River Estuary, and Pacific Ocean nearshore environment in the short term or the long term

Potential Impact 3.2-2 Short-term and long-term alterations in seasonal water temperatures in the Klamath River Estuary due to morphological changes induced by dam removal sediment release and subsequent deposition in the estuary.
Increased sediment deposition in the Klamath River Estuary due to sediment releases from dam removal may change the shape of the estuary in a way that could impact water temperatures. Such morphological changes could be from, for example, shifted

[48] The State Water Board's draft water quality certification is available online at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 11, 2018).

[49] The Oregon Department of Environmental Quality's final water quality certification is available online at: https://www.oregon.gov/deq/FilterDocs/ferc14803final.pdf (Accessed December 14, 2018).

bed elevations or changes to the contours of the bottom of the estuary. The amount of sediment deposition in the estuary as a result of dam removal is anticipated to be small, as sediment release would coincide with and be driven by high flows associated with dam removal; therefore, sediment deposition in the estuary associated with dam removal is not expected to be widespread, but it would occur in backwaters or vegetated areas, if at all (Stillwater Sciences 2008, USBR 2012) (see also Potential Impact 3.11-5). Morphological changes that decrease the depth of Klamath River Estuary waters or the volume of the estuary waters could result in more solar radiation being absorbed by a smaller water volume, which would tend to increase estuary water temperatures. Additionally, morphological changes that reduce estuary mixing conditions can produce more backwater or slack water areas within the estuary. This could effectively reduce the amount of water absorbing solar radiation in these areas and could result in localized warming of estuary water in those backwater or slack water areas. Sediment deposition also could result in morphological changes that decrease the size of the salt wedge, either by increasing the frequency of mouth closure, or by elevating the bottom of the estuary above portions of the tidal range when the mouth is open. All of these morphological changes due to sediment deposition could potentially result in an increase in Klamath River Estuary water temperatures over the existing condition.

Estuary waters provide optimal habitat for juvenile salmonids that use the estuary to rear prior to returning to the Pacific Ocean. Additionally, the Klamath River Estuary is designated as critical habitat for Southern Oregon/Northern California Coast (SONCC) evolutional significant unit for coho salmon (NMFS 1999) and would benefit for cooler water temperatures. Sediment scouring would increase the estuary depth, the size of the estuary, the mixing conditions, and/or the size of salt wedge, so the volume of water absorbing solar radiation would increase and estuary water temperatures would not be expected to increase. Therefore, should sediment scouring occur in association with the Proposed Project, it would be unlikely to increase short-term or long-term water temperature conditions in the Klamath River Estuary.

Under existing conditions, high concentrations of silt and clay are transported through the estuary on an annual basis. Sediment sampling by USBR (2010) documented the absence of fine material in the estuary except in the backwater and vegetated areas (see Section 3.11.2.4 *Sediment Load* for more details). Modeling of sediment transport due to reservoir drawdown indicates that only fine sediments (silts, clays, and organics) would be transported to the estuary, and fine sediments would not deposit in significant quantities in the estuary (USBR 2012). If dam removal occurs under dry water years conditions, small volumes of fine sediment may deposit in the backwater and vegetated areas in the estuary due to lower river flows in dry water years (USBR 2012). However, even under this scenario, since limited sediment deposition is expected to occur in the Klamath River Estuary as a result of the Proposed Project (see Potential Impact 3.11-6), small morphological changes in the estuary that may occur due to dam removal sediment releases would not be likely to increase short-term estuary water temperatures in an manner that would cause or substantially exacerbate an exceedance of water quality standards or would result in a failure to maintain existing beneficial uses currently supported.

With respect to the potential for long-term impacts, estimates of baseline sediment delivery for the Klamath Basin indicate that sediment delivery rates would not change substantially under the Proposed Project (Stillwater Sciences 2010) (see also Potential

Impact 3.11-5). Accordingly, there would be no long-term morphological changes in the estuary that would affect water temperatures under the Proposed Project.

As discussed above for Potential Impact 3.2-1, the State Water Board has issued a draft water quality certification which sets forth proposed water quality monitoring and adaptive management requirements for the Proposed Project, as Condition 1[50].

Significance

No significant impact

3.2.5.2 Suspended Sediments

For the purposes of the Lower Klamath Project EIR, "suspended sediment" refers to settleable suspended material in the water column. Bed materials, such as gravels and larger substrates, are discussed in Geology and Soils Section 3.11.5 *Potential Impacts and Mitigation*. Two types of suspended material are considered for water quality impacts in the Klamath River: algal-derived (organic) suspended material and mineral (inorganic) suspended material. Sources of each type of suspended material differ, as do spatial and temporal trends for each, within the Upper, Middle, and Lower Klamath River reaches (see Section 3.2.2.3 *Suspended Sediments*).

Potential Impact 3.2-3 Increases in suspended sediments due to release of sediments currently trapped behind the dams.

Increases in suspended sediment due to release of reservoir sediments currently trapped behind the Lower Klamath Project dams are discussed by Klamath River reach below. As discussed in Section 3.2.4.2 *Suspended Sediments*, the analysis for this EIR interprets USBR (2012) modeled suspended sediment concentrations (SSCs) during and after reservoir drawdown, based on KRRC's proposed reservoir drawdown rates, where the latter would increase peak SSCs, increase the rate SSCs would decrease, and decrease the overall duration of elevated SSCs relative to the drawdown rates that were previously modeled (USBR 2012). While the USBR (2012) model results would underestimate peak SSCs relative to the KRRC's Proposed Project, the modeled SSCs provide a conservative estimate of the short-term impacts of suspended sediment releases due to dam removal since the underestimate of peak SSCs would still be within model uncertainty (i.e., approximately a factor of two) and model results would overestimate the duration of elevated SSCs.

Additionally, the Proposed Project would support erosion and transport of sediments deposited within the Copco No. 1 and Iron Gate reservoir footprints by using barge-mounted pressure sprayers to jet water onto newly exposed reservoir-deposited sediments as the water level decreases during drawdown, a process called sediment jetting. The barge-mounted pressure sprayers would use water from the reservoir, so sediment jetting would only be conducted when reservoir levels are sufficiently high to safely operate the barge and no sediment jetting would occur once reservoir drawdown is complete. Sediment jetting would maximize the erosion of reservoir-deposited sediments during drawdown within the six areas where restoration actions are proposed within the Copco No. 1 Reservoir footprint (Figure 2.7-11) and the three areas where

[50] The State Water Board's draft water quality certification is available online at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 11, 2018).

restoration actions are proposed within the Iron Gate Reservoir footprint (Figure 2.7-12). Sediment jetting would also minimize the potential for reservoir sediment erosion and the associated increase in SSCs outside of the reservoir drawdown period by mobilizing sediments during drawdown. While sediment jetting would primarily transport reservoir deposited sediments that are already anticipated to be eroded during drawdown, some additional reservoir deposited sediments may be transported by the combination of drawdown and sediment jetting flows compared to only drawdown flows. The total sediment behind the dams by 2020[51] and the range of sediment volume anticipated to erode from each reservoir during dam removal was estimated by USBR (2012) as part of the sediment transport modeling. The range of sediment volume that potentially would be transported from sediment jetting during drawdown was estimated for Copco No. 1 and Iron Gate reservoirs from the approximate areas where the restoration actions would occur in the individual reservoirs (Figure 2.7-8 and 2.7-9) and the maximum and minimum sediment depths measured in the vicinity of those restoration actions. Sediment depths were measured in sediment cores taken by Shannon and Wilson (2006) and USBR (2009) and summarized in USBR (2012). Sediment jetting during drawdown would potentially transport between approximately 13 and 41 percent of the sediment volume expected to erode during dam removal (Table 3.2-12).

[51] Between 2020 and 2021 (i.e., dam removal year 2 when drawdown would primarily occur under the KRRC's revised schedule), the sediment volume present behind the dams would increase by approximately 81,300 cubic yards in Copco No. 1 Reservoir and approximately 100,000 cubic yards in Iron Gate Reservoir based on estimates of annual sedimentation rates for each reservoir (USBR 2012). The increase in sediment volume between 2020 and 2021 be an order of magnitude less than the uncertainty of the 2020 total sediment volume estimates, so model results using the 2020 sediment volumes would still be applicable to the Proposed Project.

Table 3.2-12. Estimated Range of Sediment Volume Transported by Sediment Jetting During Drawdown Compared to Total Sediment Volume Anticipated to Erode with Dam Removal.

Reservoir	Total 2020 Sediment Volume[1,2,3] (cubic yards)	2020 Sediment Volume Erosion[3,4] (cubic yards)		Estimated 2020 Sediment Volume Transported by Sediment Jetting[3,5] (cubic yards)		Percentage of 2020 Sediment Volume Transported by Sediment Jetting (%)	
		Minimum	Maximum	Minimum	Maximum	Minimum	Maximum
Copco No. 1	8,250,000	3,713,000	6,270,000	970,000	1,278,000	15%	34%
Iron Gate	5,690,000	1,366,000	1,821,000	237,000	554,000	13%	41%

1 Total 2020 sediment volume is from USBR (2012) which estimated the total sediment volume from the sediment cores taken in the individual reservoirs and projected to 2020 based on annual sedimentation rates for each reservoir.
2 Between 2020 and 2021 (i.e., dam removal year 2 when drawdown would primarily occur), the sediment volume present behind the dams would increase by approximately 81,300 cubic yards in Copco No. 1 Reservoir and approximately 100,000 cubic yards in Iron Gate Reservoir based on estimates of annual sedimentation rates for each reservoir (USBR 2012). The increase in sediment volume between 2020 and 2021 would be an order of magnitude less than the uncertainty of the 2020 total sediment volume estimates, so model results using the 2020 sediment volumes would still be applicable to the Proposed Project.
3 Rounded to nearest 10,000 cubic yards.
4 Sediment volume erosion is based on the USBR (2012) estimated total 2020 sediment volume and erosion rates during drawdown. The maximum and minimum erosion rates for each reservoir (see Table 2.7-11) are based on hydrologic conditions recorded for the March to June flow volume at Keno gage on the Klamath River from water year 2001 (90 percent exceedance) and 1984 (10 percent exceedance). Sediment volume from individual reservoirs may not equal the total amounts indicated because masses taken from USBR (2012) were rounded to the nearest 10,000 tons.
5 Sediment volume erosion transported by sediment jetting is estimated from the approximate areas where restoration actions would occur in the individual reservoirs (Figure 2.7-8 and 2.7-9) and the maximum and minimum sediment depth measured in the vicinity of those restoration actions.

SSCs that would occur during reservoir drawdown under the KRRC's Proposed Project would increase relative to the prior model results (USBR 2012) due to the influence of sediment jetting, while SSCs after drawdown completes are expected to be similar or less than the modeled SSCs since sediment jetting would increase transport of reservoir sediments during drawdown and less sediment would remain in the reservoir after drawdown. Variations in SSCs downstream of Copco No. 1 and Iron Gate reservoirs due to sediment jetting within the reservoir footprint are discussed in the relevant reaches below.

Hydroelectric Reach

Sediment transport modeling of the impacts of dam removal indicate high short-term SSCs in the Hydroelectric Reach under the Proposed Project (Stillwater Sciences 2008; USBR 2012, 2016). Modeled SSCs downstream of J.C. Boyle Reservoir would be high in the short term, but concentrations would be considerably less than those anticipated to occur downstream from Copco No. 1 and Iron Gate reservoirs due to the relatively small volume of the sediment deposits behind J.C. Boyle Dam (eight percent of total volume for the Lower Klamath Project, see also Tables 2.7-7 and 2.7-8). Model output indicates that SSCs immediately downstream of J.C. Boyle Dam under dry (WY 2004), median (WY 1968), and wet (WY 1999) water year types would exhibit peak values of 2,000–3,000 mg/L occurring within one to two months of reservoir drawdown. Model results indicate SSCs greater than 100 mg/L for two weeks or more would potentially occur downstream of J.C. Boyle Dam for one to three months under the Proposed Project, coinciding with the drawdown period. During these one to three months, modeled SSC exceed 100 mg/L over two weeks for several non-consecutive periods, with SSCs remaining above 100 mg/L for approximately two to seven consecutive weeks depending on the water year. The suspended sediments released from J.C. Boyle Reservoir would quickly move into the California portion of the Hydroelectric Reach. SSCs exceeding 100 mg/L for two consecutive weeks was selected as a threshold of significance because exposure for SSCs above 100 mg/L for two weeks would be a significant adverse impact to cold-water fishery species (i.e., salmonids, including rainbow trout) and associated designated beneficial uses, including cold freshwater habitat (COLD), rare, threatened, or endangered species (RARE), and migration of aquatic organisms (MIGR) in the Hydroelectric Reach (see Section 3.2.3.1 *Thresholds of Significance, Suspended Sediment*). Modeled SSCs downstream of J.C. Boyle Dam are greater than 100 mg/L for two consecutive weeks during drawdown, thus there would be a significant impact to SSCs in the short term in the Hydroelectric Reach due to increases in suspended sediment from releases of sediment trapped behind J.C. Boyle Dam. Modeled SSCs decrease to less than 100 mg/L within five to seven months following drawdown, and concentrations further decrease to less than 10 mg/L within six to 10 months following drawdown of J.C. Boyle Reservoir (Figure 3.2-11 through Figure 3.2-13).

The higher drawdown rate under the Proposed Project than under modeled conditions is expected to increase peak SSCs and decrease the duration of elevated SSCs compared to modeled SSCs (see Section 3.2.4.2 *Suspended Sediments*), but variations in modeled SSCs due to a higher drawdown rate would be unlikely to reduce the duration of SSCs above 100 mg/L to less than two consecutive weeks under all water years types. Peak SSCs would be expected to double from approximately 2,000 – 3,000 mg/L under modeled conditions to approximately 4,000–6,000 mg/L under the higher drawdown rate in the Proposed Project, based on a previous analysis how suspended sediments vary under different drawdown rates in Lower Klamath Project reservoirs (Stillwater Sciences 2008). A higher drawdown rate would also be expected to decrease the duration of elevated SSCs by approximately one to two weeks (Stillwater Sciences). Modeled SSCs greater than 100 mg/L downstream of J.C. Boyle Dam occur for up to seven consecutive weeks, depending on the water year type (see Figure 3.2-11 to Figure 3.2-13), so SSCs under the Proposed Project with a higher drawdown rate would be likely to remain greater than 100 mg/L for two consecutive weeks. However, SSCs after drawdown would potentially decrease to less than 10 mg/L more rapidly under the Proposed Project than estimated by the modeled SSCs. Overall, the short-term impact based on an analysis of modeled SSCs downstream of J.C. Boyle Dam would remain the same under the higher drawdown rate in the Proposed Project since SSCs is expected to exceed 100 mg/L for two consecutive weeks regardless of the drawdown rate.

In the year following dam removal year 2 (post-dam removal year 1), modeling indicates suspended sediments would not be greater than 100 mg/L over a continuous two-week period under all water-year types. In dry and normal water-year types, modeled suspended sediment concentrations were always below 100 mg/L during post-dam removal year 1. In wet water-year types, the modeled suspended sediment concentrations are usually less than 100 mg/L during post-dam removal year 1, but there is an approximately one-week period when modeled suspended sediment concentrations are greater than 100 mg/L associated with storm conditions. Modeling indicates the suspended sediment concentrations return to modeled background levels (i.e., existing conditions) under all water year types during post-dam removal year 1 (USBR 2012).

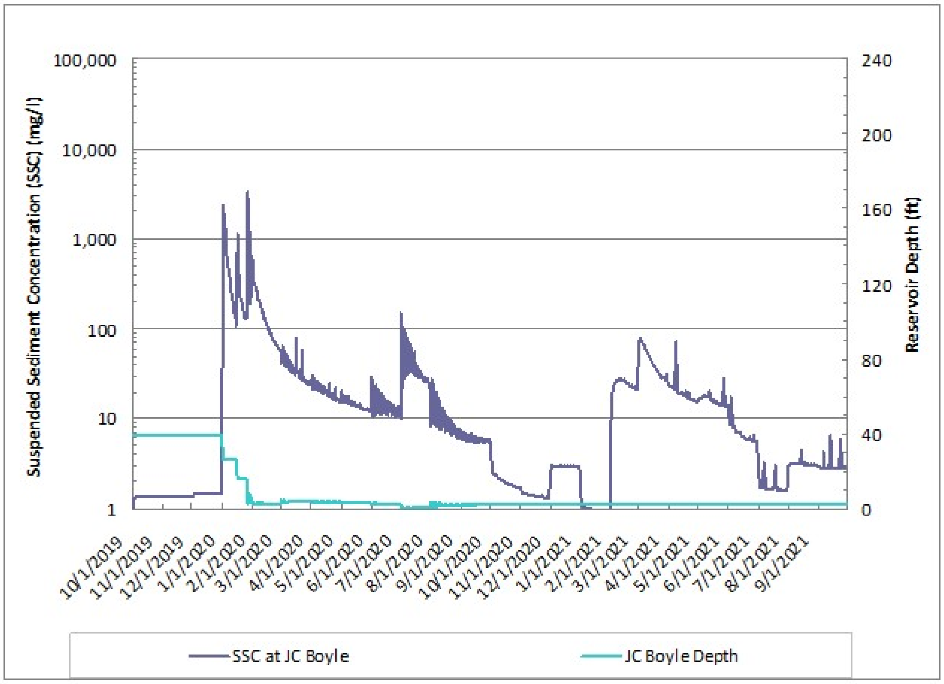

Figure 3.2-11. Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Project Assuming Typical Dry Hydrology (WY2001). Dam removal year 1 is represented by the year 2019, dam removal year 2 is represented by the year 2020, and post-dam removal year 1 is represented by the year 2021.

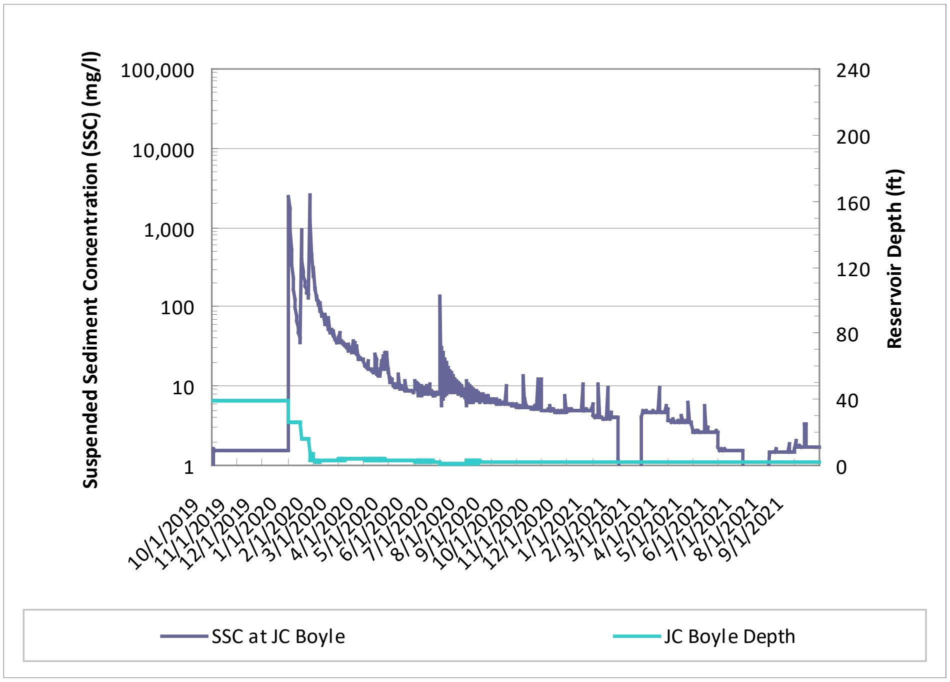

Figure 3.2-12. Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Project Assuming Median Hydrology (WY1976). Dam removal year 1 is represented by the year 2019, dam removal year 2 is represented by the year 2020, and post-dam removal year 1 is represented by the year 2021.

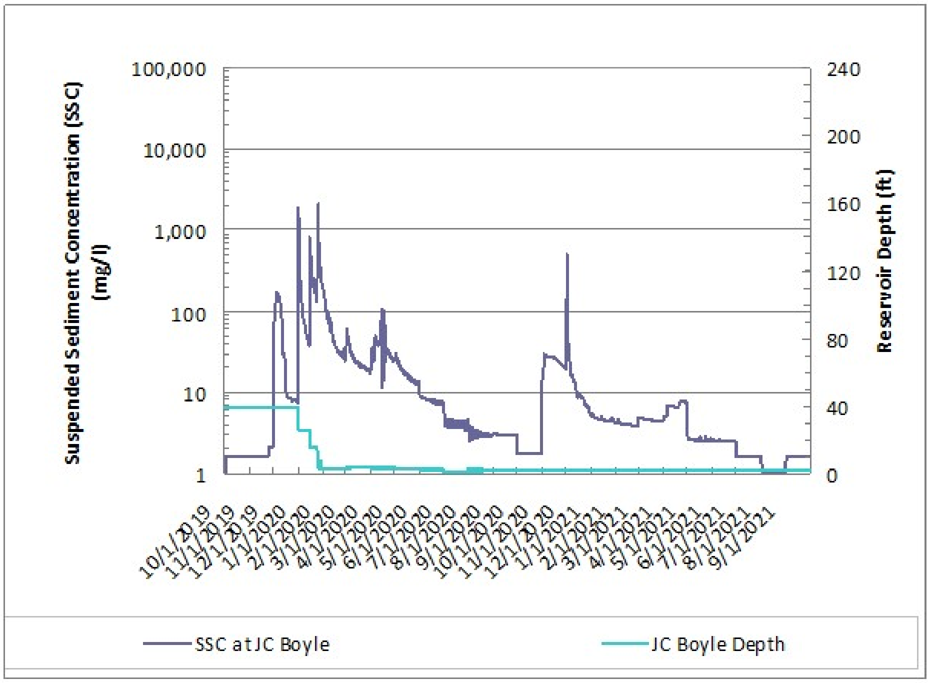

Figure 3.2-13. Suspended Sediment Concentrations Modeled at J.C. Boyle Reservoir Under the Proposed Project Assuming Typical Wet Hydrology (WY1984). Dam removal year 1 is represented by the year 2019, dam removal year 2 is represented by the year 2020, and post-dam removal year 1 is represented by the year 2021.

Modeling of sediment concentrations downstream of Copco No. 1 Reservoir during drawdown also indicates short-term sediment concentrations would be high in the California portion of the Hydroelectric Reach due to dam removal (Figure 3.2-14). Modeled SSCs downstream of Copco No. 1 Reservoir in dry, average and wet water year types peaked at approximately 7,000–8,000 mg/L within one to two months of initiation of reservoir drawdown; SSCs then decrease to generally less than 1,000 mg/L by approximately one and a half to two and a half months after initiation of reservoir drawdown. During this period, the modeled SSCs would exceed the suspended sediments potential short-term significance threshold of 100 mg/L over a continuous two-week period. Predicted spikes in SSC after one to two months of reservoir drawdown correspond to increases in Klamath River flow through the Hydroelectric Reach due to spring storm events (Figure 3.2-14).

Similar to conditions immediately downstream of J.C. Boyle, higher maximum drawdown rate under the Proposed Project (i.e., 5 feet per day) would not alter the short-term impact determination since the higher drawdown rate under the Proposed Project would be unlikely to reduce the duration of SSCs above 100 mg/L to less than two consecutive weeks under all water years types. Peak SSCs would be expected to double from approximately 7,000–8,000 mg/L under modeled conditions to approximately 14,000–16,000 mg/L under the higher drawdown rate in the Proposed Project, based on a previous analysis how suspended sediments vary under different drawdown rates in Lower Klamath Project reservoirs (Stillwater Sciences 2008). The duration of modeled SSCs greater than 100 mg/L downstream of Copco No. 1 likely would decrease under the Proposed Project with a higher drawdown rate, but the overall all duration of SSCs greater than 100 mg/L would likely occur for two consecutive weeks or more. SSCs after drawdown would potentially decrease to less than 10 mg/L more rapidly under the Proposed Project than estimated by the modeled SSCs. Thus, the short-term impact, which is based on an analysis of modeled SSCs downstream of Copco No. 1 Dam, would remain the same under the higher drawdown rate in the Proposed Project since SSCs is expected to exceed 100 mg/L for two consecutive weeks regardless of the drawdown rate.

Sediment jetting is anticipated to also increase the magnitude of modeled SSCs downstream of Copco No. 1 during drawdown (USBR 2012), but it also would not alter the overall impact of suspended sediment in the Klamath River downstream of Copco No. 1 Dam during drawdown since the increase in SSCs due to sediment jetting would primarily occur during peak SSCs and sediment jetting would not increase the duration of SSCs greater than 100 mg/L by only mobilizing more sediment during the drawdown period. Klamath River flows during drawdown at Copco No. 1 Dam range from approximately 800 cfs in a Dry water year to 13,600 cfs in a Wet water year (see Appendix B: *Definite Plan – Section 4.6*). Assuming a sediment jetting flow of approximately 10 to 30 cfs (similar to sediment jetting flows used on the Mill Pond Dam removal project, Washington Department of Ecology [2016]). SSCs in sediment jetting flows would vary depending on the pressure of the water jet, the angle of the water jet, and the cohesiveness of the reservoir deposited sediments, but SSCs in sediment jetting flows would likely range from less than 1,000 mg/L to approximately 100,000 mg/L.

SSCs in the Klamath River downstream of Copco No. 1 during drawdown with sediment jetting compared to modeled SSCs without sediment jetting are estimated to typically increase by approximately 350 mg/L to 1,400 mg/L, but SSCs would potentially increase up to approximately 2,200 mg/L compared to modeled SSCs in the Klamath River during drawdown without sediment jetting. This projected increase in SSC is based on the estimated range of sediment volume to be transported by sediment jetting, the duration of drawdown when sediment jetting would occur, and the modeled flow and SSCs for the Klamath River and the estimated flow and SSCs for sediment jetting. The typical increase in SSCs would be the expected increase under the range of typical drawdown flows under all water year types, while the maximum increase in SSCs would only be likely to occur under Klamath River minimum flows during a dry water year. Additionally, the maximum increase in SSCs in the Klamath River downstream of Copco No. 1 is a conservative estimate since it assumes sediment jetting would mobilize all the sediment in the areas undergoing jetting in the approximately three-month drawdown period. In actuality, drawdown flows would mobilize a portion of that sediment, so the actual maximum increase in SSCs downstream of Copco No. 1 would likely be less than 2,200 mg/L.

While sediment jetting would increase the magnitude of SSCs during drawdown, most of the variations in the modeled SSCs during sediment jetting would be within the range of modeled SSCs and the increase in the magnitude would not extend beyond the drawdown period since sediment jetting would only occur during drawdown. Peak SSCs during drawdown under sediment jetting would potentially increase above the range of modeled SSCs with the maximum SSCs downstream of Copco No. 1 potentially increasing from approximately 14,000–16,000 mg/L under the higher maximum drawdown flows (i.e., 5 feet per day) to approximately 16,200–18,200 mg/L under the higher maximum drawdown flows with sediment jetting. The SSCs under drawdown flows with or without sediment jetting would exceed the suspended sediments potential short-term significance criteria of 100 mg/L over a continuous two-week period. While the magnitude of SSCs would increase during drawdown with sediment jetting, the magnitude of SSCs would potentially decrease after drawdown is complete since sediment jetting would mobilize more sediment than anticipated under drawdown flows alone. Within the general uncertainty of the modeled SSCs and estimates of SSCs with sediment jetting (see Table 3.2-12), the SSCs in the Klamath River downstream of Copco No. 1 with sediment jetting would be similar to or less than the modeled SSCs without sediment jetting after drawdown ends in March.

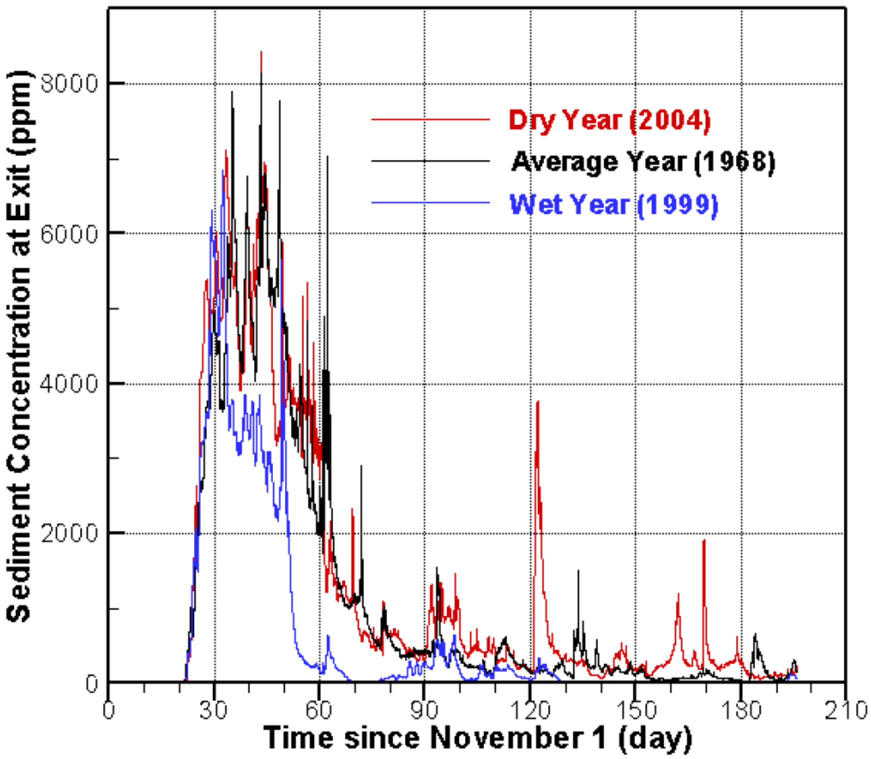

Figure 3.2-14. Sediment Concentration Downstream of Copco No. 1 Reservoir During Drawdown Using SRH-2D v3 Under Three Hydrological Scenarios. Drawdown began on November 15 and continued for six months. Source: USBR 2012.

Note that the shift in the Proposed Project Copco No. 2 drawdown timing from January 1 (Appendix B: *Detailed Plan*) to May 1 (Appendix B: *Definite Plan*) would not change the anticipated magnitude or timing of significant impacts due to elevated SSCs in the Hydroelectric Reach during dam removal year 2. SSCs associated with Copco No. 2 were not explicitly considered in the SRH-1D model, since 1) construction of Copco No. 2 dam was completed seven years after the substantially larger, upstream Copco No. 1 dam was completed, where the larger dam effectively cut off the source of sediments that would have been transported into Copco No. 2 Reservoir and potentially stored over time, and 2) Copco No. 2 Reservoir storage volume (70 ac-ft) is negligible compared with that of the upstream Copco No.1 (33,724 ac-ft) and J.C. Boyle (2,267 ac-ft) reservoirs, such that even if sediment deposits were to occur in Copco No. 2 Reservoir, either historically or during the Proposed Project drawdown of the upstream Copco No. 1 and J.C. Boyle reservoirs, the smaller Copco No. 2 Reservoir would not meaningfully increase downstream SSCs beyond currently predicted values for the period five to seven months following drawdown (May−July). Short-term increases in SSCs from removal of Iron Gate Dam are discussed for the Middle and Lower Klamath River (see below), since sediment releases from Iron Gate Reservoir would primarily impact the Klamath River downstream of the Hydroelectric Reach.

After reservoir drawdown, a significant amount of sediment is expected to remain within the reservoir footprints. Reservoir sediment field sampling and laboratory testing in 2012 (USBR 2012) and 2018 (Appendix B: *Definite Plan – Appendix H*) indicates that sediments remaining in the reservoir footprint would strengthen (i.e., harden) as they dry out, but wetting and drying cycles of unvegetated reservoir sediment would cause the sediment to produce erodible fine particles and aggregates. There is the potential for unvegetated sediments to cause significant short-term or long-term elevated SSCs during fall rain events if not stabilized with vegetation, especially from Iron Gate Reservoir where the highest levels of fine sediment and particles were produced in response to the laboratory wetting and drying cycles. These results are consistent with suspended sediment modeling results (USBR 2012) indicating that SSCs can periodically increase during post-dam removal year 1 due to storm conditions.

The Proposed Project includes revegetation of reservoir sediments remaining on the floodplain and the surrounding slopes after drawdown to stabilize the sediments and reduce the potential for short-term and long-term elevated SSCs. Stabilization of sediments through planting is expected to be effective since laboratory revegetation "grow tests" showed vegetation stabilized sediments from Copco No. 1 (Appendix B: *Definite Plan – Appendix H, Section 8.1.1 Reservoir Sediment Characteristics*). The Proposed Project Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*; see also Section 2.7.4 *Restoration Within the Reservoir Footprint*) includes activities to promote revegetation and sediment stabilization such as sediment preparation and amendment, irrigation, aerial seeding using pioneer seed mixes, planting of pole cuttings, acorns, and container plants, and adaptively re-seeding/re-planting areas that do not sufficiently establish following initial restoration activities.

During the drawdown period in January to March of dam removal year 2, aerial seeding would occur as the reservoir water level drops before the exposed reservoir sediments dry and form a surface crust. Pioneer seed mixes would contain a variety of riparian and upland common native species and possibly a small amount of sterile non-native species to enhance the initial erosion protection. The species included in the seed mix typically germinate early in the spring (March−April) and their germination would be sustained by dispersal over moist reservoir sediments during drawdown in the winter and early spring (January−March). Reservoir footprint areas that are re-inundated by larger storm events would be re-seeded after the water level recedes.

Aerial seeding would not result in any further disturbance of soil on the exposed reservoir terraces in the Hydroelectric Reach and the establishment of vegetation on the terraces would potentially reduce erosion of fine sediments. In areas not accessible by ground equipment because of rough terrain, steep slopes, and sediment instability, and as a potential alternative to aerial seeding, the Proposed Project may hydroseed from a barge located in Proposed Project reservoirs.[52]

During the dam removal period from March to December of dam removal year 2, additional revegetation efforts would be undertaken, including seed plantings, monitoring of plant growth and vegetation cover, re-seeding of areas with poor growth, continued

[52] If it occurs, barge hydroseeding would be unlikely to exacerbate erosion impacts beyond the impacts of reservoir drawdown itself. Reservoir drawdown would extend potential wave-induced erosion impacts below the existing normal fluctuation zone with brief (i.e., hours to a day) periods of interaction with the "new shoreline" as drawdown continues. Barges tend to generate low wave heights due to their wide, flat bottoms and low operating speeds and any concentrated additional wave-induced erosion from barge hydroseeding would be limited to a shorter duration (i.e., over several hours within a single day) than that of wind-action on the slowly downward-moving reservoir surface.

installation of pole cuttings, and maintenance of existing and previously planted vegetation. Woody riparian species would be planted in the riparian areas to increase natural bank stability along with providing ecological benefits for fish. Irrigation systems would be installed along key segments of the river banks to expedite riparian bank zone development. Several repeated seedings and/or plantings would be adaptively performed as necessary during the first two years following reservoir drawdown in order to increase native vegetation coverage in underperforming areas.

In addition to planting and revegetation activities, the Proposed Project also includes creation of physical features or conditions (e.g., grading, swales, wetlands, floodplain roughness features, and river bank roughness features) that would stabilize remaining reservoir sediments deposits and reduce the potential for short-term and long-term increases in SSCs (Appendix B: *Definite Plan – Appendix H, Section 5.5 Description of Restoration Actions*). As detailed in the Proposed Project Reservoir Area Management Plan (see Section 2.7 *Proposed Project*), grading would only occur for reservoir deposited sediments between January and April of the drawdown year, with no grading below the historical ground surface prior to dam construction. In the newly exposed reservoir footprints under the Proposed Project, swales, wetlands, floodplain roughness features (e.g., partially buried brush or wood), and bank roughness features (e.g., large woody habitat) would be constructed to stabilize the remaining reservoir sediments, reduce velocities along the floodplain and riverbank that would increase suspended sediments, and reduce unnatural erosion that would potentially degrade water quality (i.e., by elevating suspended sediments) while still maintaining natural river processes. Creation of the other physical features and conditions are likely to be effective sediment stabilization and suspended sediment reduction methods because they slow down stormwater runoff, floodplain flows, and river flows along the river banks that would potentially cause elevated suspended sediments, allow for suspended sediments to settle out prior to entering tributaries or Klamath River, and provide storage for sediment that may settle (CSQA 2003; Stubblefield et al 2006; Knox et al. 2008). The State Water Board's draft water quality certification includes Condition 13, which requires submission of a Restoration Plan that incorporates the major elements discussed above regarding revegetation, and also other activities that can reduce sediment loading to the Klamath River over the long term, including grading, swales, and wetland construction.

Although revegetation of the reservoir sediment deposits would stabilize the sediment and reduce the potential for short-term and long-term elevated suspended sediment concentrations in the Hydroelectric Reach after vegetation begins to grow and establish (i.e., summer drawdown year 2 to post-dam removal year 1) and other restoration plan elements such as grading, swales, and wetland construction would reduce both short-term and long-term sediment loading, there still is the potential for short-term increases in SSCs in the months following reservoir drawdown prior to the establishment of vegetation to stabilize sediments. Laboratory tests of reservoir sediments determined repeated wetting (e.g., from rainfall) and drying of reservoir sediment deposits under conditions similar to those expected to occur in the reservoir footprints after drawdown would form easily erodible fine particles, so unvegetated sediments would potentially produce elevated SSCs during rainfall events (Appendix B: *Definite Plan – Appendix H, Section 8.1.1 Reservoir Sediment Characteristics*). Short-term potential increases in SSCs from rainfall on reservoirs sediments without established vegetation alone would be unlikely to result in SSCs greater than 100 mg/L for a continuous two-week period. However, the short-term potential increases in SSCs due to rainfall on reservoir sediments without established vegetation combined with the short-term increases in

SSCs due to the release of reservoir sediments from behind the Lower Klamath Project dams would potentially result in SSCs greater than 100 mg/L for a longer duration than would occur due to only the short-term increases in SSCs from the release of reservoirs sediment from behind Lower Klamath Project dams, thus the short-term potential increases in SSCs from rainfall on reservoir sediments without established vegetation would have a significant adverse impact to salmonids and cause a substantial change in water quality (i.e., suspended sediment) that would result in a failure to maintain existing beneficial uses at the levels currently supported, resulting in a short-term significant impact to suspended sediments in the Hydroelectric Reach.

Physical removal of reservoir bottom sediments prior to drawdown is not feasible because dredging would remove only a maximum of 43 percent of erodible reservoir sediment, would only provide a marginal benefit to fish during drawdown with 57 percent of erodible sediment remaining, and would have a large environmental impact on terrestrial resources and possibly cultural resources (Lynch 2011). Slower drawdown to potentially mobilize less sediment or altering the timing of drawdown to lessen the potential of precipitation after drawdown and before plantings have stabilized sediments have also been suggested as potential approaches to reduce sediment impacts. However, both of these alterations would increase the time elevated SSCs would occur during sensitive fish life-stages, resulting in greater adverse impacts to designated beneficial uses and/or fish (see Section 4.1.1.4 *Elimination of Potential Alternatives that Would Not Avoid or Substantially Lessen Significant Environmental Effects of the Proposed Project*). Thus, the short-term significant impact of increased SSCs due to dam removal in the Hydroelectric Reach cannot be avoided or substantially decreased through feasible mitigation.

With respect to the potential for long-term increases in SSCs in the Hydroelectric Reach due to the Proposed Project, modeling indicates SSCs return to modeled background levels (i.e., existing conditions) under all water year types during post-dam removal year 1 (USBR 2012). Potential long-term increases in SSCs due to production of erodible sediments from the remaining reservoir sediment deposits would likely be almost to completely offset by long-term decreases in SSCs due to revegetation of remaining reservoirs sediment deposits. To address uncertainties associated with revegetation and sediment stabilization activities (e.g., variations in plant germination success, plant growth rate, seasonal precipitation, reservoir sediment changes), monitoring and adaptive management of these revegetation and sediment stabilization activities would occur under the Proposed Project (Appendix B: *Definite Plan – Appendix H, Section 6 Monitoring and Adaptive Management*). Monitoring of the remaining reservoir sediment deposits would be conducted yearly for post-dam removal year 1 to 5 to evaluate the effectiveness of these activities using yearly visual inspection (aerial and ground photos) as well as yearly Light Detection and Ranging (LiDAR) flights of the reservoir area to estimate changes in the remaining reservoir sediment deposits. Adaptive management under the Proposed Project would utilize the monitoring data, threshold metrics for evaluating whether actions would be needed, and potential actions to be undertaken if threshold metrics are not achieved. For example, aerial and ground photos would be used to evaluate the percent relative vegetation cover with additional vegetation seeding or planting occurring if vegetation cover does not meet annually specified average percent relative vegetation cover targets. Overall, monitoring and adaptive management would likely result in revegetation that stabilizes remaining reservoirs sediments, so long-term potential increases in SSCs due to production of erodible sediments from the remaining would be unlikely to result in elevated SSCs in the Klamath River and there would be a long-term less than significant impact on SSCs in the Hydroelectric Reach.

Slowly, over several decades, high winter flows in the Hydroelectric Reach are expected to gradually widen the floodplain in the reservoir footprints through natural fluvial processes (USBR 2012). Erosion associated with the widening of the floodplain is not anticipated to result in SSCs above modeled background levels (i.e., existing conditions) due to the anticipated slow pace of this change (i.e., decades), so long-term erosion and associated SSCs from widening of the floodplain would not cause an exceedance of water quality standards related to suspended sediments or cause changes in suspended sediments that would result in a failure to maintain existing designated beneficial uses at the levels currently supported. Therefore, there would be no significant impact to the Hydroelectric Reach in the long term due to the release of sediments currently trapped behind the Lower Klamath Project dams since SSCs are expected to resume modeled background levels (i.e., existing conditions) in the long term, regardless of the water year type present during the dam removal.

Middle and Lower Klamath River and Klamath River Estuary

Sediment transport modeling of the impacts of dam removal on suspended sediment also indicates high short-term loads immediately downstream from Iron Gate Dam under the Proposed Project (Stillwater Sciences 2008; USBR 2012, 2016). As described above, the Proposed Project involves drawdown for Copco No. 1 Reservoir beginning on November 1 and drawdown for J.C. Boyle and Iron Gate reservoirs beginning on January 1 (USBR 2012), which allows maximum SSCs to occur during winter months when flows and SSCs are naturally high in the mainstem river (see Appendix C, Figure C-15). Drawdown of Copco No. 2 occurs on May 1 (Appendix B: *Definite Plan*) under the Proposed Project, but Copco No. 2 Reservoir would not meaningfully increase downstream SSCs due to lack of sediment storage under current conditions and its small size relative to the upstream reservoirs, as discussed for the Hydroelectric Reach above.

Suspended sediment model predictions immediately downstream of Iron Gate Dam due to the release of sediments within J.C. Boyle, Copco No. 1, and Iron Gate reservoirs under the Proposed Project are presented in Figure 3.2-15 through Figure 3.2-17 for three water year types[53] (dry, median, wet) considered as part of the Klamath Dam Removal Secretarial Determination process. As discussed in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*, model predictions made using hydrology assumptions adopted for the Klamath Dam Removal Secretarial Determination are still appropriate for assessing Proposed Project impacts since the NMFS 2013 Biological Opinion mandatory flows are encompassed within the modeled range of flows (USBR 2016). Model predictions are discussed below and summarized in Table 3.2-13.

[53] SSCs downstream of Iron Gate Dam cannot be directly compared with the SSCs modeled downstream of Copco No. 1 Reservoir. SSC modeling downstream of Copco No. 1 Reservoir use different years to represent the three water year types than the SSC modeling downstream of J.C. Boyle Dam or Iron Gate Dam, so the specific hydrologic conditions (i.e., timing and magnitude of flow changes from storms) and resulting SSCs are different.

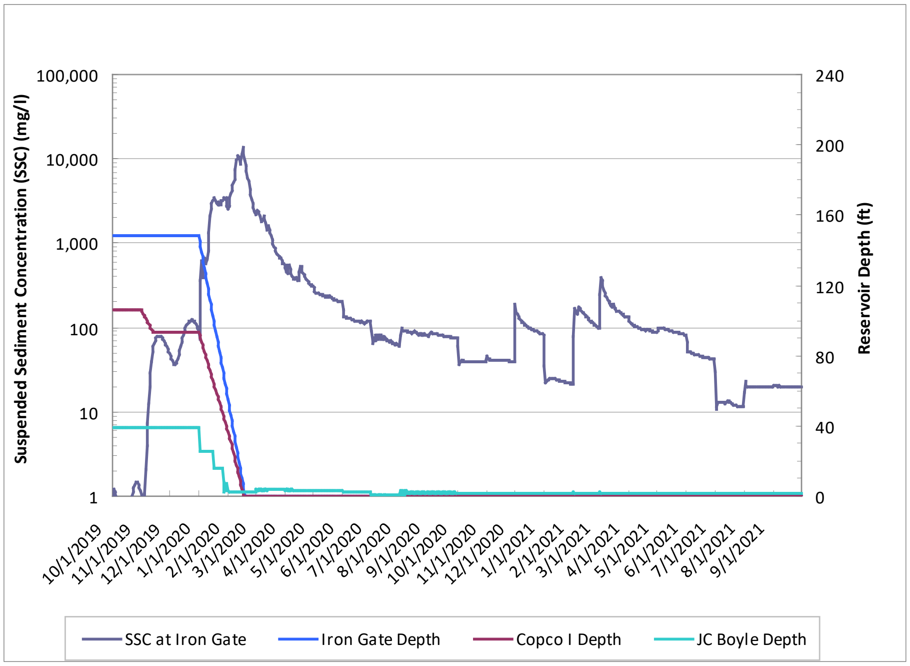

Figure 3.2-15. SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Project Assuming Typical Dry Hydrology (WY2001). Dam removal year 1 is represented by the year 2019, dam removal year 2 is represented by the year 2020, and post-dam removal year 1 is represented by the year 2021.

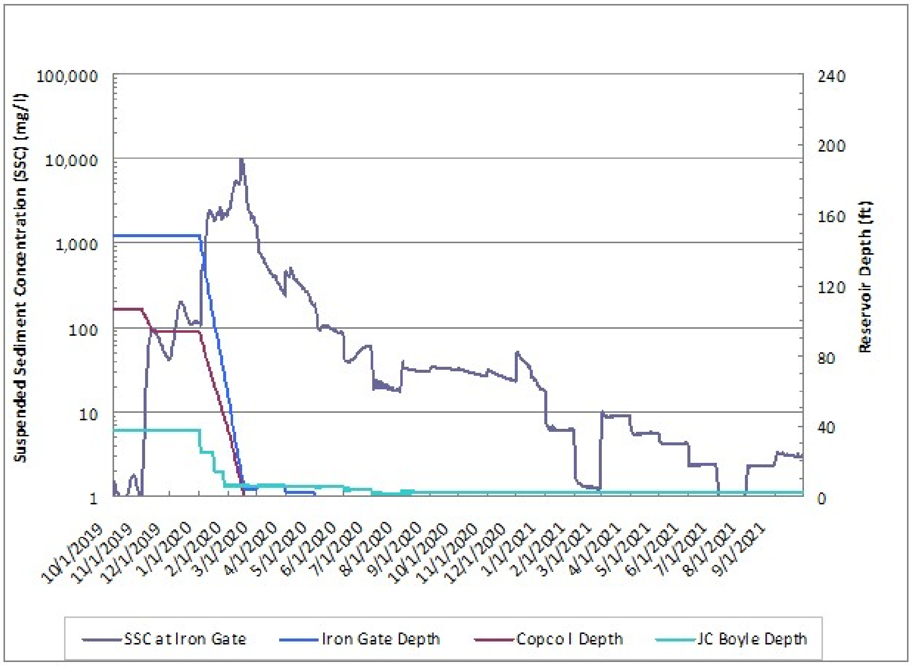

Figure 3.2-16. SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Project Assuming Median Hydrology (WY1976). Dam removal year 1 is represented by the year 2019, dam removal year 2 is represented by the year 2020, and post-dam removal year 1 is represented by the year 2021.

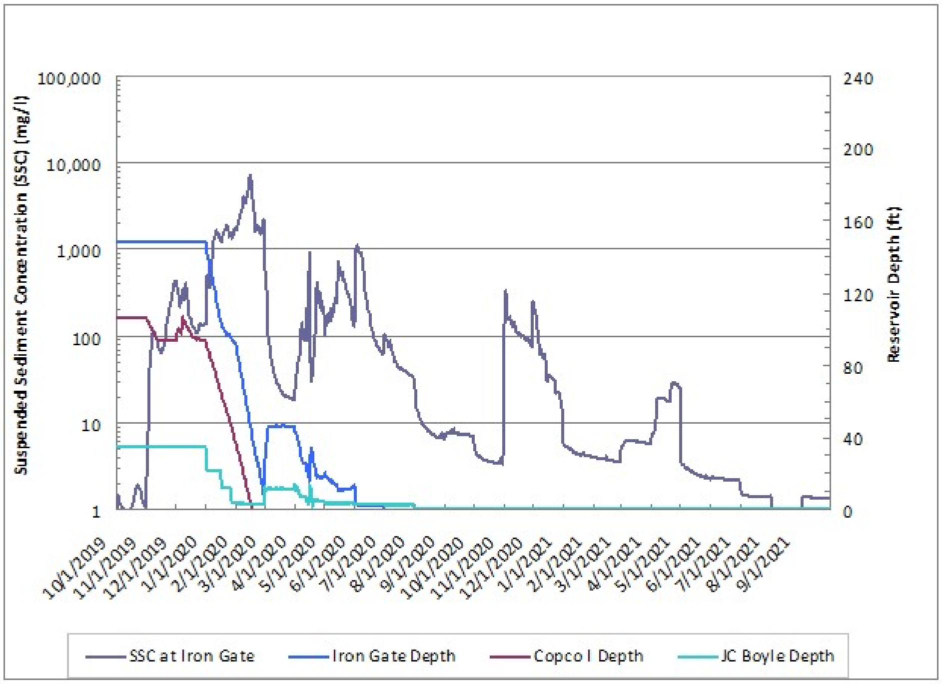

Figure 3.2-17. SSCs Modeled Downstream from Iron Gate Dam Under the Proposed Project Assuming Typical Wet Hydrology (WY1984). Dam removal year 1 is represented by the year 2019, dam removal year 2 is represented by the year 2020, and post-dam removal year 1 is represented by the year 2021.

Table 3.2-13. Summary of Model Predictions for SSCs in the Klamath River Downstream from Iron Gate Dam for the Proposed Project During Dam Removal Years 1 and 2

Water Year Type	Peak SSC[1] (mg/L)	SSC-1,000 mg/L		SSC-100 mg/L		SSC-30 mg/L	
		Duration (Months)	Time Period[2]	Duration (Months)	Time Period[2]	Duration (Months)	Time Period[2]
Dry (WY2001)	13,600	3	January–March	6	January–June	10	January–October
Median (WY1976)	9,900	2	January–February	5	January–May	6	January–June
Wet (WY1984)	7,100	2	January–February and April–July	7	November–February and April–July	9	November–July

[1] Actual peak concentrations may greater than predicted peak concentrations due to the proposed 5 feet per day maximum drawdown rate for the Proposed Project (see also Section 3.2.4.2 *Suspended Sediments*).
[2] All months shown are during dam removal year 2.

For typical dry year (WY2001) hydrologic conditions, modeled SSCs in the Klamath River immediately downstream from Iron Gate Dam experience a relatively small increase to near 100 mg/L in mid-November of dam removal year 1 as Copco No. 1 undergoes early drawdown at a maximum rate of two feet per day. A second, relatively large increase (greater than 1,000 mg/L) would occur in early January of dam removal year 2 when Iron Gate and J.C. Boyle begin drawdown at rates of two to five feet per day and Copco No. 1 enters a second phase of drawdown, also at a rate of two to 5 feet per day. Concentrations remain very high (greater than 1,000 mg/L) for approximately three months from January through April of dam removal year 2 (see Figure 3.2-11), with peak values exceeding 10,000 mg/L for a short period (four to five days) in mid-February of dam removal year 2. SSCs generally return to less than 100 mg/L by July, and to concentrations near 30 mg/L by October of dam removal year 2. Predicted SSCs increase again to levels between 200–400 mg/L during winter and spring of post-dam removal year 1 (2021) due to flushing of sediments that were not removed during the first year following drawdown.

Model predictions for median year (WY1976) hydrologic conditions follow a pattern similar to that of a typical dry year (WY2001), with a relatively small increase in SSCs (to near 200 mg/L) in mid-December of dam removal year 1, and a large increase (greater than 1,000 mg/L) again in early January of dam removal year 2. Peak SSCs downstream from Iron Gate Dam are predicted to be somewhat lower for the median year condition, reaching levels just under 10,000 mg/L. Relative to the typical dry year, the lower median year peak SSCs are a result of greater flows flushing nearly the same volume of sediment out of the reservoir and downstream. Peak concentrations also occur in mid-February of dam removal year 2 for the median year hydrologic condition (see Figure 3.2-16). Predicted SSCs downstream from Iron Gate Dam remain very high (greater than 1,000 mg/L) for approximately two months following the beginning of drawdown in Iron Gate and Copco No. 1 reservoirs, from January through February of dam removal year 2. There is a slightly earlier return to SSCs less than 100 mg/L for the median year (WY1976), with concentrations decreasing by May of dam removal year 2 due to the higher Klamath River flow under a median year. Modeled SSCs decrease to less than 30 mg/L by June of dam removal year 2 and fluctuate between 10 mg/L and 100 mg/L through the remainder of dam removal year 2. Modeled SSCs do not exceed 100 mg/L for two consecutive weeks after June of dam removal year 2 since SSCs remain below 100 mg/L after June of dam removal year 2. The Proposed Project is not expected to increase SSCs above 100 mg/L for the typical median water year condition in post-dam removal year 1 (2021) with modeled SSCs always less than 100 mg/L, but SSCs may vary between approximately 1 and 100 mg/L in that year due to erosion of sediment deposits remaining in the reservoir footprint area. Thus, model results indicate SSCs would remain below the 100 mg/L for two consecutive weeks threshold of significance for SSCs after June of dam removal year 2.

Model predictions for typical wet year (WY1984) hydrologic conditions indicate a higher initial pulse of fine sediments following the Copco No. 1 Reservoir drawdown in early to mid-December of dam removal year 1, with concentrations at or near 400 mg/L. Model predictions indicate that for typical wet year conditions, the outlet capacity at Copco No. 1 Dam is exceeded during the same timeframe and the reservoir fills slightly (see Figure 3.2-17). Very high (greater than 1,000 mg/L) SSCs are experienced for approximately two months following the beginning of drawdown in the reservoirs, from January through February of dam removal year 2 (see Figure 3.2-17). SSCs reach approximately 7,100 mg/L, with peak values occurring in mid-February of dam removal year 2. SSCs generally return to less than 100 mg/L during the month of March, but then secondary peaks (approximately 1,000 mg/L) in SSCs occur in mid-April and June of dam removal year 2 for wet year (WY1984) hydrologic conditions. After the secondary peaks, SCCs again returns to less than 100 mg/L by the beginning of July in dam removal year 2 and continues to decrease until SSCs are less than 30 mg/L by the end of July in dam removal year 2. Predicted SSCs increase again to levels between 200–400 mg/L during the end of dam removal year 2 (i.e., November) and the beginning of post-dam removal year 1 (2021) (i.e., January) before decreasing below 30 mg/L by February as high winter flows in the Klamath River flush sediments downstream that were not removed during drawdown. A secondary increase in SSCs to approximately 30 mg/L occurs around April to May in post-dam removal year 1 from a storm event, but rapidly decreases once Klamath River flows decrease.

As discussed for the *Hydroelectric Reach*, the shift in the Proposed Project Copco No. 2 drawdown timing from January 1 (Appendix B: *Detailed Plan*) to May 1 (Appendix B: *Definite Plan*) would not change the anticipated magnitude or timing of significant impacts due to elevated SSCs in the Hydroelectric Reach during dam removal year 2.

For all three water year types, predicted SSCs in the Middle and Lower Klamath River decrease to 60 to 70 percent of the Iron Gate Dam value by Seiad Valley (RM 132.7) and to 40 percent of the Iron Gate Dam value by about RM 58.9, downstream from Orleans (USBR 2012). SSCs in the Middle and Lower Klamath River and the Klamath River Estuary are predicted to resume modeled background levels (i.e., existing conditions) by the end of post-dam removal year 1 under all water year types, especially with revegetation of the reservoir sediments immediately following dam removal which would stabilize the sediment from erosion due to rainfall and reduce SSCs after drawdown compared to the modeled SSCs (USBR 2012). Modeled SSCs did not consider reductions in SSCs due to revegetation activities.

Modeled SSCs across the three water year types would have peak values of approximately 7,000 to 14,000 mg/L immediately downstream of Iron Gate Dam and these peak values would occur within two to three months of reservoir drawdown. Model results indicate SSCs in excess of 1,000 mg/L would occur on a timescale of weeks to months (see Table 3.2-13), as compared to SSCs greater than 1,000 mg/L that can occur during winter storm events on a timescale of days to weeks under existing conditions in the Klamath River downstream from Iron Gate Dam (see Appendix C, Section C.2.2.2 *[Suspended Sediments] Salmon River to Klamath River Estuary*). Predicted SSCs would remain greater than or equal to 100 mg/L for five to seven months following drawdown, and concentrations would remain greater than or equal to 30 mg/L for six to 10 months following drawdown (Table 3.2-13), as compared to suspended sediments downstream of Iron Gate Dam under existing conditions typically ranging from approximately 1 to 20 mg/L between May and December with only occasional peaks of approximately 56 to 437 mg/L (see Appendix C, Section C.2.2.2 *[Suspended Sediments] Salmon River to Klamath River Estuary*).

Similar to conditions downstream of J.C. Boyle and Copco No. 1, the higher maximum drawdown rate under the Proposed Project (i.e., 5 feet per day) than under modeled conditions is expected to increase peak SSCs and decrease the duration of elevated SSCs compared to modeled SSCs (see Section 3.2.4.2 *Suspended Sediments*), but variations in modeled SSCs due to a higher drawdown rate would be unlikely to reduce the duration of SSCs above 100 mg/L to less than two consecutive weeks under all water years types. Peak SSCs would be expected to double from approximately 7,000 to 14,000 mg/L immediately downstream of Iron Gate Dam under modeled conditions to approximately 14,000–28,000 mg/L under the higher drawdown rate in the Proposed Project, based on a previous analysis how suspended sediments vary under different drawdown rates in Lower Klamath Project reservoirs (Stillwater Sciences 2008). The higher drawdown rate would also potentially decrease the duration of elevated suspended sediments by approximately one to two weeks since suspended sediments decrease more rapidly after peak SSCs occur due to the increased transport of reservoir deposits at the higher drawdown rate (Stillwater Sciences 2008). While potential decreases in the duration of elevated suspended sediments under a higher drawdown rate would be unlikely to significantly alter the duration of SSCs greater than 1,000 mg/L (i.e., peak SSCs) downstream of Iron Gate, the duration of modeled SSCs downstream of Iron Gate Dam greater than 100 mg/L would likely occur as SSCs decrease more rapidly following a higher drawdown rate. Modeled SSCs downstream of Iron Gate Dam were greater than 1,000 mg/L for two to three weeks and greater than 100 mg/L for five to seven weeks (Table 3.2-13), so SSCs still would likely be greater than 100 mg/L for at least three consecutive weeks under the higher drawdown rate in the Proposed Project. SSCs after drawdown would potentially decrease to less than 10 mg/L more rapidly under the Proposed Project than estimated by the modeled SSCs due to the increased transport of reservoir deposits at the higher drawdown rate. Thus, overall, the short-term impact based on an analysis of modeled SSCs downstream of Copco No. 1 would remain the same under the higher drawdown rate in the Proposed Project since SSCs is expected to exceed 100 mg/L for two consecutive weeks regardless of the drawdown rate.

Similar to Copco No. 1 Reservoir, sediment jetting within the Iron Gate reservoir footprint is anticipated to increase the magnitude of modeled SSCs downstream of Iron Gate during drawdown, but it would not alter the overall impact of suspended sediment in the Klamath River downstream of Iron Gate Dam during drawdown since the increase in SSCs due to sediment jetting would primarily occur during peak SSCs and sediment jetting would not increase the duration of SSCs greater than 100 mg/L by mobilizing more sediment only during drawdown. Klamath River flows during drawdown at Iron Gate Dam range from approximately 1,000 cfs in a Dry water year to 24,500 cfs in a Wet water year (see Appendix B: *Definite Plan – Section 4.6*). A typical sediment jetting flow would be approximately 10 to 30 cfs with SSCs the flow likely ranging from less than 1,000 mg/L to approximately 100,000 mg/L, assuming the Proposed Project operations would be similar to sediment jetting flows used on the Mill Pond Dam removal project, Washington Department of Ecology [2016]).

Sediment jetting in the Iron Gate Reservoir footprint during drawdown is estimated to typically increase SSCs by approximately 270 mg/L to 1,200 mg/L compared to modeled SSCs without sediment jetting, but SSCs would potentially increase up to approximately 1,700 mg/L based on the estimated sediment volume to transport by sediment jetting, the duration of drawdown, and the flow and SSCs for the Klamath River and the sediment jetting. The typical increase in SSCs would be the expected increase under the range of typical drawdown flows under all water year types, while the maximum increase in SSCs would only be likely to occur under Klamath River minimum flows during a dry water year. Additionally, the maximum increase in SSCs from sediment jetting within the Iron Gate Reservoir footprint is a conservative estimate, since it assumes sediment jetting would mobilize all the sediment in the areas undergoing jetting. Drawdown flows would mobilize a portion of that sediment, so the actual maximum increase in SSCs would likely be less than 1,700 mg/L. SSCs in the Klamath River downstream of Iron Gate Dam would also be increased by sediment jetting activities in the Copco No. 1 reservoir footprint, so the overall SSCs increase in the Klamath River downstream of Iron Gate Dam from sediment jetting in both reservoirs during drawdown would typically range from 620 mg/L to 2,600 mg/L compared to modeled SSCs without sediment jetting, reaching up to approximately 3,900 mg/L if the maximum increase in SSCs from sediment jetting in Copco No. 1 and Iron Gate occurred simultaneously.

Sediment jetting would increase the magnitude of SSCs during drawdown, but most of the variations in the modeled SSCs during sediment jetting would be within the range of modeled SSCs and the increase in the magnitude would not extend beyond the drawdown period since sediment jetting would only occur during drawdown. Peak SSCs during drawdown under sediment jetting would potentially increase above the range of SSCs anticipated with the higher drawdown rate (i.e., 5 feet per day) with the maximum SSCs downstream of Iron Gate Dam potentially increasing from 14,000–28,000 mg/L (under only drawdown flows at a 5 feet per day drawdown rate) to approximately 17,900–31,900 mg/L (under drawdown flows at a 5 feet per day drawdown rate with sediment jetting in both the Copco No. 1 and Iron Gate reservoir footprints). The SSCs under drawdown flows at the higher drawdown rate with or without sediment jetting would exceed the suspended sediments potential short-term significance criteria of 100 mg/L over a continuous two-week period. While the magnitude of SSCs would increase during drawdown with sediment jetting, the magnitude of SSCs would potentially decrease after drawdown is complete since sediment jetting would mobilize more sediment than anticipated under drawdown flows alone. Within the general uncertainty of the modeled SSCs and estimates of SSCs with sediment jetting (see Table 3.12-2), the SSCs in the Klamath River downstream of Iron Gate Dam with a higher drawdown rate (i.e., 5 feet per day) and sediment jetting would be similar to or less than the modeled SSCs without sediment jetting after drawdown ends in March.

Model results also indicate that tributary inflow would create dilution in the lower Klamath River that would decrease SSCs, so the SSCs at Seiad Valley (RM 132.7) would be 60 to 70 percent of the SSCs immediately downstream of Iron Gate Dam and SSCs at Orleans (approximately RM 59) would be 40 percent of the SSCs immediately downstream of Iron Gate Dam. However, modeled SSCs in the Middle and Lower Klamath River would be greater than 100 mg/L for two consecutive weeks or more during drawdown depending on the water year type (USBR 2012), thus there would be a substantial adverse impact on salmonids and beneficial uses throughout these reaches and in the Klamath River Estuary in the short term. After consideration of the changes in modeled SSCs due to a higher maximum drawdown rate (i.e., 5 feet per day) and sediment jetting, SSCs in the Middle and Lower Klamath River and the Klamath River Estuary still would likely remain greater than 100 mg/L for two consecutive weeks or more. As such, SSCs in the Middle and Lower Klamath River and Klamath River Estuary due to release of reservoir sediments under the Proposed Project would be a substantial adverse impact on water quality in the short term and also result in a substantial adverse impact to salmonids and associated designated beneficial uses. A more detailed analysis of the anticipated suspended sediment impacts on key fish species, including salmonids, in the lower river is presented in Section 3.3.5.1 *Suspended Sediment.*

Sediment release associated with the Proposed Project would cause short-term increases in suspended material (greater than 100 mg/L for two or more consecutive weeks) that would cause an exceedance of water quality standards. Additionally, sediment release associated with the Proposed Project would cause water quality changes that would result in a failure to maintain existing beneficial uses at the levels currently supported due to non-attainment of applicable Basin Plan water quality objectives for suspended material in the Middle and Lower Klamath River and the

Klamath River Estuary; and substantial water quality changes that would adversely affect the cold freshwater habitat (COLD), rare, threatened, or endangered species (RARE), and migration of aquatic organisms (MIGR) beneficial uses. Sediment release associated with the Proposed Project would also result in non-attainment of applicable Hoopa Valley Tribe and Yurok Tribe narrative suspended material, settleable material, and sediment water quality objectives applicable the portions of the Klamath River within tribal boundaries.

Consistent with conditions described above in the *Hydroelectric Reach*, the short-term significant impact of increased SSCs due to dam removal in the Middle and Lower Klamath River and the Klamath River Estuary cannot be avoided or substantially decreased through reasonably feasible mitigation.

As discussed above for the *Hydroelectric Reach*, SSCs are expected to resume modeled background (i.e., existing conditions) SSCs by the end of post-dam removal year 1 regardless of the type of hydrology (dry, normal, or wet conditions) present during the drawdown period (USBR 2012). Thus, in the long term there would be no significant impact due to elevated SSCs in the Middle and Lower Klamath River and the Estuary due to the release of sediments currently trapped behind the Lower Klamath Project dams.

Pacific Ocean Nearshore Environment

Sediment transport modeling predicted that 1.2 to 2.3 million tons of sediment (5.4 to 8.6 million cubic yards, or 36 to 57 percent of the total sediments deposited behind the dams by 2020) would be eroded from the reservoir areas upon dam removal (USBR 2012) (see also Tables 2.7-7 through 2.7-9). The range of potential erosion volumes is due to the range in potential water year types that could occur during the year of dam removal. The sediment transported by the Klamath River to the Pacific Ocean due to dam removal is expected to be less than the total amount transported in a typical wet year, but greater than that transported during a dry year. See Section 3.11.5 *[Soil, Geology, and Mineral Resources] Potential Impacts and Mitigation* and Figure 3.11-12 for further details.

The California Marine Life Protection Act (MLPA) 2008 Draft Master Plan identifies freshwater plumes as one of three prominent habitats with demonstrated importance to coastal species (California Marine Life Protection Act 2008). The California MLPA Master Plan Science Advisory Team (2011) Methods Report designates river plumes as a key habitat to be included in marine protected areas because they harbor a particular set of species or life stages, have special physical characteristics, or are used in ways that differ from other habitats. While Goal 4 of the California MPLA 2016 Final Master Plan for the North Coast specifies protection of habitats identified by the California MLPA Master Plan Science Advisory Team, the MPLA 2016 Final Master Plan does not explicitly consider freshwater plumes as one of the habitat types (CDFW 2016).

A recent USGS overview report on the sources, dispersal, and fate of fine sediment delivered to California's coastal waters (Farnsworth and Warrick 2007) found the following:

- Rivers dominate the supply of fine sediment to the California coastal waters, with an average annual flux of 34 million metric tons.

- All California coastal rivers discharge episodically, with large proportions of their annual sediment loads delivered over the course of only a few winter days.

Farnsworth and Warrick (2007) conclude that fine sediment is a natural and dynamic element of the California coastal system because of large, natural sediment sources and dynamic transport processes.

After exiting the river mouth, the high SSCs (greater than 1,000 mg/L) transported by the Lower Klamath River would form a surface plume of less dense (i.e., less salty), turbid, surface water floating on more dense, salty ocean water (Mulder and Syvitski 1995). No detailed investigations of the likely size and dynamics of the Klamath River plume have been conducted. Thus, it is not possible to predict the sediment deposition pattern and location in the nearshore environment with exactitude. However, the general dynamics and transport mechanisms of fine sediment can be surmised based upon regional oceanographic and sediment plume studies.

In northern California, plume zones are primarily north of river mouths because alongshore currents and prevailing winds are northward during periods of strong runoff (Geyer et al. 2000, Pullen and Allen 2000, Farnsworth and Warrick 2007, California MLPA Master Plan Science Advisory Team 2011). Surface plumes occurring during periods of northerly upwelling-favorable winds will thin and stretch offshore, while in the presence of southern downwelling-favorable winds the plume may hug the coastline and mix extensively (Geyer et al. 2000, Pullen and Allen 2000, Borgeld et al. 2008). River plume area, location, and dynamics are also affected by the magnitude of river discharge, SSCs, tides, the magnitude of winter storms, and regional climatic and oceanographic conditions such as El Niño-Southern Oscillation (ENSO) and Pacific Decadal Oscillation climate cycles (Curran et al. 2002).

During several large flood events on the geographically near Eel River in the winter of 1997 and 1998, Geyer et al. (2000) found the following: (1) flood conditions were usually accompanied by strong winds from the southern quadrant; (2) the structure of the river plume was strongly influenced by the wind-forcing conditions; (3) during periods of strong southerly (i.e., downwelling favorable) winds, the plume [in the Pacific Ocean nearshore environment] was confined inside the 164 feet isobath (sea floor contour at 164 feet below the water surface), within about 4 miles of shore; (4) occasional northerly (upwelling favorable) winds arrested the northward motion of the plume and caused it to spread across the shelf; (5) transport of the sediment plume was confined to the inner shelf (water depths less than 164 feet), during both southerly and northerly wind conditions; (6) during southerly wind periods, fine, un-aggregated sediment was rapidly transported northward to at least 18 miles from the river mouth, but flocculated sediment was deposited within 0.6 to 6 miles of the river mouth; and (7) during northerly (upwelling favorable) winds, most of the sediment fell out within three miles of the mouth, and negligible sediment was carried farther offshore (Geyer et al. 2000). The Eel River mouth is 75 miles to the south of the Klamath River mouth and thus serves as a reasonable system for comparison.

Based upon Eel River plume studies and current knowledge of northern California oceanographic patterns, the fine sediment discharged to the Pacific Ocean nearshore environment under the Proposed Project would likely be delivered to the ocean in a buoyant river plume that hugs the shoreline as it is transported northward. However, since the flushing of sediments from behind the dams will occur over a number of weeks to months (and perhaps to some degree over one to two years), the plume carrying reservoir sediments would likely be influenced by a range of meteorological and ocean conditions (e.g., storm and non-storm periods, differing storm directions). Therefore, some of the time the plume would likely be constrained to shallower nearshore waters, while at other times it would likely extend further offshore and spread more widely, before depositing along the continental shelf in the vicinity of the mouth of the Klamath River.

The narrative California marine water quality objectives (Table 3.2-6) are applied as the threshold of significance rather than the freshwater numeric SSCs threshold of significance of 100 mg/L over a continuous two-week exposure period since the Pacific Ocean nearshore environment is a marine environment and salmonids within the Pacific Ocean nearshore environment would have more of an opportunity to avoid elevated SSCs conditions compared to opportunities within the Klamath River. While elevated SSCs (10 to 100 mg/L) created in the nearshore plume would affect physical water quality characteristics specified in the Ocean Plan (e.g., visible floating particulates, natural light attenuation, the deposition rate of inert solids), the impacts would be within the range caused by historical storm events (i.e., less than that transported in a typical wet year). While the total amount of sediment delivered to the Pacific Ocean nearshore environment under the Proposed Project is within the historical range of annual sediment supplied to the Pacific Ocean nearshore environment by the Klamath River (USBR 2012; see Potential Impact 3.11-5), the duration of elevated SSCs under the Proposed Project would be greater than the range occurring under natural (i.e., storm) conditions. Natural storm conditions would be expected elevate SSCs in the Pacific Ocean nearshore environment on the time scale of days (Geyer et al. 2000), but SSCs would be elevated in the Pacific Ocean nearshore environment on the time scale of weeks to months based on duration of elevated SSCs modeled in the Klamath River downstream of Iron Gate Dam, at Seiad Valley (RM 132.7), and at Orleans (approximately RM 59) (USBR 2012). Thus, the elevated SSCs created in the nearshore plume under the Proposed Project in the short term would produce variations in the physical characteristics of the Pacific Ocean nearshore environment greater the duration occurring under natural (i.e., storm) conditions, potentially causing water quality changes that would result in a failure to maintain existing beneficial uses at the levels currently supported and resulting in a significant impact to the Pacific Ocean nearshore environment in the short term.

As discussed above for the Hydroelectric Reach and the Middle and Lower Klamath River and the Klamath River Estuary, model results indicate that the SSCs would resume modeled natural background levels by the end of post-dam removal year 1 regardless of the type of hydrology (dry, normal, or wet conditions) present during the drawdown period (USBR 2012). Thus, SSCs in the Pacific Ocean nearshore environment in the long term would be within the range of natural conditions, so the variations in the physical characteristics of the Pacific Ocean nearshore environment similar to natural conditions and there would be no significant impact on SSCs in the long term in the Pacific Ocean nearshore environment due to the release of sediments currently trapped behind the Lower Klamath Project dams. See Section 3.11.5 for analysis of sediment deposition along the nearshore environment due to dam removal.

In summary, the magnitude of SSCs released to the nearshore environment with the anticipated rapid dilution of an expanding sediment plume in the ocean is within the range of natural conditions, but the duration of elevated SSCs is greater than would occur under natural (i.e., storm) conditions. Therefore, elevated SSCs under the

Proposed Project would potentially cause water quality changes that would result in a failure to maintain existing beneficial uses at the levels currently supported, thus short-term increases in SSCs in the Pacific Ocean nearshore environment under the Proposed Project would be significant and unavoidable impact.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes turbidity and suspended sediment concentration monitoring along with adaptive management requirements. Please note that the State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section 401. The State Water Board has issued a draft water quality certification which sets forth water quality monitoring, adaptive management, and compliance requirements for any Water Quality Monitoring Plan to meet, as Condition 1 and Condition 2[54]. Condition 2 acknowledges that the Proposed Project will have temporary (short-term) exceedances of water quality objectives associated with reservoir drawdown and the export of reservoir sediments into the Klamath River and Pacific Ocean. Restoration projects may exceed water quality objectives in the short term in light of the long-term water quality and ecosystem benefits they provide.

Additionally, the Oregon Department of Environmental Quality has issued a water quality certification[55] that sets forth water quality monitoring and adaptive management conditions for points upstream of California, including an assessment of baseline river conditions upstream of dam removal operations.

Significance

Significant and unavoidable in the short term for the Hydroelectric Reach, Middle Klamath River, Lower Klamath River, Klamath River Estuary, and Pacific Ocean nearshore environment

No significant impact in the long term for the Hydroelectric Reach, Middle Klamath River, Lower Klamath River, Klamath River Estuary, and the Pacific Ocean nearshore environment.

Potential Impact 3.2-4 Increases in suspended material from stormwater runoff due to pre-construction, dam deconstruction and removal, and restoration activities in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam.

Under the Proposed Project, pre-construction activities with the potential to affect water quality include canal and diversion tunnel modifications, road improvements, Iron Gate and Fall Creek hatchery modifications, Yreka pipeline modifications, and dam site preparation between June and November of dam removal year 1 (Table 2.7-1). Dam removal activities would begin in October of dam removal year 1 with removal of the Copco No. 1 Powerplant and would include demolition of the dams and their associated

[54] The State Water Board's draft water quality certification is available online at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 11, 2018).

[55] The Oregon Department of Environmental Quality's final water quality certification is available online at: https://www.oregon.gov/deq/FilterDocs/ferc14803final.pdf (Accessed December 14, 2018).

structures, power generation facilities, and transmission lines, installation of temporary cofferdams, hauling, recreation facilities removal, regrading of recreation access roads and parking areas, and other activities (Table 2.7-1). Immediately following dam removal, any potential non-natural fish barriers within the historical reservoir footprints would be modified as needed to enable volitional fish passage, which may include in-water work. Restoration activities would include irrigation system installation and maintenance, as well as active seeding, planting, and weed management in the reservoir footprint and disturbed upland areas within the Limits of Work (Table 2.7-1). For greater detail on these activities, please see Section 2.7 *Proposed Project*. All of the aforementioned activities could result in the disturbance of soil within the Limits of Work and result in loose sediment that could then be suspended in stormwater runoff during rainfall events. Please see Potential Impacts 3.2-16 and 3.22-2 for consideration of the accidental release of hazardous materials from construction equipment and/or vehicles under the Proposed Project.

Within the Limits of Work (Figures 2.2-5, 2.7-1, and 2.7-3), the Proposed Project includes the following construction and other ground-disturbing activities best management practices (BMPs) to reduce potential impacts to water quality in wetlands and other surface waters during construction and other ground-disturbing activities (Appendix B: *Definite Plan – Appendix J*):

- Pollution and erosion control measures will be implemented to prevent pollution caused by construction operations and to reduce contaminated stormwater runoff.
- Oil-absorbing floating booms will be kept onsite, and the contractor will respond immediately to aquatic spills during construction.
- Vehicles and equipment will be kept in good repair, without leaks of hydraulic or lubricating fluids. If such leaks or drips do occur, they will be cleaned up immediately.
- Equipment maintenance and/or repair will be confined to one location at each project construction site. Runoff in this area will be controlled to prevent contamination of soils and water.
- Dust control measures will be implemented, including wetting disturbed soils.
- A Stormwater Pollution Prevention Plan (SWPPP) will be implemented to prevent construction materials (fuels, oils, and lubricants) from spilling or otherwise entering waterways or waterbodies.

In addition, for the protection of wetlands, results of a wetland delineation would be incorporated into the Proposed Project design to avoid and minimize direct impacts on wetlands to the maximum extent feasible, and wetland areas adjacent to the construction Limits of Work would be fenced. As discussed in Potential Impact 3.5-1, there could be impacts to wetlands if the fencing does not include an appropriate buffer; implementation of Mitigation Measure TER-1, which stipulates a minimum 20-foot buffer requirement, would reduce potential short-term impacts on wetland communities to less than significant.

The BMPs identified above focus on general stormwater-related contamination, but their implementation is expected to also minimize or eliminate the potential for construction-related increases in suspended material that could enter wetlands and other surface waters located within the Limits of Work (Figures 2.2-5, 2.7-1, and 2.7-3), including the Hydroelectric Reach, tributaries of the Klamath River that enter this reach (as appropriate), or the Middle Klamath River immediately downstream of Iron Gate Dam. The Proposed Project does not, however, specifically identify BMPs for pre-construction, reservoir restoration, or upland restoration activities that would occur within the Limits of Work. Further, the proposed BMPs are not sufficiently comprehensive to avoid all potential violations of water quality standards or other degradation of water quality in affected portions of the wetlands, Hydroelectric Reach, tributaries to the Klamath River that enter this reach (as appropriate), or the Middle Klamath River immediately downstream of Iron Gate Dam, during these other periods of Proposed Project activity. Such violations of water quality standards or other related degradation of water quality would be a significant impact without mitigation. Implementation of mitigation measures WQ-1, TER-1, and HZ-1 would reduce any potential impacts not already addressed by the BMPs to less than significant.

Mitigation Measure WQ-1 Best Management Practices to reduce potential impacts to water quality due to pre-construction, dam removal, and restoration-related activities.
For the protection of all potentially affected waterbodies within the Limits of Work (see Figures 2.2-5, 2.7-2, and 2.7-4), the proposed construction BMPs (listed above) shall apply to all ground-disturbing activities occurring for the Proposed Project. Construction associated with these activities shall be subject to the BMPs required under the Construction General Permit.

Significance
No significant impact with mitigation

Potential Impact 3.2-5 Long-term alterations in mineral (inorganic) suspended material from the lack of continued interception and retention by the dams.
Under the Proposed Project, peak concentrations of mineral (inorganic) suspended material (silts and clays with a diameter less than 0.063 millimeters) during the winter/early spring (November through April) would likely continue to be associated with high-flow events following dam removal. Any long-term increases in mineral (inorganic) suspended material due to the lack of interception by the dams would not be large; estimates of baseline sediment delivery for the Klamath Basin indicate that a relatively small fraction of total sediment (151,000 tons per year or 2.4 percent of the cumulative average annual delivery from the basin) is supplied to the Klamath River on an annual basis from the watershed upstream of Iron Gate Dam due to the generally lower rates of precipitation and runoff, more resistant and permeable geologic terrain, and relatively low topographic relief and drainage density of the Upper Klamath Basin as compared with the lower basin (Stillwater Sciences 2010) (see also Section 3.11.2.4 Sediment Load). The majority of the mineral (inorganic) suspended material (6,086,471 tons per year or 97.6 percent of the cumulative average annual delivery from the basin) enters the Klamath River from tributaries downstream of Iron Gate Dam which is a pattern that is expected to continue following dam removal.

Long-term increases in suspended material from the lack of continued interception and retention of mineral (inorganic) suspended materials by the Lower Klamath dam are not expected to cause an exceedance or exacerbate an existing exceedance of a water quality standard or result in a failure to maintain a beneficial use. Accordingly, for the Hydroelectric Reach, the Middle and Lower Klamath River, the Klamath River Estuary, and the Pacific Ocean nearshore environment, there would be a less than significant long-term impact from removal of the dams on amounts or concentrations of mineral (inorganic) suspended material.

Significance

No significant impact

Potential Impact 3.2-6 Long-term alterations in algal-derived (organic) suspended material from the lack of continued interception and retention by the dams.
As discussed in Section 3.2.2 *Environmental Setting*, Section 3.4.2 *[Phytoplankton and Periphyton] Environmental Setting*, and Appendix C, Section C.2.1 *Upper Klamath Basin*, Upper Klamath Lake is a hypereutrophic system with considerable algae growth and suspended organic matter. Under existing conditions, the majority of the interception and retention of suspended material from upstream sources (Upper Klamath Lake, Klamath Straights Drain, Lost River) occurs in the Keno Impoundment/Lake Ewauna, with the largest relative decreases in TSS (total suspended solids) occurring between Link River and Keno Dam (see Appendix C, Figure C-13). In addition to interception by the dams, concentrations of organic suspended material from upstream decrease in the rivers due to mechanical breakdown of dead and decaying algae in the turbulent river reaches between J.C. Boyle and Copco No. 1 reservoirs, and dilution from the springs downstream from J.C. Boyle Dam (see Appendix C, Section C.2.1). Mechanical breakdown and dilution from springs are ongoing processes that would continue under the Proposed Project.

Episodic increases (10 to 20 mg/L) in algal-dominated (organic) suspended material resulting from in-reservoir algal productivity are not expected to occur in the Hydroelectric Reach following dam removal (see Section 3.2.2.3 *Suspended Sediments*). At the upstream end of the Hydroelectric Reach (i.e. at the upstream of J.C. Boyle Reservoir) and prior to mechanical breakdown or dilution downstream of J.C. Boyle Dam, suspended materials may attain levels similar to those observed upstream of J.C. Boyle Dam under existing conditions during May through October (greater than 15 mg/L; see Appendix C) as algal-dominated organic suspended material is transported downstream. In the Hydroelectric Reach downstream of the J.C. Boyle Dam location to Iron Gate, mechanical breakdown in the existing and newly created free-flowing river reaches, along with dilution, would be likely to reduce concentration of algal-derived (organic) suspended material, but the exact magnitude of the reduction in algal-derived (organic) suspended material cannot be quantified with available data or models. Measurements of organic suspended sediment between 2001 and 2003 and median turbidity values over the long-term historical record (1950–2001) both follow a similar pattern, with values decreasing with distance downstream to J.C. Boyle Reservoir, indicating it is likely that the suspended sediment concentrations crossing the Oregon-California state line under the Proposed Project would not increase beyond typical existing conditions concentrations of 10 to 15 mg/L (see Section 3.2.2.1 and Appendix C, Section C.2).

While it is likely that mechanical breakdown and dilution within the Hydroelectric Reach would reduce algal-derived (organic) suspended material concentrations entering the Hydroelectric Reach, it is conservatively assumed no decrease in algal-derived (organic) suspended material would occur within the Hydroelectric Reach due to the reservoirs no longer providing calm, slow-moving water conditions for algal-derived (organic) suspended material to settle out of the water column. Thus, downstream of Iron Gate Dam, there potentially would be a slight relative long-term increase in algal-dominated (organic) suspended materials under the Proposed Project, due to the conservative assumption that there would be no decrease in suspended material through the Hydroelectric Reach.

Following completion of the Proposed Project, it is very unlikely that summertime algal-dominated (organic) suspended material in the Middle and Lower Klamath River would increase beyond a sustained 100 mg/L for two weeks (the water quality criterion adopted for significant adverse impacts on the COLD beneficial use for the Lower Klamath Project EIR analysis (see Section 3.2.3.1). If slight long-term increases in suspended materials did occur, such increases would be well below the algal-derived suspended material previously produced in Copco No. 1 and Iron Gate reservoirs and would not exceed levels that would substantially adversely affect the cold freshwater habitat (COLD) beneficial use or any other existing designated beneficial use at the levels currently supported, exacerbate an existing exceedance of water quality standards, or result in a failure to maintain an existing beneficial use.

Significance
No significant impact

3.2.5.3 Nutrients

Potential Impact 3.2-7 Short-term increases in sediment-associated nutrients due to release of sediments currently trapped behind the dams.
Hydroelectric Reach, Middle and Lower Klamath River, and Klamath River Estuary
As discussed in Section 2.7.3 *Reservoir Sediment Deposits and Erosion During Drawdown*, a significant portion of the sediment anticipated to be removed during reservoir drawdown is dead phytoplankton [algae] that have settled on the reservoir bottom. These sediments are very high in nutrients. Short-term increases in total nitrogen (TN) and total phosphorus (TP) concentrations in the Hydroelectric Reach, Middle Klamath River, Lower Klamath River, Klamath River Estuary, and the Pacific Ocean nearshore environment would occur because the transported sediments are nutrient-rich. However, minimal deposition of fine suspended sediments, including associated nutrients, would occur in the river channel and the estuary (USBR 2012; Stillwater Sciences 2008). Further, reservoir drawdown under the Proposed Project would occur during winter months when rates of primary production and microbially mediated nutrient cycling (e.g., nitrification, denitrification) are also expected to be low, such that nutrient uptake potential in the river reaches will be low during drawdown. Light limitation for primary producers that do persist during winter months is also likely to occur because of high turbidity; this would further decrease the potential for uptake of the TN and TP that are released along with reservoir sediment deposits. While there would be a temporary upward pulse in TP and TN away from the numeric TMDL targets, this pulse would not support the growth of nuisance and/or noxious phytoplankton or nuisance periphyton. Particulate nutrients released along with sediment deposits are not expected to be bioavailable, should be well-conserved during transport through the mainstem river and the estuary, therefore in the short-term sediment-associated TP and TN are not expected result in a failure to maintain a beneficial use, or cause an exceedance or exacerbate an existing exceedance of a water quality. Overall, this would be a less than significant short-term impact.

Pacific Ocean Nearshore Environment

Under the Proposed Project, fine sediments and associated nutrients released during reservoir drawdown would be dispersed as a buoyant river plume into the Pacific Ocean nearshore environment, where the sediments and associated nutrients would likely deposit along the continental shelf in the vicinity of the mouth of the Klamath River. Similar to conditions in the Klamath River and Klamath River Estuary, the biostimulatory effect of nutrient uptake from suspended or recently deposited fine sediments is expected to be low in the Pacific Ocean nearshore environment because reservoir drawdown would occur in winter when light availability is relatively low and primary productivity (i.e., phytoplankton growth) and microbially-mediated nutrient cycling are correspondingly low. In the summer following drawdown (dam removal year 2), resuspension of nutrients deposited on the continental shelf by coastal upwelling would make a negligible contribution to overall nutrient availability in the Pacific Ocean nearshore environment. This is because coastal upwelling near the mouth of the Klamath River supplies approximately 1,700 tons to 4,000 tons of nitrate per day per 100 meters of coastline, and approximately 225 tons to 450 tons of phosphate per day per 100 meters of coastline, using estimates for average California Current coastal upwelling near the Klamath River latitude (Bruland et al. 2001) and typical nutrient concentrations in coastal upwelling off the California coast (Bograd et al. 2009). Lower Klamath Project reservoir sediments would deposit between 1,200 tons to 5,500 tons of TN and 190 tons to 680 tons of TP along the continental shelf in the Pacific Ocean nearshore environment, based on the range of sediment TN (130 mg/kg to 2,800 mg/kg) and sediment TP (92 mg/kg to 370 mg/kg) from reservoir sediment cores (USBR 2011) and the range of sediment expected to erode during dam removal (1,460,000 tons to 2,310,000 tons; see also Section 2.7.3 *Reservoir Sediment Deposits and Erosion During Drawdown* and USBR [2012]). While only a fraction of the nutrients deposited on the continental shelf would have the potential to be resuspended during summer coastal upwelling, more nutrients would be supplied to marine nearshore surface waters by coastal upwelling in two days than the maximum amount of nutrients associated with the Lower Klamath Project reservoir sediments that would be mobilized during dam removal.

In addition to TN and TP, micronutrients in the Lower Klamath Project reservoir sediments could act as biostimulatory substances in the Pacific Ocean nearshore environment, where micronutrient availability can limit biological production in coastal waters (Bruland et al. 1991). Iron in the Lower Klamath Project reservoir sediments is the most abundant micronutrient that could influence phytoplankton productivity in the Pacific Ocean nearshore environment, since iron is important in photosynthetic and respiratory electron transport, nitrate reduction, and N-fixation (Morel et al. 1991; Bruland et al. 2001; Street and Paytan 2005). Iron is typically supplied at very low rates (0.04 tons to 0.10 tons per day per 100 meters of coastline) by coastal upwelling (Bruland et al. 2001; Bograd et al. 2009), such that river discharges are the primary source of iron to the California nearshore coastal environment (Bruland et al. 2001). During high-flow winter conditions, iron associated with riverine suspended particles is delivered to the continental shelf, and during summer, iron is remobilized by coastal upwelling (Chase et al. 2007). In coastal regions with large riverine inputs and a broad continental shelf, phytoplankton productivity in the Pacific Ocean nearshore environment is not considered to be iron-limited, since the combination of riverine supply and continental shelf storage can meet phytoplankton iron needs through particle resuspension (Chase et al. 2005; Lohan and Bruland 2006). Coastal regions with narrower shelves (less storage) and lower river discharge (less supply) can have iron-limited phytoplankton productivity (Hutchins and Bruland 1998; Bruland et al. 2001).

Studies of iron availability along the Oregon coast (Chase et al. 2007) and the central California coast between Monterey Bay and Point Reyes (Bruland et al. 2001) have found the shape of the continental shelf in those regions to be sufficiently large that enough iron can be stored from winter deposition that the Pacific Ocean nearshore environment is not iron-limited. Narrower continental shelf regions, like those found along the central California coast near Big Sur, have been found to be iron-limited (Bruland et al. 2001). The iron availability in the Pacific Ocean nearshore environment at the mouth of the Klamath River is unknown, but the shape of the continental shelf near the mouth of the Klamath River is similar to the shape of the continental shelf along the Oregon coast and central California coast between Monterey Bay and Point Reyes, suggesting that Pacific Ocean nearshore environment along the Klamath River is not iron-limited.

Estimates of typical sediment transport to the Pacific Ocean nearshore environment from the Mid- and Lower Klamath Basin downstream of Iron Gate Dam (Stillwater Sciences 2010) combined with estimates of the iron content of soils in the Mid- and Lower Klamath Basin (USGS NGS 2008) indicate that the total iron delivered to the nearshore coastal environment and the continental shelf near the Klamath River ranges from approximately 194,000 tons to 390,000 tons per year. Estimates of the amount of sediment expected to be released during dam removal (Table 2.7-11) combined with estimates of the iron content of the sediment trapped behind the Lower Klamath Project dams (8,200 mg/kg to 32,000 mg/kg; USBR 2011) indicate that an additional 23,000 tons to 62,000 tons of iron would be contributed to the Pacific Ocean nearshore environment by sediment released during dam removal. The 6 percent to 32 percent short-term increase in total iron loading to the Pacific Ocean nearshore environment as a result of Lower Klamath Project dam removal would not significantly alter iron nutrient conditions in the Pacific Ocean nearshore environment, since only a fraction of the iron would be resuspended by coastal upwelling and only a fraction of the resuspended iron would occur in a bioavailable form (Morel et al. 1991; Bruland et al. 2001; Buck et al. 2007).

Overall, the short-term increases in sediment-associated nutrients (TN and TP) would be less than significant because any biostimulatory effects would be limited in winter months by naturally low phytoplankton productivity and diluted in summer months by much higher background levels of resuspended nutrients supplied by coastal upwelling. Short-term increases in sediment-associated micronutrients (iron) also would be less than significant since iron-limitation of phytoplankton is not expected to occur in the Pacific Ocean nearshore environment near the mouth of the Klamath River, and the additional iron loading from Lower Klamath Project sediment deposits would be small compared to typical annual iron loading rates from natural erosion processes in the Mid- and Lower Klamath Basin. Thus, TP and TN in the reservoir sediment releases would not cause objectionable aquatic growths or degrade indigenous biota (see Table 3.2-6), and these nutrients are not expected result in a failure to maintain a beneficial use or cause an exceedance or exacerbate an existing exceedance of a water quality.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes monitoring of total nitrogen and total phosphorous. Please note that the State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section

401. The State Water Board has issued a draft water quality certification which sets forth monitoring and adaptive management requirements for any Water Quality Monitoring Plan to meet, as Condition 1[56]. Additionally, the Oregon Department of Environmental Quality has issued a water quality certification[57] that sets forth water quality monitoring and adaptive management conditions for points upstream of California. This EIR does not find that the effect of the Proposed Project on sediment-associated nutrients would be significant in either the short or the long term, and this analysis of Potential Impact 3.2-7 does not further discuss the water quality monitoring and adaptive management conditions.

Significance

No significant impact

Potential Impact 3.2-8 Long-term alterations in nutrients from the lack of interception and retention by the dams and conversion of the reservoir areas to a free-flowing river.

The two largest reservoirs in the Lower Klamath Project (Copco No. 1 and Iron Gate reservoirs) intercept and retain suspended material behind the dams, including nutrients (TP and TN) originating from upstream. Under the Proposed Project, these nutrients would be transported downstream and potentially be available for biological uptake (e.g., by periphyton [attached algae]). Analyses of the impacts of dam removal on nutrients have been conducted by PacifiCorp for its relicensing efforts (FERC 2007), the North Coast Regional Board for development of the California Klamath River TMDLs (North Coast Regional Board 2010), and the Yurok Tribe (Asarian et al. 2010) as part of an evaluation to improve previous nutrient budgets for the Klamath River and increase understanding of nutrient retention rates in free-flowing river reaches.

Hydroelectric Reach

The results of all the above-referenced evaluations (FERC 2007, North Coast Regional Board 2010, and Asarian et al. 2010) recognize the trapping efficiency of Copco No. 1 and Iron Gate reservoirs with respect to annual TP and TN, such that under the Proposed Project total nutrient concentrations in the Klamath River downstream from Iron Gate Dam would increase on an annual basis. However, the majority of the existing analyses results are focused on the Middle and Lower Klamath River downstream from Iron Gate Dam, rather than on the Hydroelectric Reach.

Modeling conducted for development of the California Klamath River TMDLs (North Coast Regional Board 2010) does provide some information applicable to the assessment of long-term impacts of the Proposed Project on nutrients at locations in the Hydroelectric Reach (Kirk et al. 2010). Klamath River TMDL model results indicate that if the Lower Klamath Project dams were to be removed ("TMDL dams-out, Oregon" [TOD2RN] scenario), TP and TN in the Hydroelectric Reach immediately downstream from J.C. Boyle Dam would increase slightly (by less than 0.015 mg/L TP and less than 0.05 mg/L TN) during summer months compared to existing conditions ("TMDL dams-in"

[56] The State Water Board's draft water quality certification is available online at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 14, 2018).

[57] The Oregon Department of Environmental Quality's final water quality certification is available online at: https://www.oregon.gov/deq/FilterDocs/ferc14803final.pdf (Accessed December 14, 2018).

[T4BSRN] scenario). This slight increase is due to the absence of nutrient interception and retention in both Keno Impoundment/Lake Ewauna and J.C. Boyle Reservoir. With respect to conditions in Keno Impoundment/Lake Ewauna, the Klamath River TMDL model assumes that the upstream Keno Dam is replaced by the historical natural Keno Reef in the "TMDL dams-out" scenario (TOD2RN and TCD2RN) but not in the "TMDL dams-in" scenario (T4BSRN). In the model, the Keno Reach is still partially impounded even though the reef's elevation is two feet lower than the current full pool elevation of Keno Impoundment/Lake Ewauna. While the Klamath River TMDL model assumption regarding Keno Reef does not materially influence model applicability to inform impact determinations for the Proposed Project and alternatives identified in this EIR, it could mean that the slight predicted increase in TP and TN under the modeled "TMDL dams-out" scenario (TOD2RN and TCD2RN) is an over-estimate under the Proposed Project, which does not propose any changes to Keno Dam, such that TP and TP concentrations in the Hydroelectric Reach immediately downstream from J.C. Boyle Dam would be the same as under existing conditions.

At the Oregon-California state line, the total nutrient supply also would be essentially the same under the Proposed Project as under existing conditions. The lack of hydropower peaking operations at J.C. Boyle Dam under the Proposed Project may result in decreased daily variation in TP and TN (North Coast Regional Board 2010). Overall however, the predicted nutrient changes are very small and thus this effect of the Proposed Project is not considered to be of potential benefit. Further, the Klamath River TMDL model predictions generally agree with empirical data regarding J.C. Boyle Reservoir; with its shallow depth and short residence time, this reservoir does not retain high amounts of nutrients (PacifiCorp 2006a) (see Appendix C for more detail) and its removal would not be expected to increase long-term nutrient transport in the Hydroelectric Reach downstream of the Oregon-California state line.

It is important to note that the Klamath River TMDL model scenarios are useful for informing impacts associated with the Proposed Project and alternatives identified in Section 4 *Alternatives*, but they include as a starting assumption that there will be full implementation of the TMDLs. For example, the "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios for California both assume that water entering into California from Oregon meets California water quality standards for water temperature, organic enrichment/low dissolved oxygen, nutrients, pH, and microcystin. In other words, the starting point for the California models is that all necessary reductions in pollution to address the current impaired conditions at the Oregon-California state line for these constituents would already have been implemented upstream. The full TMDL compliance modeling assumption does not reflect the existing conditions, and it would be speculative at this point to identify either the mechanisms necessary to implement the TMDLs or the timing required to achieve full compliance. However, the nutrient retention mechanism modeled in the Klamath River TMDL would be the same even if model inputs for nutrients were increased to concentrations under existing conditions, such that the general trend indicated by the Klamath River TMDL model output (i.e., dam removal would slightly increase downstream transport of total nutrients) is still informative for conditions where full TMDL compliance has not occurred.

Based on available information, the slight nutrient increases in the Hydroelectric Reach would not be expected to result in exceedances of California North Coast Regional Board Basin Plan water quality objectives for biostimulatory substances beyond levels experienced under existing conditions. Further, the elimination of seasonal releases of dissolved forms of nutrients from anoxic reservoir bottom waters during periods of reservoir stratification would reduce nutrient availability for supporting large summer and fall phytoplankton blooms, including blue-green algae blooms, in Copco No. 1 and Iron Gate reservoirs (see also discussion for *Middle and Lower Klamath River and Klamath River Estuary*). While seasonal periphyton colonization would likely increase in this reach under the Proposed Project, the increases would be due to habitat increases (i.e., conversion of a reservoir into a riverine habitat) rather than nutrient increases (see Potential Impact 3.4-4). Further, the reservoir environment that supports the growth of nuisance phytoplankton blooms such as *Microcystis aeruginosa* and other blue-green algae would be eliminated under the Proposed Project (see Section 3.4 *Phytoplankton and Periphyton*), reducing the possibility of uptake of the slightly increased total nutrient concentrations by any nuisance and/or noxious phytoplankton blooms that might, however unlikely, occur in the riverine reaches that replace the reservoirs. The nuisance phytoplankton problem is mainly relevant for Copco No. 1 and Iron Gate reservoirs, where the longer residence times support seasonal nuisance phytoplankton blooms (see Section 3.4 *Phytoplankton and Periphyton*). Thus, under the Proposed Project, there would be a less than significant long-term increase in total nutrient levels in the Hydroelectric Reach from the lack of continued interception by the Lower Klamath Project dams and conversion of the reservoir areas to a free-flowing river, and a beneficial effect of eliminating seasonal releases of dissolved forms of nutrients from anoxic reservoir bottom waters.

Middle and Lower Klamath River and Klamath River Estuary

As described above in this potential impact analysis, Copco No. 1 and Iron Gate reservoirs currently intercept and retain suspended material behind the dams, including nutrients (TP and TN) associated with suspended material that originates upstream of the Hydroelectric Reach. Results of all the existing evaluations (FERC 2007; North Coast Regional Board 2010; Asarian et al. 2010) recognize the trapping function of the reservoirs with respect to TP and TN, and they provide results indicating that ending this trapping by converting the reservoirs to free-flowing river reaches would, on an annual basis, result in a slight increase in *annual* TN and TP in the Middle and Lower Klamath River and the Klamath River Estuary. On a *seasonal* basis, the reservoirs can be a source of TP and TN in the form of dissolved nutrients (e.g., ortho-phosphorus, nitrate, and ammonium) to the Middle Klamath River, as nutrients contained within bottom sediments are released back into the water column under low dissolved oxygen conditions (see also Section 3.2.2.1 *Overview of Water Quality Processes in the Klamath Basin* and Figure 3.2-2). For example, in an analysis of nutrient dynamics in the Klamath River comparing the Klamath River TMDL model output against available empirical studies, while the *annual* modeled TP retention rate was approximately 6 percent for Iron Gate Reservoir and 1 percent for Copco No. 1, the model results indicated a *seasonal* TP release (2 percent to 40 percent) from Iron Gate Reservoir during late summer/fall, with the highest release (40 percent) occurring at reservoir fall turnover (see Figure 3.2-2 for a schematic of reservoir turnover), and a *seasonal* TP release (2 percent to 26 percent) from Copco No. 1 Reservoir during late summer/fall and into winter months. Similarly, albeit to a lesser degree, the *annual* modeled TN retention was approximately 18 percent for Iron Gate Reservoir, with a 4 percent *seasonal* release of TN in winter of the model year. For Copco No. 1, the annual modeled TN retention was 4 percent for Copco No. 1, with a *seasonal* release of 3 to 15 percent in winter months (North Coast Regional Board 2010, Appendix 3). Asarian et al. (2009) notes that the seasonal release of nutrients can occur periodically between the late summer and early winter, but on balance the annual retention of nutrients is greater than the seasonal releases.

Based on the Yurok Tribe analysis (Asarian et al. 2010), TP concentrations in the Middle and Lower Klamath River would increase by approximately 2 to 12 percent for the June–October period if the dams were to be removed, while increases in TN concentrations would be relatively larger, at an estimated 37 to 42 percent for June through October and 48 to 55 percent for July through September (see Figure 3.2-18). The Yurok Tribe conducted their analysis using two different approaches: (1) calculated reach-specific nutrient retention rates based on measured nutrient concentration data, and (2) predicted retention rates using an empirical relationship between observed retention rates and measured concentrations developed for the river from Iron Gate Dam to Turwar (this approach was only applicable to TN because TP data demonstrated a weak relationship between retention rate and measured TP concentrations). The two approaches used by the Yurok Tribe implicitly include nutrient recycling processes such as assimilative uptake for seasonal phytoplankton and periphyton growth and subsequent downstream release, as these processes were ongoing and inherently included in the retention estimates determined for existing conditions. The first (and only TP-applicable) approach indicated small increases in TP concentrations downstream from Iron Gate Dam under the Proposed Project, and a diminishment of this effect with distance downstream due to both tributary dilution and nutrient retention (i.e., uptake of nutrients). Both approaches yielded similar TN results, indicating relatively larger increases in TN concentrations than the TP concentration, following the same diminishment pattern due to dilution and nutrient retention.

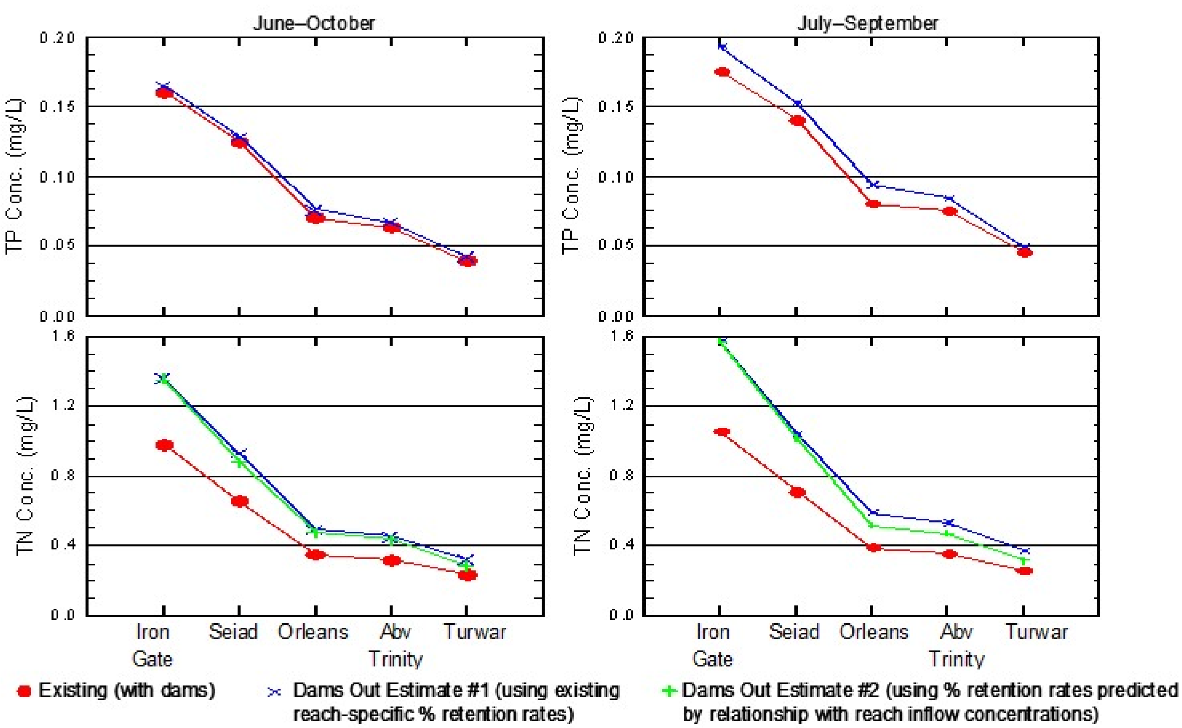

Figure 3.2-18. Comparison of Annual TP and TN Concentrations from Iron Gate Dam to Turwar (RM 5.6) for June–October and July–September 2007–2008: (a) Measured Current Conditions (Red Circle), (b) Dams-Out Estimate using Calculated Percent Retention Rates by Reach (Blue Cross), and (c) Dams-Out Estimate

using Percent Retention Rates Predicted by the Empirical Relationship between Reach Inflow Concentration and Retention (Green Cross). Source: Asarian et al. 2010.

Unlike the Yurok Tribe analysis, the Klamath River TMDL modeling efforts include an assumption of full compliance with upstream TP and TN load allocations for California (North Coast Regional Board 2010). Despite this, results of the Klamath River TMDL model are in general agreement with PacifiCorp (FERC 2007) and Yurok Tribe (Asarian et al. 2010) analyses regarding dam removal impacts on nutrients, with very small annual increases in TP (0.01 to 0.015 mg/L) and relatively larger annual increases in TN (0.1 to 0.125 mg/L) immediately downstream from Iron Gate Dam due to dam removal. Increases in nutrients would diminish with distance downstream from Iron Gate Dam. It should be noted that while following the same relative trend as the Yurok Tribe analysis, the absolute increases predicted by the Klamath River TMDL model for the "TMDL dams-out" California scenario (TCD2RN) are much lower (e.g., 0.1–0.125 mg/L TN increase for the TMDL model vs. 0.1 to 0.5 mg/L TN increase for the Yurok Tribe analysis). This finding is in accord with the prediction in Asarian et al. (2010) that decreased nutrient input into California would decrease the annual TN and TP effect of dam removal.

Variability in TP and TN are predicted by the Klamath River TMDL model (see Appendix D) under the "TMDL dams-out" California scenario (TCD2RN) during summer months, presumably due to nutrient uptake dynamics by periphyton and macrophytes in the free-flowing river segments that would replace the reservoirs. The Klamath River TMDL model does not include denitrification as a possible nitrogen removal term in river segments (Tetra Tech 2009), meaning that TN concentrations being transported into the Middle Klamath River under the Proposed Project may be over-predicted. The magnitude of this potential over-prediction would be expected to increase with distance downstream (i.e., relatively lower over-prediction at Iron Gate Dam and the Upper Klamath Basin, but relatively higher over-prediction at sites in the lowest portion of the Klamath River such as Orleans), due to a longer distance of river within which denitrification and other nitrogen removal processes would operate. Corresponding small differences in ortho-phosphorus, nitrate, and ammonium concentrations under the Proposed Project (as compared with existing conditions, including TMDL compliance) are predicted by the Klamath River TMDL model; however, within the uncertainty of future nutrient dynamics these differences are not clearly discernable as increases or decreases. Klamath River TMDL model results indicate that while resulting TP levels would meet the existing Hoopa Valley Tribe numeric water quality objective (0.035 mg/L TP) in all months at the Hoopa reach (approximately RM 45) of the Klamath River, TN levels would continue to be in excess of the existing objective (0.2 mg/L TN) in all months, as would TN levels for the modeled "natural conditions" (T1BSR) and the modeled "dams-in" scenario (T4BSRN) (for the months of October through June) (North Coast Regional Board 2010). However, as noted previously, TN concentrations in the model may be over-predicted and therefore the Hoopa Valley Tribe objective may be met.

While there would be a slight increase in absolute nutrient concentrations entering the Middle Klamath River under the Proposed Project, phytoplankton, especially blue-green algae, would be limited in their ability to use those nutrients for growth and reproduction without calm reservoir habitat (Potential Impact 3.4-2). Further, the elimination of potential seasonal releases of dissolved forms of nutrients from anoxic reservoir bottom waters and into downstream reaches of the Klamath River would reduce nutrient availability for phytoplankton during the growing season. Overall, the slight increase in annual nutrient concentrations would not result in significant biostimulatory impacts on phytoplankton growth under the Proposed Project relative to existing conditions, and the elimination of potential seasonal releases of dissolved nutrients from the reservoir bottom waters would be beneficial.

For periphyton, despite the overall increases in absolute nutrient concentrations anticipated under the Proposed Project, the small but relatively greater increases in TN also may not result in significant biostimulatory impacts during the growth season (i.e., late spring through fall). Existing data regarding TN:TP ratios suggest the potential for the Klamath River to be N-limited to the extent that there is a nutrient limitation. However, concentrations of both nutrients are high enough in the Klamath River from Iron Gate Dam to approximately Seiad Valley (RM 132.7) (and potentially further downstream) that nutrients are not likely to be limiting primary productivity (e.g., periphyton growth) in this more upstream portion of the Middle Klamath River (FERC 2007, HVTEPA 2008, Asarian et al. 2010). In addition, N-fixing species dominate the periphyton communities in the lower portions of the Middle Klamath River as well as the Lower Klamath River where inorganic nitrogen concentrations are low (Asarian et al. 2010, 2014, 2015). Since these species can fix their own nitrogen from the atmosphere, increases in TN due to dam removal may not significantly increase algal biomass in these reaches (see also Section 3.4 *Phytoplankton and Periphyton*).

In general, although dam removal would result in a slight long-term increase in TP and TN away from the numeric targets, such an increase would not support the growth of nuisance and/or noxious phytoplankton or nuisance periphyton. Therefore, in the long term the lack of continued interception of TN and TP on an *annual* basis by the Lower Klamath Project dams and conversion of the reservoir areas to a free-flowing river would not result in a failure to maintain a beneficial use or cause an exceedance or exacerbate an existing exceedance of a water quality. Overall, this would be a less than significant long-term impact. The elimination of potential seasonal releases of dissolved nutrients from the reservoir bottom waters to downstream reaches of the Klamath River would be beneficial.

Pacific Ocean Nearshore Environment

Copco No. 1 and Iron Gate reservoirs currently intercept and retain suspended material behind the dams, including nutrients (TN, TP) and micronutrients (iron) that are potentially important for phytoplankton growth in the Pacific Ocean nearshore environment. Similar to conditions in the Middle and Lower Klamath River and Klamath River Estuary, under the Proposed Project the Pacific Ocean nearshore environment also would experience a small increase in total annual nutrient concentrations on an annual basis since nutrients would no longer be trapped upstream by the Lower Klamath Project dams. The slight nutrient increases would not be expected to result in exceedances of water quality objectives for biostimulatory substances beyond levels experienced under existing conditions for the reasons described under Potential Impact 3.2-7 in the Pacific Ocean nearshore environment (because in the winter any biostimulatory effect would be limited by low productivity and light availability and during summer, any increase in nutrients in the Pacific Ocean nearshore environment would amount to considerably less than the background supply of nutrients from coastal upwelling (Bruland et al. 2001; Bograd et al. 2009). Overall, under the Proposed Project, there would be a less than significant long-term increase in nutrients in the Pacific Ocean nearshore environment due to the lack of continued interception by the Lower Klamath Project dams and conversion of the reservoir areas to a free-flowing river.

Significance

No significant impact in the long term due to lack of annual interception and retention of total nutrients

Beneficial in the long term due to elimination of potential seasonal releases of dissolved nutrients

3.2.5.4 Dissolved Oxygen

Potential Impact 3.2-9 Short-term increases in oxygen demand and reductions in dissolved oxygen due to release of sediments currently trapped behind the dams.

Hydroelectric Reach

Under the Proposed Project, high SSCs are expected to occur along the reaches of the Klamath River downstream of reservoirs and within the Klamath Estuary during and following drawdown (see Potential Impact 3.2-3). Because reservoir sediment deposits contain unoxidized organic matter from algal detritus (see Section 3.2.2.3 *Suspended Sediments*), resuspension of these materials during reservoir drawdown is likely to reduce oxygen concentrations in downstream reaches until oxygen consumption is balanced by reaeration as the river continues to flow. To put it more in terms of biochemical processes, decomposition of algal detritus is facilitated by natural bacteria associated with reservoir sediments. Once suspended during dam removal and exposed to the water column, these sediments would result in an oxygen demand generated by microbial oxidation and as well as chemical oxidation of reduced mineral compounds in the sediment (e.g., sulfides), especially from deeper in the sediment profile.

To estimate the potential magnitude of oxygen depletion and recovery at various SSC levels along the Klamath River, a modeling approach was adapted from Streeter and Phelps (1925) including laboratory estimates of dissolved oxygen depletion from both the rapid or immediate oxygen demand (IOD) of oxygen-demanding substances such as ferrous iron, followed by the slower microbially mediated biological oxygen demand (BOD) (Stillwater Sciences 2011). Using modeled estimates of SSC corresponding to expected river discharges during three representative water year types (see Section 3.2.5.2), the analysis of this potential impact accounts for changes in oxygen demand and river reaeration with distance (i.e., travel time of suspended sediments) to estimate corresponding dissolved oxygen concentrations in the various reaches of the Klamath River. Because prior analyses indicated that IOD and BOD are generally met at all expected SSC levels within the Klamath River (Stillwater Sciences 2011), the analysis below does not separately address potential impacts to the Pacific Ocean.

Modeled short-term oxygen demand as a function of SSC is not available for the Hydroelectric Reach. However, the results for the mainstem Klamath River downstream from Iron Gate Dam can also be applied to the Hydroelectric Reach. As a worst-case scenario, the reduction in dissolved oxygen due to short-term oxygen demand from sediment release in the Hydroelectric Reach is assumed to be the same as those for the Middle and Lower Klamath River. This is a conservative assumption because peak

SSCs downstream from J.C. Boyle Reservoir would be much lower and present for a shorter duration (2,000 to 3,000 mg/L occurring within one to two months of reservoir drawdown) than those predicted downstream from Iron Gate Dam (7,000 to 14,000 mg/L occurring within two to three months of reservoir drawdown) (Figure 3.2-11 through Figure 3.2-13). As is the case for the Middle Klamath River immediately downstream of Iron Gate Dam (see below), short-term reductions in dissolved oxygen due to release of sediment deposits within the Lower Klamath Project reservoir footprints would substantially exacerbate an existing exceedance of applicable water quality standards and therefore be a significant and unavoidable impact for the Hydroelectric Reach.

Middle and Lower Klamath River and the Klamath River Estuary

Based on results of short-term oxygen demand modeling of estimated SSCs across dam removal year 1 and 2 (see also Section 3.2.4.4), IOD downstream from Iron Gate Dam would be 0.0 to 8.6 mg/L and BOD would be 0.3 to 43.8 mg/L for all water year types considered (i.e., wet, median, dry) and for six months following initiation of reservoir drawdown (see Table 3.2-14). The highest predicted IOD and BOD levels are anticipated to occur during February of dam removal year 2, and they would correspond to the peak SSCs in the river (Figure 3.2-15 through Figure 3.2-17).

During dam removal year 1, with initial dissolved oxygen assumed to be on the order of 70 percent and 80 percent saturation in November and December, respectively, the low IOD and BOD from initial drawdown results in a less than 1 mg/L decrease in dissolved oxygen concentrations during these two months within the first mile downstream from Iron Gate Dam (Table 3.2-14), followed by gradual increases to near saturation at locations farther downstream. Under an assumption that high initial dissolved oxygen conditions persist into January through May of dam removal year 2, dissolved oxygen concentrations downstream from Iron Gate Dam would generally be greater than 5 mg/L despite the relatively high predicted IOD and BOD values (Table 3.2-14). Exceptions include predicted concentrations in February of dam removal year 1 for median (WY1976) and typical dry year (WY2001) hydrologic conditions, which exhibit minimum values of 3.5 mg/L and 1.3 mg/L, respectively. For all water year types (wet, median, dry), the predicted dissolved oxygen minimum values would occur by approximately RM 191–193.1 (approximately 0 to 2 miles downstream from Iron Gate Dam) and would return to at least 5 mg/L by approximately RM 178 to 180 (within 12 to 15 miles of the dam), or near the confluence with the Shasta River (RM 179.5).

Recognizing that IOD/BOD model results are sensitive to initial dissolved oxygen concentrations (Stillwater Sciences 2011), an additional modeling simulation was conducted to examine results assuming complete anoxia (i.e., 0 percent saturation) during dam removal year 2 (January through May) as an initial condition at Iron Gate Dam. Modeled dissolved oxygen concentrations remained below 5 mg/L downstream to RM 145 near the Scott River confluence during February of Dry Water Years, and as far downstream as RM 121.7, or 10 miles downstream of Seiad Valley (RM 132) in Normal and Wet Water Years (Table 3.2-14). At other times, dissolved oxygen concentrations generally recover before RM 134, near Seiad Valley (RM 132).

The Basin Plan water quality objective for dissolved oxygen is expressed as percent saturation (90 percent saturation). Assuming average February (2009) water temperatures, the water quality objective for November through April would range from 9.6 mg/L to 10.6 mg/L. Based on oxygen demand model results assuming high initial dissolved concentrations in dam removal year 2, recovery to the Basin Plan water quality objective of 90 percent saturation would occur generally within the reach from Seiad Valley (RM 132.7) to the mainstem confluence with Clear Creek (RM 100), or within a distance of 62 to 93 miles downstream from Iron Gate Dam for all water year types. Assuming low initial dissolved oxygen concentrations, recovery to the Basin Plan water quality objective of 90 percent saturation would occur generally farther downstream and within the reach from Clear Creek (RM 100) to the mainstem confluence with the Salmon River (RM 66), or 93 to 127 miles downstream from Iron Gate Dam for all water year types.

Thus, upstream of the Salmon River on the Middle Klamath River, short-term increases in IOD and BOD and reductions in dissolved oxygen due to release of sediments currently trapped behind the Lower Klamath Project dams would be a significant impact because reductions in dissolved oxygen below Basin Plan water quality objectives of 90 percent saturation for November through April (see also Table 3.2-5) would cause an exceedance of a water quality objective and a failure to maintain a beneficial use (COLD). Because physical removal of reservoir bottom sediments prior to drawdown is not feasible (Lynch 2011), and dam removal alternatives to the Proposed Project that would alter the timing and amount of sediment mobilization would result in the same or greater adverse impacts to designated beneficial uses and/or fish (see Section 4.1.1.4 *Elimination of Potential Alternatives that Would Not Avoid or Substantially Lessen Significant Environmental Effects of the Proposed Project*), the short-term significant impact of increased IOD and BOD and decreased dissolved oxygen in the Middle Klamath River upstream of the Salmon River cannot be avoided or substantially decreased through reasonably feasible mitigation. Because re-aeration through the water surface is sufficient to satisfy the most conservative assumptions of low initial dissolved oxygen (0 percent saturation) combined with high initial IOD and BOD (February conditions of Normal and Wet Water Year hydrology), there would be no significant impact from reduced dissolved oxygen concentrations due to sediment releases at any locations downstream of the Salmon River confluence on the Middle Klamath River, as well as in the Lower Klamath River and the Klamath River Estuary.

Table 3.2-14. Estimated Short-term Immediate Oxygen Demand (IOD) and Biochemical Oxygen Demand (BOD) by Month for Modeled Flow and SSCs Immediately Downstream from Iron Gate Dam Under the Proposed Project.

[1] Dam removal year 1 is represented by November and December, with dam removal year 2 represented by January through May.

[2] Predicted daily flow values from USBR hydrologic model output (USBR 2012). Daily flow values correspond to the peak suspended sediment concentration (SSC) for each month.

[3] Predicted peak suspended sediment concentration (SSC) by month from USBR model output (USBR 2012)

[4] Raw daily water temperature data for 2009 from http://www.pacificorp.com/es/hydro/hl/kr.html# (PacifiCorp 2009).

[5] Assumes 70% and 80% saturation during November and December of dam removal year 1, respectively, with either high (80%) or low (0%) initial dissolved oxygen during January through May of dam removal year 2

[6] Initial dissolved oxygen concentration downstream from Iron Gate Dam was calculated using average monthly water temperature, salinity = 0 ppt, and elevation = 707 m (2,320 ft).

[7] River miles (RM) listed are those used in Stillwater Sciences (2011). The river miles listed are different from those used in this EIR, because the river miles have been updated since 2011 based on slight changes in the river path.

[8] NA = not applicable because dissolved oxygen consistently remains greater than 5 mg/L at all locations downstream of Iron Gate Dam.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes turbidity and suspended sediment concentration monitoring along with adaptive management requirements. Please note that the State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section 401. The State Water Board has issued a draft water quality certification[58] which sets forth water quality monitoring, adaptive management, and compliance requirements for any Water Quality Monitoring Plan to meet, as Condition 1 *Water Quality Monitoring and Adaptive Management* and Condition 2 *Compliance Schedule.* Condition 2 acknowledges that the Proposed Project would have temporary (short-term) exceedances of water quality objectives associated with reservoir drawdown and the export of reservoir sediments into the Klamath River and Pacific Ocean. Restoration projects may cause exceedances of water quality objectives in the short term in light of the long-term water quality and ecosystem benefits they provide. Additionally, the Oregon Department of Environmental Quality has issued a water quality certification[59] that sets forth water quality monitoring and adaptive management conditions for points upstream of California, including an assessment of baseline river conditions upstream of dam removal operations.

Significance

Significant and unavoidable in the short term for Hydroelectric Reach and Middle Klamath River from Iron Gate Dam to the Salmon River

No significant impact in the short term for the Middle Klamath River downstream from the Salmon River, in the Lower Klamath River, or in the Klamath River Estuary

Potential Impact 3.2-10 Long-term alterations in dissolved oxygen concentrations and daily variability due to conversion of the reservoir areas to a free-flowing river.

Hydroelectric Reach

Modeling conducted for development of the Klamath River TMDLs indicates that in the long term under the "TMDL dams-out" scenario for Oregon reaches (TOD2RN), average dissolved oxygen concentrations in the Hydroelectric Reach downstream of J.C. Boyle Dam and at the Oregon-California state line would be the same or slightly greater during July through October than those under the "TMDL dams-in" scenario (T4BSRN) (North Coast Regional Board 2010). The same pattern is predicted for 30-day mean minimum and 7-day mean minimum dissolved oxygen criteria. With respect to daily variability in dissolved oxygen, the Klamath River TMDL model predicts somewhat reduced variability under the "TMDL dams-out" scenario for California reaches (TCD2RN) as compared to the "TMDL dams-in" scenario (T4BSRN) (Figure 3.2-19). The predicted decreases in daily variability at the Oregon-California state line may be due to elimination of hydropower peaking operations; however, since daily variability in dissolved oxygen is not currently an issue in the J.C. Boyle Peaking Reach, slightly reducing this variability would not be considered a beneficial effect.

[58] The State Water Board's draft water quality certification is available at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 14, 2018).

[59] The Oregon Department of Environmental Quality's final water quality certification is available at: https://www.oregon.gov/deq/FilterDocs/ferc14803final.pdf (Accessed December 14, 2018).

For the free-flowing reaches of the river replacing Copco No. 1 and Iron Gate reservoirs, long-term dissolved oxygen levels in the river would differ substantially from the super-saturation (i.e., greater than 100 percent saturation) that currently occurs in surface waters and the hypolimnetic oxygen depletion in that occurs in bottom waters of the reservoirs during the April/May through October/November period (see Section 3.2.2.5 *Dissolved Oxygen*). Dissolved oxygen in the free-flowing reaches of the river replacing the reservoirs would not exhibit such extremes and would instead show the typical dissolved oxygen concentrations of a flowing river. Long-term increases in summer and fall dissolved oxygen would be beneficial. Long-term dissolved oxygen levels or variability during winter and spring would not be significantly different under the Proposed Project compared to existing conditions, so the Proposed Project would not have the potential to cause or substantially exacerbate an exceedance of water quality standards or result in a failure to maintain existing beneficial uses currently supported, and would therefore have a less than significant impact on winter and spring dissolved oxygen concentrations for the Hydroelectric Reach.

Note that the Klamath River TMDL model scenarios are useful for informing impacts associated with the Proposed Project and alternatives identified in Section 4 *Alternatives*, but they include as a starting assumption that there will be full implementation of the TMDLs. For example, the "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios for California both assume that water entering into California from Oregon meets California water quality standards for water temperature, organic enrichment/low dissolved oxygen, nutrients, pH, and microcystin. In other words, the starting point for the California models is that all necessary reductions in pollution to address the current impaired conditions at the Oregon-California state line for these constituents would already have been implemented upstream. The full TMDL compliance modeling assumption does not reflect the existing conditions, and it would be speculative at this point to identify either the mechanisms necessary to implement the TMDLs or the timing required to achieve full compliance. However, the dissolved oxygen mechanism modeled in the Klamath River TMDLs would be the same even if model inputs for dissolved oxygen were changed to concentrations under existing conditions, such that the general trend indicated by the Klamath River TMDL model output (i.e., dam removal would eliminate the seasonal thermal stratification and phytoplankton bloom patterns that occur in the reservoirs under existing conditions and affect dissolved oxygen) is still informative for conditions where full TMDL compliance has not occurred.

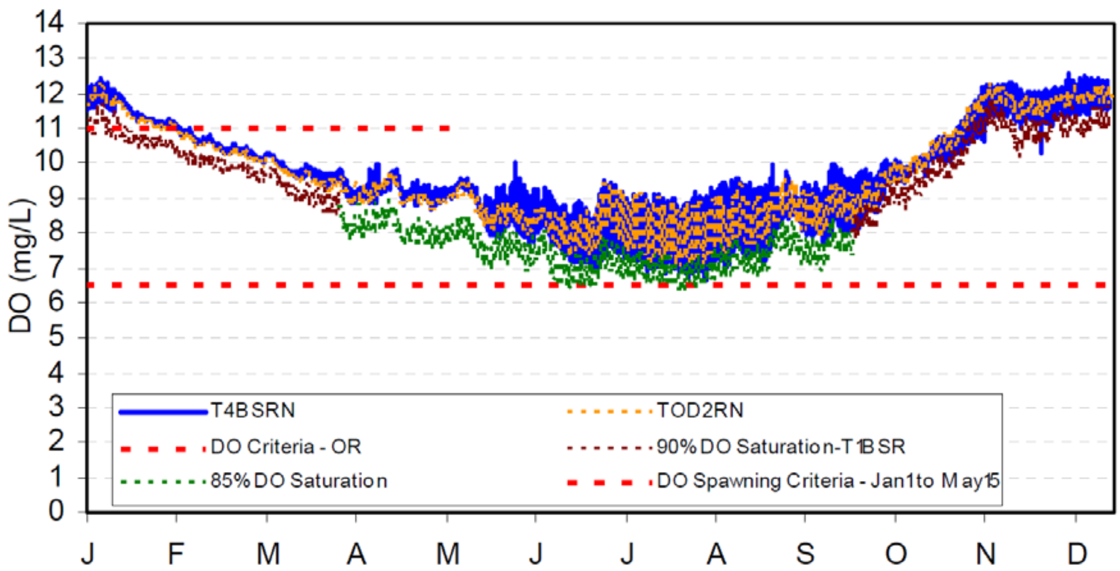

Figure 3.2-19. Predicted Dissolved Oxygen at the Oregon-California State Line (RM 214.1) for the Klamath River TMDL Scenarios Similar to the Proposed Project ("TMDL dams-out, Oregon" [TOD2RN] Scenario) and Existing Conditions ("TMDL dams-in" [T4BSRN] Scenario). Source: North Coast Regional Board 2010.

Middle and Lower Klamath River, Klamath River Estuary, and Pacific Ocean Nearshore Environment

KRWQM results using 2001 to 2004 data indicate that substantial improvements in long-term dissolved oxygen may occur immediately downstream from Iron Gate Dam if the Lower Klamath Project dams are removed, with increases of three to four mg/L possible during summer and late fall (PacifiCorp 2005). KRWQM output also predicts greater daily variations in dissolved oxygen concentrations downstream from Iron Gate Dam to the Trinity River confluence (RM 43.3) in the absence of the Lower Klamath Project dams, based upon the assumption that periphyton growth would occur in this reach if the dams were removed and would increase daily dissolved oxygen fluctuations due to photosynthetic oxygen production and respiratory consumption. However, the KRWQM does not include nutrient retention in the mainstem river downstream from Iron Gate Dam and assumes relatively high nutrient contributions from tributaries (Asarian and Kann 2006b). These input assumptions lead to a likely overestimate of the increase in periphyton growth, and therefore a likely overestimate of modeled predicted daily variations in dissolved oxygen.

Like the KRWQM model, the Klamath River TMDL model (see Appendix D) also indicates that under the "TMDL dams-out" scenario for California reaches (TCD2RN), long-term dissolved oxygen concentrations immediately downstream from Iron Gate Dam during July through November would be greater than those under the "TMDL dams-in" scenario (T4BSRN), due to the lack of stratification and oxygen depletion in bottom waters in the upstream reservoirs as compared with a free-flowing river condition (see Figure 3.2-20). Although the Klamath River TMDL model assumes full TMDL compliance (see below discussion regarding applicability of this assumption for analysis of the Proposed Project), the "TMDL dams-in" scenario (T4BSRN) results follow the same basic trend as existing conditions dissolved oxygen concentrations immediately downstream of Iron Gate Dam, where concentrations regularly fall below 8.0 mg/L and the Basin Plan minimum dissolved oxygen criteria of 85 to 90 percent saturation (depending on season) (see also Section 3.2.2.5 *Dissolved Oxygen*). Under existing conditions, low dissolved oxygen concentrations during late summer and fall continue to occur immediately downstream of Iron Gate Dam despite ongoing turbine venting at the Iron Gate Powerhouse required under KHSA Interim Measure 3.

The Klamath River TMDL model also predicts that daily fluctuations in dissolved oxygen immediately downstream of Iron Gate Dam during June through October would be greater under the "TMDL dams-out" scenario for California reaches (TCD2RN) than the "TMDL dams-in" scenario (T4BSRN) (Figure 3.2-20), a condition potentially linked to periphyton establishment in the free-flowing reaches of the river that are currently occupied by reservoirs, and associated daily swings in photosynthetic oxygen production and respiratory consumption. Again, although the Klamath River TMDL model assumes full TMDL compliance (see below discussion regarding applicability of this assumption for analysis of the Proposed Project), the "TMDL dams-in" scenario (T4BSRN) results follow the same basic trend as existing conditions dissolved oxygen percent saturation immediately downstream of Iron Gate Dam, where concentrations regularly fall below the Basin Plan minimum dissolved oxygen criteria of 85 – 90 percent saturation during June through October (see also Section 3.2.2.5 *Dissolved Oxygen*).

Differences in long-term dissolved oxygen concentrations and percent saturation between the "TMDL dams-out" scenario and the "TMDL dams-in" scenario diminish with distance downstream from Iron Gate Dam, with similar or the same predicted dissolved oxygen concentrations and similar magnitude and duration of daily fluctuations by Seiad Valley (RM 132.7) and no differences by the confluence with the Trinity River (RM 43.3) (see Figure 3.2-20 to Figure 3.2-23). The Klamath River TMDL model trends are consistent with existing conditions for this reach (see also Section 3.2.2.5 *Dissolved Oxygen*).

At all modeled locations, the Klamath River TMDL model indicates consistent compliance with the Basin Plan water quality objective of 85 percent saturation (see Figure 3.2-20 to Figure 3.2-23). Further downstream, near the confluence with the Trinity River (see Figure 3.2-23), results also indicate that while minimum values may occasionally dip below the current Hoopa Valley Tribe minimum water quality objective (8 mg/L, applicable at approximately RM 45), they would not fall below the 85 percent saturation objective modeled for the TMDL and would likely also not fall below the 90 percent saturation[60] Hoopa Valley Tribe objective[61]. Winter time (January through March) dissolved oxygen concentrations would be slightly lower under the Proposed Project but would not fall below Basin Plan minimum criteria for the winter season (90 percent saturation). The Klamath River TMDL model trends are consistent with existing conditions for this reach (see also Section 3.2.2.5 *Dissolved Oxygen*).

Note that the Klamath River TMDL model scenarios are useful for informing impacts associated with the Proposed Project and alternatives identified in Section 4 *Alternatives*, but they include as a starting assumption that there will be full

[60] This objective is not shown in Figure 3.2-23, but the general trend for 90 percent saturation can be estimated from the 85 percent saturation shown in the figure.
[61] As noted, there is no difference between the "TMDL dams-in" and "TMDL dams-out" scenarios by the confluence with the Trinity River where the Hoopa Valley Tribe's water quality standards are applicable.

implementation of the TMDLs. For example, the "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios for California both assume that water entering into California from Oregon meets California water quality standards for water temperature, organic enrichment/low dissolved oxygen, nutrients, pH, and microcystin. In other words, the starting point for the California models is that all necessary reductions in pollution to address the current impaired conditions at the Oregon-California state line for these constituents would already have been implemented upstream. The full TMDL compliance modeling assumption does not reflect the existing condition, and it would be speculative at this point to identify either the mechanisms necessary to implement the TMDLs or the timing required to achieve full compliance. However, the dissolved oxygen mechanism modeled in the Klamath River TMDLs would be the same even if model inputs for dissolved oxygen were changed to concentrations under existing conditions, such that the general trend indicated by the Klamath River TMDL model output (i.e., dam removal would eliminate the seasonal thermal stratification and phytoplankton bloom patterns that occur in the reservoirs under existing conditions and affect dissolved oxygen) is still informative for conditions where full TMDL compliance has not occurred.

Under the Proposed Project, the magnitude of the increased daily fluctuations in dissolved oxygen immediately downstream from Iron Gate Dam predicted by the PacifiCorp and Klamath River TMDL modeling efforts contain some uncertainty since the role of photosynthesis and community respiration from periphyton growth in the free-flowing reaches of the river that would replace the reservoirs at the Lower Klamath Project is unknown because nutrient cycling and resulting rates of primary productivity under modeled existing conditions are uncertain (see Section 3.4 *Phytoplankton and Periphyton*). Although the magnitude of the increased variability is somewhat uncertain, the overall daily fluctuations in dissolved oxygen are expected to increase in the Middle Klamath River from immediately downstream of Iron Gate Dam to Seiad Valley under the Proposed Project, especially during summer and fall. Even with the increase in daily fluctuations, the dissolved oxygen concentrations from immediately downstream of Iron Gate Dam to Seiad Valley would remain above Basin Plan dissolved oxygen saturation objectives throughout the year, so the Proposed Project would have a less than significant impact on dissolved oxygen in the long term. Downstream of Seiad Valley, the daily fluctuations in dissolved oxygen under the Proposed Project would be similar to existing conditions with the dams and the Proposed Project would have no impact. In addition to the increase in daily fluctuations, the removal of the Lower Klamath Project under the Proposed Project would cause beneficial long-term increases in summer and fall dissolved oxygen in the Middle Klamath River immediately downstream from Iron Gate Dam. Long-term decreases in winter and spring dissolved oxygen in the Middle Klamath River would be less than significant since the dissolved oxygen concentration would remain above Basin Plan dissolved oxygen saturation objectives. Effects would diminish with distance downstream from Iron Gate Dam, such that there would be no measurable impacts on dissolved oxygen by transition to the Lower Klamath River (i.e., the confluence with the Trinity River) and no impacts to the Klamath River Estuary or the Pacific Ocean nearshore environment.

Significance

No significant impact for daily fluctuations in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam

Beneficial for elimination of summer and fall extremes in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam

No significant impact for winter and spring concentrations in the Hydroelectric Reach and Middle Klamath River

No significant impact in the Lower Klamath River, Klamath River Estuary, and Pacific Ocean nearshore environment

3.2.5.5 pH

Potential Impact 3.2-11 Alterations in pH and daily pH fluctuations due to a conversion of the reservoir areas to a free-flowing river.

Surface water pH in the water quality Area of Analysis may be affected by changes in the amount of photosynthesis occurring during the summer and fall in the Klamath River. Conversion of the reservoir areas to a free-flowing river would change the available habitat for phytoplankton and/or periphyton, and changes in the growth patterns of these organisms would then change overall pH levels and variability in pH over a diel cycle (i.e., 24-hour period). The Hoopa Valley Tribe water quality objective for pH (7.0–8.5) is met the vast majority of the time under the Proposed Project (similar to the TMDL dams-out" [TCD2RN] scenario) for the Middle Klamath River at the reach of Hoopa jurisdiction (approximately RM 45), with a small number of predicted pH values of approximately 8.6 in summer months (July and August).

Hydroelectric Reach

While the Hydroelectric Reach is not currently identified as being impaired for pH specifically and the California Klamath River TMDLs do not include specific allocations or targets for pH itself, pH is identified as a secondary indicator of biostimulation, and pH impacts (i.e., exceedances of Basin Plan numeric pH objectives, see Table 3.2-3) are closely related to excessive nutrient inputs to the Klamath River (North Coast Regional Board 2010). pH values in Copco No. 1 and Iron Gate reservoirs can exceed the Basin Plan instantaneous maximum pH objective of 8.5 s.u., with large (0.5 to 1.5 s.u.) daily fluctuations occurring in reservoir surface waters during summertime periods of intense phytoplankton blooms (see Section 3.2.2.6 *pH*).

Modeling of pH conducted for development of the Klamath River TMDLs (Kirk et al. 2010, North Coast Regional Board 2010) provides information applicable to the assessment of long-term impacts of the Proposed Project on pH levels in the Hydroelectric Reach. Klamath River TMDL model results indicate that under the "TMDL dams-out" scenario for Oregon reaches (TOD2RN), pH at the Oregon-California state line would exhibit less daily variability during spring (March to May) and fall (October to November) (see Figure 3.2-24) than the "TMDL dams-in" scenario (T4BSRN). Daily variability in river pH during the summertime (June to September) would be similar or somewhat greater under the "TMDL dams-out" scenario (TOD2RN) than the "TMDL dams-in" scenario (T4BSRN), with the slight increase likely due to periphyton growth in the free-flowing river reaches currently occupied by the upstream J.C. Boyle Reservoir and the cessation of hydropower peaking flows in the Peaking Reach that may play a role in preventing establishment of mats under existing conditions. The "TMDL dams-out" scenario (TOD2RN) model results at the Oregon-California state line would occasionally exceed 8.5 s.u. However, because the frequency of exceeding 8.5 s.u. under the "TMDL dams-out" scenario (TOD2RN) would generally be the same as under existing conditions, removal of the Lower Klamath Project dams under the Proposed Project would not result in a failure to meet the instantaneous maximum pH objective at the levels currently supported in either the short term or the long term and there would be no significant impact.

Note that the Klamath River TMDL model scenarios are useful for informing impacts associated with the Proposed Project and alternatives identified in Section 4 *Alternatives*, but they include as a starting assumption that there will be full implementation of the TMDLs. For example, the "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios for California both assume that water entering into California from Oregon meets California water quality standards for water temperature, organic enrichment/low dissolved oxygen, nutrients, pH, and microcystin. In other words, the starting point for the California models is that all necessary reductions in pollution to address the current impaired conditions at the Oregon-California state line for these constituents would already have been implemented upstream. The full TMDL compliance modeling assumption does not reflect the existing condition, and it would be speculative at this point to identify either the mechanisms necessary to implement the TMDLs or the timing required to achieve full compliance. Further, the changes in daily fluctuations for pH indicated by the Klamath River TMDL modeling efforts are not entirely certain because growth rates of periphyton (attached algae) that could influence pH through photosynthesis in the free-flowing reaches of the river replacing Copco No. 1 and Iron Gate reservoirs are not precisely known. However, because modeled pH peak values and daily variability would be influenced by increasing nutrient concentrations in both the "TMDL dams-in" (T4BSRN) (from phytoplankton growth in reservoirs) and "TMDL dams-out" (TOD2RN) (from periphyton growth in river reaches) scenarios, the comparative model output is still informative with respect to general trends under conditions where full TMDL compliance has not occurred.

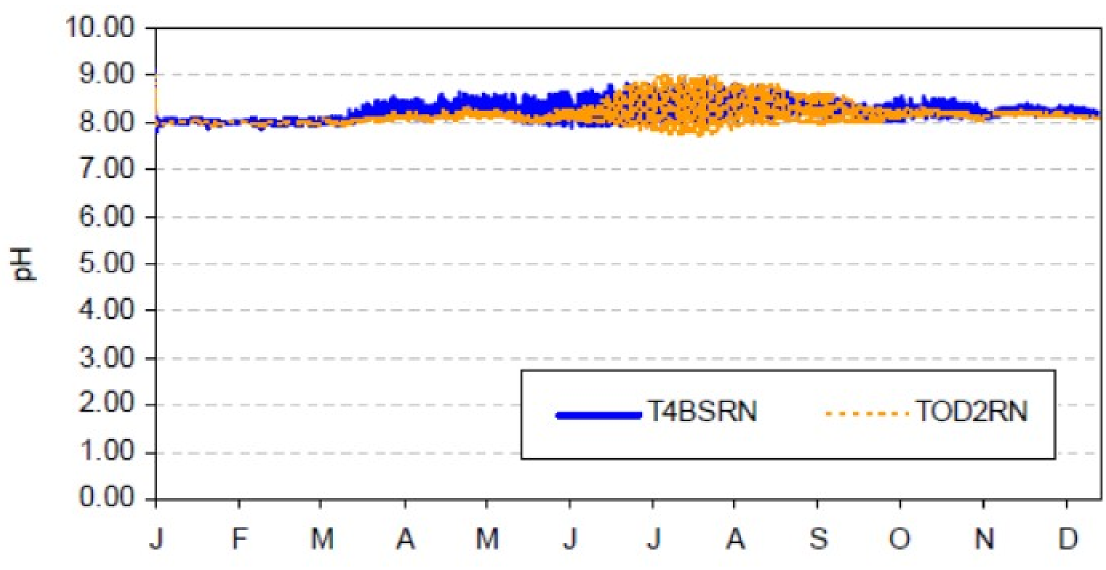

Figure 3.2-24. Predicted pH at the Oregon-California State Line (RM 214.1) for the Klamath River TMDL Scenarios Similar to the Proposed Project (TOD2RN Scenario) and the modeled existing conditions (T4BSRN Scenario). Source: North Coast Regional Board 2010.

The Proposed Project also would be expected to eliminate the occurrence of high pH (greater than 8.5 s.u.) and large daily fluctuations (0.5–1.5 s.u.) that occur in the surface waters of Copco No. 1 and Iron Gate reservoirs under existing conditions during periods of intense phytoplankton blooms (see Section 3.2.2.6 *pH*). The pH in the free-flowing reaches of the river replacing these reservoirs would not be likely to exhibit such extremes in daily pH and would not result in a failure to meet the existing instantaneous maximum pH objective at the levels currently supported and would be beneficial.

These beneficial pH changes, which would result from the conversion from a reservoir to a riverine system, would occur immediately following dam removal, in the spring of dam removal year 2. In contrast, the potential for the river reaches that replace Copco No. 1 and Iron Gate reservoirs to support periphyton growth along the river bed that increases variability in daily pH and potentially results in elevated pH values would be constrained in the short term because high SSCs and scour along the newly mobilized river bed during the winter and spring of dam removal year 2, and potentially also post-dam removal year 1, would limit establishment of extensive periphyton mats. Overall, in the short term, the Proposed Project would not result in a failure to meet the instantaneous maximum pH objective relative to the existing conditions in the reservoirs and would be beneficial.

In summary, based on Klamath River TMDL model results, dam removal under the Proposed Project would result in a similar frequency of exceeding 8.5 s.u. as existing conditions at the Oregon-California state line, and thus there would be no significant impact the short term and the long term. The decrease in high summertime daily pH fluctuations in the free-flowing reaches of the river that replace Copco No. 1 and Iron Gate reservoirs in the Hydroelectric Reach would not result in a failure to meet the instantaneous maximum pH objective at the levels currently supported and would be beneficial in the short term.

Middle and Lower Klamath River, Klamath River Estuary, and Pacific Ocean nearshore environment

Modeling of pH conducted for the development of the California Klamath River TMDLs also provides information applicable to the assessment of long-term impacts of the Proposed Project on pH in the Middle and Lower Klamath River. In general, results from the Klamath River TMDL model (see Appendix D) indicate that the “TMDL dams-out” (TCD2RN) scenario for California would result in relatively large daily variations in pH and generally high pH levels during summer and fall in the Middle Klamath River downstream from Iron Gate Dam (Figure 3.2-25); this pattern is characteristic of periphyton growth in river reaches. Although this condition would be in contrast to the “TMDL dams-in” (T4BSRN) scenario, where the Klamath River TMDL model predicts relatively low daily variation in pH in summer and fall (Figure 3.2-25), the higher daily pH variation and overall pH levels indicated for the “TMDL dams-out” (TCD2RN) scenario downstream from Iron Gate Dam are very similar to those under existing conditions (see Section 3.2.2.6 *pH*). This indicates that dam removal under the Proposed Project would not result in a failure to meet the instantaneous maximum pH objective relative to the levels currently supported downstream from Iron Gate Dam and there would be no significant impact.

Note that while the Klamath River TMDL model scenarios are useful for informing impacts associated with the Proposed Project and alternatives identified in Section 4 *Alternatives*, they include as a starting assumption that there will be full implementation of the TMDLs. For example, the "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios for California both assume that water entering into California from Oregon meets California water quality standards for water temperature, organic enrichment/low dissolved oxygen, nutrients, pH, and microcystin. In other words, the starting point for the California models is that all necessary reductions in pollution to address the current impaired conditions at the Oregon-California state line for these constituents would already have been implemented upstream. Although the "TMDL dams-out" (TCD2RN) scenario downstream of iron Gate Dam produces predicted pH values that are very similar to existing conditions, the full TMDL compliance modeling assumption does not, in fact, reflect the existing condition, particularly within the existing reservoirs. As described in Section 3.2.2.6 *pH,* the reservoirs are characterized by high daily variability and pH values that exceed 8.5 s.u. on a seasonal basis due to large phytoplankton blooms in summer and fall. Because the "TMDL dams-in" (T4BSRN) scenario shown in Figure 3.2-26 represents full compliance, it also displays evidence of limited phytoplankton production in the upstream reservoirs and hence lower pH peak values and daily variability as compared with existing conditions.

In general, because the changes in daily fluctuations for pH indicated by the Klamath River TMDL modeling efforts are not entirely certain, growth rates of periphyton (attached algae) that could influence pH through photosynthesis in the Middle and Lower Klamath River are not precisely known. However, because modeled pH peak values and daily variability would be influenced by increasing nutrient concentrations in both the "TMDL dams-in" (T4BSRN) (from phytoplankton growth in reservoirs) and "TMDL dams-out" (TCD2RN) (from periphyton growth in river reaches) scenarios, the comparative model output is still informative with respect to general trends under conditions where full TMDL compliance has not occurred.

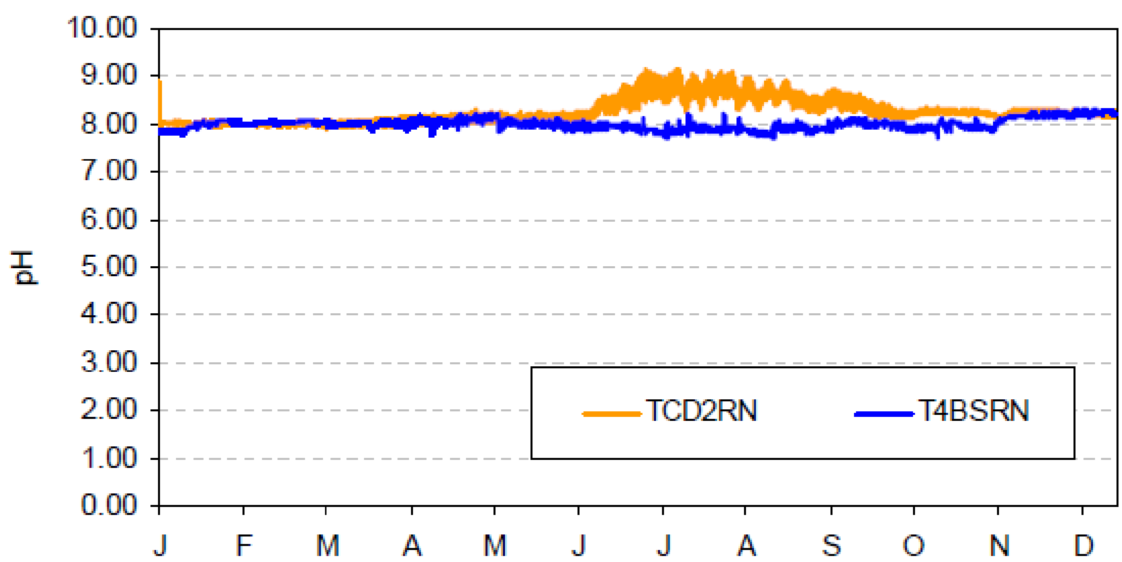

Figure 3.2-25. Predicted Klamath River pH Immediately Downstream from Iron Gate Dam for the Klamath River TMDL Scenarios Similar to the Proposed Project (TCD2RN Scenario) and the No Project Alternative (T4BSRN Scenario). Source: North Coast Regional Board 2010.

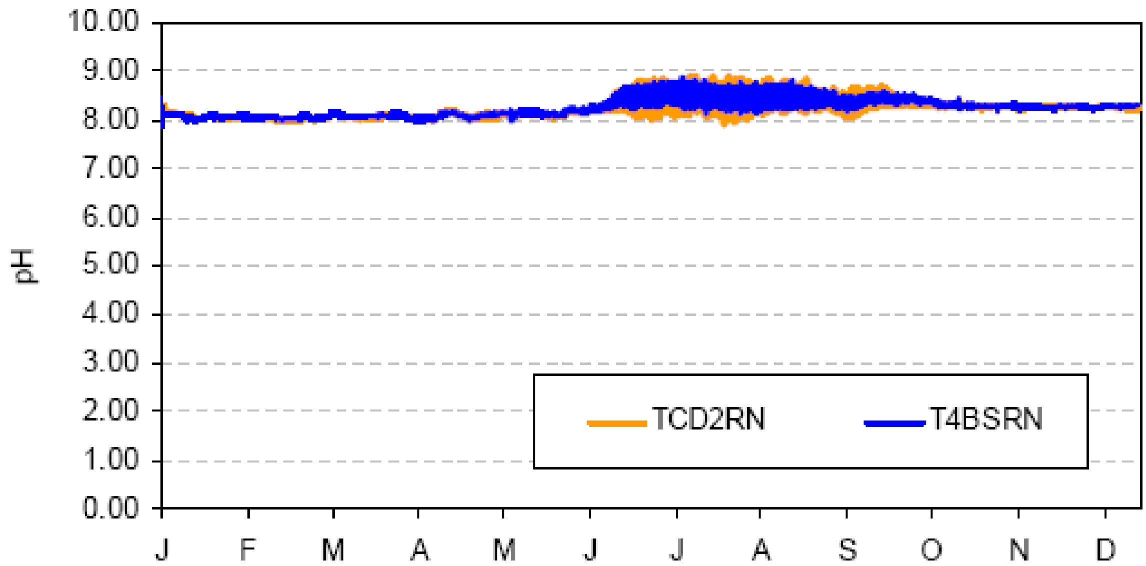

Figure 3.2-26. Predicted Klamath River pH upstream of the Scott River (RM 145.1) for the Klamath River TMDL Scenarios Similar to the Proposed Project (TCD2RN Scenario) and the No Project Alternative (T4BSRN Scenario). Source: North Coast Regional Board 2010.

As discussed above, the Proposed Project also would be expected to eliminate the occurrence of high pH (greater than 8.5 s.u.) and large daily fluctuations (0.5–1.5 s.u.) that occur in the surface waters of Copco No. 1 and Iron Gate reservoirs under existing conditions during periods of intense phytoplankton blooms, where the blooms can be transported downstream into the Middle Klamath River and adversely affect pH (see Section 3.2.2.6 *pH*). Consequently, under the Proposed Project pH in the Middle Klamath River immediately downstream of Iron Gate Reservoir would not be likely to exhibit extremes in daily pH due to seasonal phytoplankton blooms, which would reduce the potential for a failure to meet the instantaneous maximum pH objective at the levels currently supported and would be beneficial in the long term.

Klamath River TMDL modeling indicates that the Hoopa Valley Tribe water quality objective for pH (7.0–8.5) would be met the vast majority of the time under the Proposed Project (similar to the TMDL dams-out" [TCD2RN] scenario) for the Middle Klamath River at the reach of Hoopa jurisdiction (approximately RM 45), with a small number of predicted pH values of 8.5 or 8.6 in July and August. The Yurok Tribe water quality objective for pH (6.5–8.5) would be met at all times under the "TMDL dams-out" (TCD2RN) scenario for the Middle Klamath River at the reach of Hoopa jurisdiction (approximately RM 45). This suggests that dam removal under the Proposed Project would not increase the potential for exceedance of the instantaneous maximum pH objective relative to the existing conditions downstream from Iron Gate Dam.

While Klamath River TMDL modeling contains uncertainty about the periphyton response to dam removal within the Hydroelectric Reach and it assumes full TMDL compliance (see above discussion), monitoring data at multiple locations further downstream in the Middle and Lower Klamath River indicate that pH patterns over a 24-hour period are driven primarily by photosynthesis and respiration of periphyton (Ward and Armstrong 2010; Asarian et al. 2015; see Section 3.4.2.2 *Periphyton*) rather than phytoplankton. Since N-fixing species dominate the periphyton communities in the lower portions of the Middle Klamath River as well as the Lower Klamath River where inorganic nitrogen concentrations are low (Asarian et al. 2010, 2014, 2015), changes in nutrients due to dam removal are not expected to alter the periphyton community in these reaches (see Potential Impact 3.4-5). Thus, there is no evidence to indicate that there would be a change in pH relative to existing conditions that would have the potential to cause or substantially exacerbate an exceedance of water quality standards or result in a failure to maintain existing beneficial uses currently supported in these periphyton-dominated reaches, the downstream Klamath River Estuary, and the Pacific Ocean nearshore environment under the Proposed Project, and therefore there would be a less than significant impact to pH in the long term.

The beneficial pH changes in the Middle Klamath River immediately downstream of Iron Gate Dam that would result from the conversion from a reservoir to a riverine system in the upstream Hydroelectric Reach, would occur immediately following dam removal, in the spring of dam removal year 2. In contrast, the potential for this reach to support periphyton growth along the river bed that increases variability in daily pH and potentially results in elevated pH values would be constrained in the short term because high SSCs and scour along the newly mobilized river bed during the winter and spring of dam removal year 2, and potentially also post-dam removal year 1, would limit establishment of extensive periphyton mats. Overall, in the short term, the Proposed Project would reduce the potential for a failure to meet the instantaneous maximum pH objective relative to the existing conditions and would be beneficial.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes pH monitoring. Please note that the State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section 401. The State Water Board has issued a draft water quality certification which sets forth monitoring and adaptive management requirements for any Water Quality Monitoring Plan to meet, as Condition 1[62]. Additionally, the Oregon Department of Environmental Quality has issued a water quality certification[63] that sets forth water quality monitoring and adaptive management conditions for points upstream of California. Because the effect of the Proposed Project on pH is anticipated to be beneficial or would not result in a significant impact in either the short and long term, this analysis of Potential Impact 3.2-11 does not further discuss the water quality monitoring and adaptive management conditions.

Significance

No significant impact for the Hydroelectric Reach at Oregon-California state line in the short term and long term.

Beneficial for the Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam in the short term and long term.

---

[62] The State Water Board's draft water quality certification is available at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 14, 2018).

[63] The Oregon Department of Environmental Quality's final water quality certification is available at: https://www.oregon.gov/deq/FilterDocs/ferc14803final.pdf (Accessed December 14, 2018).

No significant impact for the Middle Klamath River downstream of Iron Gate Dam, the Lower Klamath River, the Klamath River Estuary, and the Pacific Ocean nearshore environment in the short term and long term.

3.2.5.6 Chlorophyll-a and Algal Toxins

Potential Impact 3.2-12 Alterations in chlorophyll-*a* and algal toxins due to a conversion of the reservoir areas to a free-flowing river.

While fast-moving rivers do not provide good habitat for phytoplankton growth, slow-moving, calm water like the reservoirs created by Copco No. 1 and Iron Gate dams provide ideal habitat conditions for phytoplankton growth, especially blue-green algae species (see Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*, Section 3.4.2.1 *Phytoplankton*, and Appendix C – *Section C.6 Chlorophyll-a and Algal Toxins*). Chlorophyll-*a* is a pigment produced by phytoplankton, including blue-green algae, so concentrations of chlorophyll-*a* are often used to evaluate whether there is excessive phytoplankton growth in rivers, lakes, or reservoirs. Most importantly, several types of blue-green algae produce algal toxins, especially during excessive growth of blue-green algae (i.e., blooms), that can have negative health impacts on animals and humans (see Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*, Section 3.4.2.1 *Phytoplankton*, and Appendix C – *Section C.6 Chlorophyll-a and Algal Toxins*). Thus, the potential changes to chlorophyll-*a* and algal toxins due to conversion of the reservoir areas to a free-flowing river are evaluated to determine the potential impacts to water quality.

Hydroelectric Reach

Despite the slightly increased total nutrient concentrations anticipated under the Proposed Project in the Hydroelectric Reach (see Potential Impact 3.2-8), elimination of the slow-moving reservoir environment that currently supports growth for toxin-producing nuisance blue-green algae (e.g., *Microcystis aeruginosa*) would decrease the occurrence of high seasonal concentrations of chlorophyll-a (concentrations greater than 10 ug/L) and periodically high levels of algal toxins (concentrations greater than 0.8 and/or 4 ug/L microcystin; see Section 3.2.3.1 *Thresholds of Significance*) generated by suspended blue-green algae (see Potential Impact 3.4-2). This would be a beneficial effect.

Drawdown of the reservoirs would begin in winter and would be largely complete by March/April (i.e., the beginning of the algal growth season) of dam removal year 2, so complete elimination of the reservoir environment under the Proposed Project would occur by the end of dam removal year 2. Thus, the decrease in high seasonal chlorophyll-a concentrations and periodic high algal toxin concentrations would also occur by the end of dam removal year 2 due to the elimination of reservoir habitat that supported algal growth. Therefore, reductions in chlorophyll-a and algal toxins in the Hydroelectric Reach would be a short-term benefit as well as a long-term benefit since the reduction would begin during dam removal year 2 and it would continue beyond post-dam removal year 1.

Middle and Lower Klamath River and the Klamath River Estuary

In addition to the decreases in the occurrence of high seasonal concentrations of chlorophyll-a (concentrations greater than 10 ug/L) and periodically high levels of algal toxins (concentrations greater than 0.8 and/or 4 ug/L microcystin; see Section 3.2.3.1 *Thresholds of Significance*) generated by nuisance blue-green algae that are described for the Hydroelectric Reach, transport and growth of Microcystis aeruginosa in the

Middle and Lower Klamath River would be substantially reduced or eliminated in the absence of significant Lower Klamath Project reservoir blooms. Genetic and toxin analyses show that the *Microcystis aeruginosa* populations in Copco No. 1 and Iron Gate reservoirs are genetically distinct from each other and upstream populations, providing evidence that blue-green algae blooms in Iron Gate Reservoir are internally derived and not due to transport of *Microcystis aeruginosa* populations from Copco No. 1 Reservoir or further upstream (Otten et al. 2015). While algal toxins generated in Copco No. 1 could be transported downstream, Otten et al. (2015) document with genetic analysis that algal production in Iron Gate Reservoir is the principal source of *Microcystis aeruginosa* responsible for the observed public health exceedances occurring in the Klamath River downstream from Iron Gate Dam (see Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*, Section 3.4.2.3 *[Phytoplankton and Periphyton] Hydroelectric Reach* and Appendix C, Section C.6 *Chlorophyll-a and Algal Toxins*). Therefore, removal of the reservoirs under the Proposed Project would eliminate *in situ* production of seasonal blue-green algae blooms and the associated algal toxins and chlorophyll-*a*. While algal toxins and chlorophyll-*a* produced in Upper Klamath Lake may still be transported downstream after dam removal, existing data indicate that microcystin concentrations in the Klamath River decrease to below California water quality objectives (see Section 3.2.3.1 *Thresholds of Significance*) by the upstream end of J.C. Boyle Reservoir, regardless of the microcystin concentration measured leaving the Upper Klamath Lake (Watercourse Engineering, Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016). Thus, algal toxins and chlorophyll-*a* production upstream of J.C. Boyle Dam would not be expected to be transported into California and result in algal toxin or chlorophyll-*a* concentrations in a manner that would cause or substantially exacerbate an exceedance of water quality standards or would result in a failure to maintain existing beneficial uses currently supported.

Drawdown of the reservoirs would begin in winter and would be largely complete by March/April (i.e., the beginning of the growth season) of dam removal year 2, so complete elimination of the reservoir environment that transports blue-green algae, algal toxins, and chlorophyll-*a* in the Middle and Lower Klamath River and the Klamath River Estuary would occur by the end of dam removal year 2 under the Proposed Project. Thus, the decrease in high seasonal chlorophyll-*a* concentrations and periodic high algal toxin concentrations would also occur by the end of dam removal year 2 in the Middle and Lower Klamath River and the Klamath River Estuary due to the elimination of the upstream reservoir habitat. Therefore, reductions in chlorophyll-*a* and algal toxins in the Middle and Lower Klamath River and the Klamath River Estuary would be a short-term benefit as well as a long-term benefit.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes monitoring of microcystin-producing blue-green algae cell counts. Please note that the State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section 401. The State Water Board has issued a draft water quality certification which sets forth monitoring and adaptive management requirements for any Water

Quality Monitoring Plan to meet, as Condition 1[64]. Additionally, the Oregon Department of Environmental Quality has issued a water quality certification[65] that sets forth water quality monitoring and adaptive management conditions for points upstream of California. The effect of the Proposed Project on chlorophyll-*a* and algal toxins is anticipated to be beneficial in both the short and long term, and this analysis of Potential Impact 3.2-12 does not further discuss the water quality monitoring and adaptive management conditions.

Significance

Beneficial for the Hydroelectric Reach, the Middle and Lower Klamath River, and the Klamath River Estuary

3.2.5.7 Inorganic and Organic Contaminants

Potential Impact 3.2-13 Human exposure to inorganic and organic contaminants due to release and exposure of reservoir sediment deposits.

This potential impact evaluates the potential human exposure to inorganic and organic contaminants in sediments remaining within the reservoir footprints and along the river banks in addition to potential inorganic and organic contaminant concentrations in the river water in the Hydroelectric Reach, the Middle and Lower Klamath River, and the Klamath River Estuary due to the release of sediments currently trapped behind the Lower Klamath Project dams. The two main ways people would be potentially exposed to inorganic or organic contaminants in reservoir sediments would be through direct contact with reservoir sediments or eating fish or shellfish exposed to inorganic or organic contaminants in reservoir sediments. Direct human exposure to reservoir sediments due to recreational uses (e.g., camping, fishing, rafting) are evaluated by comparing inorganic and organic contaminant levels measured in reservoir sediments with USEPA and CalEPA screening levels that are conservatively protective of human health. Human exposure to inorganic and organic contaminants from eating fish or shellfish (e.g., mussels) is evaluated by comparison with available screening level values (SLVs) that assess whether contaminants in sediment would increase in fish or shellfish (i.e., bioaccumulate) to unhealthy levels for humans who eat them. While less likely than direct contact with remaining reservoir sediments after drawdown or eating fish exposed to inorganic and organic contaminants, people also would potentially be exposed to inorganic and organic contaminants from reservoir sediments in river water during drawdown when reservoir sediments and associated inorganic and organic contaminants were being transported. Human exposure to inorganic and organic contaminants from exposure to river water through consumption during drawdown and the transport of reservoirs sediments in the Klamath River is analyzed by comparing applicable human health drinking water standards[66] with the range of potential inorganic and organic contaminant concentrations in the elutriate samples, representing the highest potential concentration of these contaminants during drawdown. Comparison of

[64] The State Water Board's draft water quality certification is available online at: https://www.waterboards.ca.gov/waterrights/water_issues/programs/water_quality_cert/docs/lower_klamath_ferc14803/lkp_dwqc.pdf (Accessed December 11, 2018).

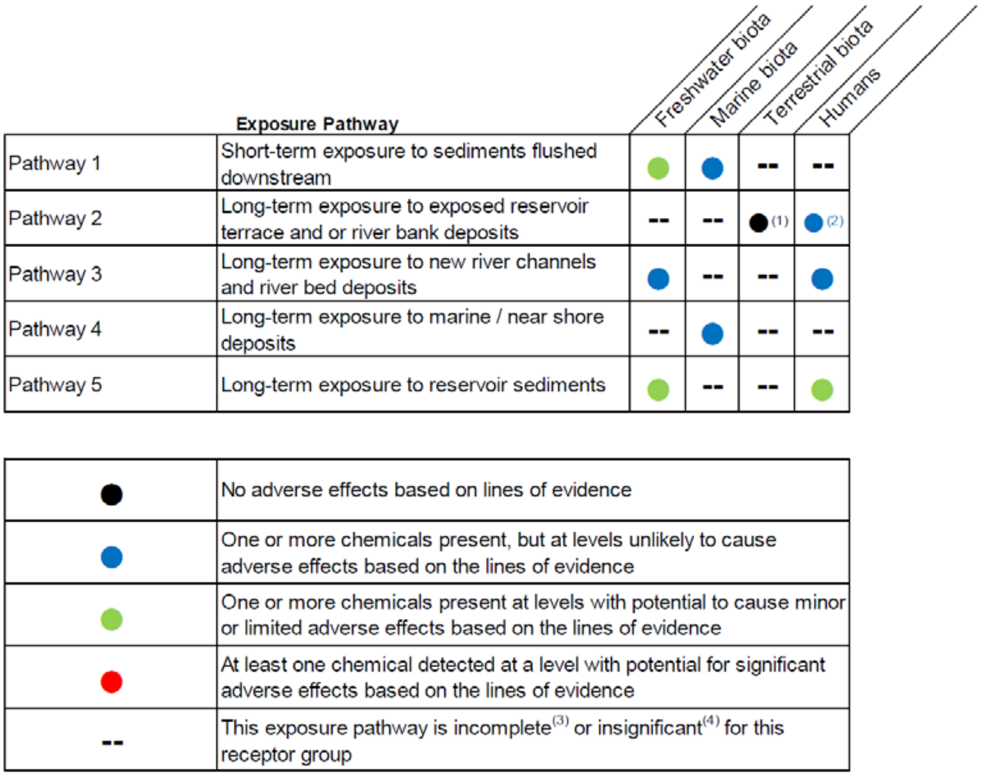
[65] The Oregon Department of Environmental Quality's final water quality certification is available online at: https://www.oregon.gov/deq/FilterDocs/ferc14803final.pdf (Accessed December 11, 2018).

[66] Human Health drinking water standards are listed Table B-6 of the Screening-Level Evaluation of Contaminants in Sediments from Three Reservoirs and the Estuary of the Klamath River, 2009-2011 (CDM 2011), which is included by reference and provided in Appendix W of this EIR.

the applicable human health drinking water standards with reservoir elutriate sample concentrations identified arsenic, aluminum, total PCB, chromium, and lead as detected potential chemicals of concern during reservoir drawdown (CDM 2011) and these are evaluated in more detail with consideration of actual concentrations expected during drawdown below. In a review of records maintained by the State Water Board's Division of Water Rights and Division of Drinking Water, only two drinking water diversions were identified in the Klamath River below Iron Gate Dam: (1) CalTrans' Randolph E. Collier Northbound and Southbound Rest Areas located near Hornbrook; and (2) Klamath Community Services District in Del Norte County located near the mouth of the Klamath River. The analysis below addresses the potential drinking water impacts to the Klamath River between the Oregon-California state line to the Klamath River Estuary, with consideration of the Hydroelectric Reach between J.C. Boyle Reservoir and the Oregon-California state line only to the extent it would influence downstream conditions in California.

Hydroelectric Reach

Potential human health risks associated with exposure to remaining sediment deposits within the reservoir footprints (i.e., "exposed reservoir terraces" as defined by CDM [2011]) and river banks within the Hydroelectric Reach were evaluated using comparisons of the 2009–2010 Klamath Dam Removal Secretarial Determination reservoir sediment core data to USEPA and CalEPA residential soil screening levels, and calculation of human/mammal toxic equivalency values (TEQs) ("Exposure Pathway 2 and 3" in CDM [2011]) (Figure 3.2-27). The analysis of exposure pathways using the 2009 SEF screening levels was updated based on 2018 SEF screening levels, as appropriate (Appendix C – *Section C.7*).



Note:
This does not include an evaluation of the physical effects (e.g., dissolved oxygen in the water, suspended sediment)
(1) Qualitative evaluation conducted for this exposure pathway
(2) Limited quantitative, along with qualitative evaluations conducted for this exposure pathway
(3) Incomplete - receptor group is unlikely to come in contact with sediment-associated contaminants under this exposure pathway
(4) Insignificant - exposure pathway not considered a major contributor to adverse effects in humans based on best professional judgment

Figure 3.2-27. Summary of Exposure Pathway Conclusions for Inorganic and Organic Contaminants. Source: CDM 2011.

As part of the Secretarial Determination process, the Water Quality Sub-Team identified USEPA soil screening levels and CalEPA California Human Health Screening Levels (CHHSLs) for soil as appropriate thresholds for determining the potential for sediment contaminants to adversely affect human health. USEPA residential exposure uses a 30-year exposure duration, 365 days per year exposure frequency with a soil ingestion rate of 200 mg/day for children over 6 years and 100 mg/day for adults over 24 years (USEPA 1991). CalEPA CHHSLs are based on the USEPA approach, with the residential exposure using a 30 year duration, 350 days per year exposure frequency with a soil ingestion rate of 200 mg/day for children over 6 years and 100 mg/day for adults over 24 years and the commercial exposure using a 25 year duration, 250 days per year exposure frequency with a soil ingestion rate of 200 mg/day for children over 6 years and 100 mg/day for adults over 24 years (CalEPA OEHHA 2005). In the short term, human exposure to inorganic and organic contaminants in sediments deposited on exposed reservoir terraces and river banks within the Hydroelectric Reach would be limited, short duration, non-residential exposure patterns (e.g., construction and restoration activities), resulting in less exposure to inorganic or organic contaminants (i.e., a lower ingestion rate of soil) than assumed for the USEPA and CalEPA screening levels. For example, construction/restoration worker exposure of 100 days per year for 5 years would result in only 4.8 percent of the CalEPA residential exposure. While the USEPA and CalEPA residential and commercial soil screening levels are used to evaluate the potential for adverse effects to humans, applying the USEPA and CalEPA screening levels considerably overstates the potential impact and the presence of a chemical at concentrations in excess of a USEPA and/or CalEPA screening level does not indicate that adverse impacts to human health would occur. Thus, the initial analysis of potential exposure and conclusions based on the USEPA and CalEPA screening levels would provide a very conservative estimate of potential adverse effects to humans and further interpretation of the comparisons of screening levels and inorganic and organic contaminant results, including an analysis of the exposure pathways, is necessary to assess the actual potential for human health impacts.

USEPA provides screening levels for both total carcinogenic (potentially cancer-causing) and total non-carcinogenic (not associated with cancer risk) contaminants. No reservoir sediment samples exceeded the total non-carcinogenic screening levels. Forty-five samples exceeded the USEPA total carcinogenic screening level for residential soils for arsenic or nickel, including samples from J.C. Boyle, Copco No. 1 and Iron Gate reservoirs. Those forty-five samples also exceeded the CalEPA residential and commercial screening levels for arsenic, but they did not exceed the CalEPA screening levels for nickel.

For arsenic, sampled concentrations in the reservoirs ranged from 4.3 to 15 mg/kg (see Section 3.2.2.8 *Inorganic and Organic Contaminants* and Appendix C, Table C-6), which is within the range of available measured arsenic soil concentrations for the Klamath Basin. Arsenic ranges from 0.8 to 23 mg/kg in regional soil samples from the Mid- and Lower Klamath Basin outside of the reservoir areas with typical arsenic concentrations between 2 and 7 mg/kg (USGS NGS 2008). Arsenic may be naturally elevated in the Upper Klamath Basin, with arsenic ranging from approximately 0.6 to 43.0 mg/kg and average regional background arsenic concentrations of 3.99 mg/kg ± 5.03 mg/kg in the vicinity of Upper Klamath Lake (Sturdevant 2010; ODEQ 2013; Sullivan and Round 2016). In comparison, the USEPA total carcinogenic screening level for soils is 0.39 mg/kg and the CalEPA specifies a California Human Health residential soil (0.07 mg/kg) and a commercial soil (0.24 mg/kg) screening levels.

In the long term, the Proposed Project includes the transfer of PacifiCorp lands immediately surrounding the Lower Klamath Project ("Parcel B lands") (Figure 2.7-18) from PacifiCorp to the KRRC prior to dam removal. The Proposed Project provides that the KRRC will transfer Parcel B lands to the respective states (i.e., California, Oregon), as applicable, or to a designated third-party transferee, following dam removal. The lands would thereafter be managed for public interest purposes (e.g., tribal mitigation, river-based recreation, wetland restoration, etc.) (KHSA Section 7.6.4). Pursuant to the KHSA, decisions about the land use would occur following dam removal, and the outcome of who the lands will ultimately be transferred to and what they will be used for is uncertain. Potential human exposure to arsenic measured in the Lower Klamath Project reservoir sediments under the Proposed Project would be less than that assumed for the USEPA or CalEPA screening levels since the reservoir footprint areas would be unlikely to support residential uses. Further, the exposure potential on the future public lands is likely to be considerably less than the exposure potential for residential uses. Limited, short duration, non-residential exposure patterns (e.g., recreational use) would result in less exposure to arsenic (i.e., a lower ingestion rate of soil). For example, recreational exposure of 10 to 90 days per year, every year for 30 years would result in only 3 to 25 percent of the residential exposure. Thus, overall the Proposed Project would be unlikely to result in short-term or long-term substantive adverse impacts on human health under possible "Exposure Pathway 2" due to arsenic.

For nickel, sampled concentrations in the reservoirs ranged from 18 to 33 mg/kg (see Appendix C, Table C-6), while the USEPA total carcinogenic screening level is 0.38 mg/kg and the CalEPA screening level is 1,600 mg/kg for residential exposure and 16,000 mg/kg for commercial exposure. As with arsenic, available Klamath Basin soil concentrations of nickel (median values 33 mg/kg and 65.7 mg/kg from two different studies) are in the same range as those measured in Lower Klamath Project reservoir sediments (see Appendix C – *Section C.7.1*) and they exceed the USEPA total carcinogenic screening level for residential soils by a similar factor. As discussed above for arsenic, the Parcel B lands would be transferred to the respective states as part of the Proposed Project and managed for public interest purposes, so potential human exposure to nickel measured in the Lower Klamath Project reservoir sediments under the Proposed Project would be less than that assumed for the USEPA or CalEPA screening levels. The exposure potential on the future public lands is likely to be considerably less than that for residential or commercial uses considered in USEPA and CalEPA screening levels, with recreational use resulting in only 3 to 25 percent of the residential exposure conservatively assuming 10 to 90 days per year, for 30 years exposure patterns. The highest concentrations of nickel were found in sediments from the Klamath River Estuary, which suggests that release of reservoir sediments downstream would not increase nickel concentrations in downstream reaches above existing conditions. Accordingly, the Proposed Project and release of sediments from behind the Lower Klamath Project dams is unlikely to increase the short-term or long-term exposure of humans to concentrations of nickel above Klamath Basin background levels and to result in substantive adverse impacts to human health under possible Exposure Pathway 2 from nickel.

There were 19 analytes measured during 2009 and 2010 that were not detected by laboratory tests; however, the laboratory analytical reporting limits were greater than the applicable human health screening levels (i.e., the standard laboratory tests used could not measure whether the analytes were present above human screening levels because the smallest amount the laboratory tests could detect [i.e., the reporting limit] for those analytes was greater than the human health screening level itself), including some PCBs, VOCs, and SVOCs (CDM 2011). While it is not possible to directly confirm that these compounds are above or below applicable human health screening levels, as described above for arsenic, potential human exposure to reservoir sediment deposits under the Proposed Project, in both the short-term and long-term, would involve limited, short duration, non-residential exposure patterns. Since these analytes were below levels of laboratory detection, and the potential exposure in the short and long-term would be less than the long-term residential levels of exposure, any undetected analytes would be unlikely to result in substantial adverse impacts on human health.

Elutriate concentration results (characterizing the water between grains of sediment, which can also be referred to as pore water) from the 2009–2010 sediment testing are used to evaluate human consumption exposure to inorganic and organic contaminants in river water during drawdown and transport of reservoirs sediments in the Klamath River. Elutriate concentration results represent the maximum potential concentration of contaminants in the Klamath River during drawdown since they do not take into account the mixing or dilution that would occur during transport of reservoir sediments (CDM 2011). Applicable human health drinking water standards are first compared with elutriate concentrations to provide an initial conservative assessment of human exposure to inorganic and organic contaminants, then elutriate concentrations with consideration of the expected dilution during drawdown are compared with the applicable human health drinking water standards to assess likely human exposure risk.

The dilution of inorganic and organic contaminant elutriate concentrations necessary during drawdown to meet applicable drinking water standards is determined from modeled SSCs since the SRH-1D sediment transport model uses drawdown flows similar to those expected under the Proposed Project in its estimates of SSCs. Variations in flow and dilution downstream of the reservoirs during drawdown would be inherently included in the modeled SSCs so variations in the contaminant concentrations with the potential to adversely impact human health would also be represented within these model results. The ratio of contaminant concentration to SSCs measured in laboratory elutriate tests is assumed to be equal to the ratio of the contaminant concentration to modeled SSCs in the Klamath River during drawdown (CDM 2011). As such, the dilution would decrease as the SSCs increase and the range of dilution in the Klamath River during drawdown can be calculated from the range of maximum modeled SSCs.

In the Hydroelectric Reach downstream of J.C. Boyle to the upstream end of Copco No. 1 Reservoir, the maximum SSCs would range from 2,000–3,000 mg/L (see Potential Impact 3.2-3), so dilution of mobilized sediments with reservoir and river water is expected to range from 217- to 325-fold (i.e., concentration in the river would be 217 to 325 times less than the elutriate concentration) immediately downstream of J.C. Boyle during drawdown. In the remainder of the Hydroelectric Reach from the upstream end of Copco No. 1 Reservoir through Iron Gate Reservoir, short-term SSC generally increase in the downstream direction due to the larger sediment deposits in Copco No. 1 and Iron Gate reservoirs contributing to SSCs. The minimum dilution in the Klamath River would occur immediately downstream of Iron Gate Dam during drawdown, where the maximum SSCs would occur from release of sediments in J.C. Boyle, Copco No. 1, and Iron Gate reservoirs. The minimum dilution downstream of Iron Gate Dam would range from 48- to 66-fold (CDM 2011). As a conservative estimate, the J.C. Boyle dilution is used from J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoir and the expected dilution immediately downstream of Iron Gate is used from Copco No. 1 Reservoir to Iron Gate Dam for the analysis of human exposure to inorganic and organic contaminants in the Hydroelectric Reach. The actual SSCs in the Hydroelectric Reach in Copco No. 1 Reservoir to Iron Gate Dam potentially would be less than the maximum SSCs estimated below Iron Gate Dam based on modeled SSCs below the J.C. Boyle and Copco No. 1 dams (see Potential Impact 3.2-3), so the inorganic and organic contaminant concentrations and human exposure to those contaminants in the Hydroelectric Reach of the Klamath River would be less than those estimated using the maximum SSCs estimated below Iron Gate Dam.

Before consideration of dilution, aluminum, arsenic, chromium, lead, and total PCB are the only chemicals present in elutriate sediment sample results at concentrations above Basin Plan, national priority, and national non-priority fresh water quality criteria for samples from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs (CDM 2011). After consideration of dilution, chromium, lead, and total PCB concentrations would be less than the most stringent human health drinking water standards in the Hydroelectric

Reach from J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoir since the dilution in that portion of the Hydroelectric Reach (217- to 325-fold) is greater than the dilution necessary to meet the most stringent human health drinking water standards for chromium (12-fold), lead (0.3-fold), and total PCB (45-fold). Even after consideration of dilution, aluminum and arsenic concentrations would be greater than the most stringent applicable drinking water standards in the Hydroelectric Reach from J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoir, since the minimum dilution in this portion of the Hydroelectric Reach (217-fold) would be less the dilution necessary for aluminum (219-fold) and arsenic (13,635-fold). In the Copco No. 1 Reservoir to Iron Gate Dam portion of the Hydroelectric Reach after consideration of the range of dilution (48- to 66-fold), the concentrations of chromium and lead would be less than the most stringent applicable drinking water standards. However, aluminum, arsenic, and total PCB concentrations would be greater than the most stringent applicable drinking water standards in this portion of the Hydroelectric Reach, since the range of anticipated dilution immediately downstream of Iron Gate Dam would be less than the dilution for aluminum (219-fold), arsenic (13,635-fold), and total PCB (100-fold) (CDM 2011).

While human exposure to contaminants in Klamath River water would be limited due to restricted access within the Hydroelectric Reach during drawdown, human exposure to concentrations of aluminum, arsenic, and total PCB greater than applicable drinking water standards would potentially occur during drawdown due to elevated SSCs and sediment-associated inorganic and organic contaminants and potentially cause substantial adverse impacts on human health if river water were to be used during drawdown as a drinking water supply. Dilution in the Klamath River necessary to meet the most stringent applicable drinking water standards (i.e., 13,635-fold for arsenic) would occur once SSCs decrease below 47 mg/L. Modeled SSCs are greater than 47 mg/L in the Hydroelectric Reach for approximately six to ten consecutive months after drawdown begins (see Potential Impact 3.2-3), so exposure to inorganic and organic contaminants in reservoir sediments that would potentially cause substantial adverse impacts on human health also would occur in the Hydroelectric Reach for approximately six to ten months during this period. In dry water year types, modeled SSCs downstream of Iron Gate Dam increase above 47 mg/L for approximately five to six months during the winter and spring after dam removal due to high flow associated with storms (see Figure 3.2-15), thus there also would be potential human exposure to contaminant concentrations (i.e., arsenic) above the most stringent applicable drinking water standards during this period. This would be a significant impact. Implementation of Mitigation Measure WQ-2 would reduce this impact to a less than significant level. Modeled SSCs downstream of Iron Gate Dam are consistently below 47 mg/L after July of post-dam removal year 1, (see Figures 3.2-15 to 3.2-17), indicating potential human exposure to contaminant concentrations that could cause substantial adverse impacts would be negligible after July of post-dam removal year 1 and thus there would be no significant impact after this point in time.

Long-term human exposure to concentrations of aluminum, arsenic, and total PCB greater than applicable drinking water standards due to dam removal is not anticipated since modeled SSCs would return to background levels (i.e., existing conditions) and there would be negligible deposition of reservoir sediments and the associated inorganic and organic contaminants in Hydroelectric Reach. Potential human exposure to inorganic and organic contaminants is associated with elevated SSCs, thus modeling that indicates SSCs would return to background levels (i.e., existing conditions) by the end of post-dam removal year 1 under all water year types (see Potential Impact 3.2-3) also indicates that potential human exposure to contaminants would return to background levels in this time period. Additionally, sediment modeling indicates little to no deposition of the fine or coarser (e.g., sand) sediments in the Hydroelectric Reach (CDM 2011; USBR 2012), so there would be little to no potential exposure to reservoir sediments and associated contaminants due to deposition along the streambed.

As part of the Secretarial Determination process, the Water Quality Sub-Team identified ODEQ bioaccumulation SLVs as appropriate thresholds for determining the potential for sediment contaminants to bioaccumulate to the point where the contaminants adversely affect either the health of fish or other aquatic organisms, or the health of animals or humans that consume them. ODEQ bioaccumulation SLVs have been set for humans based on fish and shellfish consumption under both general/recreational and subsidence/tribal ingestion rates (ODEQ 2007). Bioaccumulation SLVs have not been set based on bioaccumulation within vegetation exposed to contaminants and the ingestion that vegetation. While ODEQ bioaccumulation SLVs are not applicable to water bodies in California, they provide a reference for comparison purposes. Toxicity equivalent quotients (TEQs) calculated for dioxin, furan, and dioxin-like PCBs were at concentrations above ODEQ bioaccumulation SLVs for mammals in sediments from each of the reservoirs (CDM 2011). Although site-specific background data is lacking, TEQs calculated for dioxin, furan, and dioxin-like PCBs are only slightly above regional background concentrations and thus have limited potential to cause adverse impacts to humans based on consumption of aquatic life exposed to sediment deposits from the river banks or streambed. This assessment is further supported by the limited duration contaminants would occur in the river water as they are transported with drawdown flows and the limited amount of deposition expected (see Potential Impact 3.11-5). The sources of the slightly elevated dioxin, furan, and dioxin-like PCB compounds are not known; however, sources may include atmospheric deposition, regional forest fires, and possibly burning of plastic items (CDM 2011).

Summary

Results from the 2009–2010 Klamath Dam Removal Secretarial Determination sediment chemistry analyses indicate potential human exposure to inorganic and organic contaminants in reservoir sediment deposits remaining within the reservoir footprints and along the river banks or through eating fish exposed to sediment deposits would be unlikely to result in substantive adverse impacts on human health in either the short-term or the long-term, but there is potential for short-term substantive adverse impacts on human health from exposure to inorganic and organic contaminants in reservoir sediments during drawdown due exposure to river water. For the Lower Klamath Project reservoir sediments remaining in the reservoir footprint and along the river banks, arsenic and nickel are the only compounds detected at levels exceeding USEPA and/or CalEPA residential screening levels to protect human health, but exposure to arsenic in these areas would be constrained by short-term activities and long-term future land use that would support only limited exposure patterns, such that human exposure to arsenic and nickel in sediments in the reservoir footprint would be a less-than-significant impact.

Evaluation of the bioaccumulation potential of inorganic and organic contaminants indicates there is limited potential for adverse impacts to humans from eating aquatic life exposed to sediment deposits from the river banks or streambed since the detected levels of dioxin, furan, and dioxin-like PCBs are only slightly above regional background concentrations. This assessment is further supported by the limited duration contaminants would occur in the river water as they are transported with drawdown flows and the limited amount of deposition expected (see Potential Impact 3.11-5). Thus, human exposure to these chemicals in aquatic life would be a less-than-significant impact.

For exposure to river water during drawdown, aluminum, arsenic, and total PCBs greater human health water quality criteria would potentially occur in the short term due to elevated SSCs and sediment-associated inorganic and organic contaminants and potentially cause substantial adverse impacts on human health; this would be a significant impact. Implementation of Mitigation Measure WQ-2 would reduce this impact to a less than significant level. There is little to no long-term potential for adverse impacts to human health from exposure to river water due the release of reservoir sediments and associated inorganic or organic contaminants trapped behind the Lower Klamath Project dams, so there would be no significant impact in the long term for human exposure to inorganic and organic contaminants in the Hydroelectric Reach.

Middle and Lower Klamath River and Klamath River Estuary

Downstream of Iron Gate Dam, short-term and long-term human exposure to contaminants from contact with residual sediments deposited on downstream river banks is possible and the mechanism for exposure would be the same as that for potential contaminants deposited on exposed reservoir terraces and river banks in the Hydroelectric Reach. Sediment deposition on the river floodplain and/or river banks is unlikely (see also Potential Impact 3.11-6), so the amount of sediment deposits on river floodplains and/or river banks are anticipated to be much lower than the amount exposed in the reservoir beds in the Hydroelectric Reach.

Relatively few compounds were detected in reservoir sediments exceeding human health screening levels for soil, with arsenic and nickel the only compounds exceeding USEPA and/or CalEPA residential screening levels to protect human health. The likelihood of substantial adverse impacts to human health from exposure to arsenic in reservoir sediments is low in the Middle and Lower Klamath River and the Klamath River Estuary since sediment modeling indicates sediment deposition on the river floodplain and/or river banks is unlikely (see also Potential Impact 3.11-6). Nickel concentrations in the Klamath River Estuary sediments were higher than those measured in reservoirs sediments, suggesting the release of reservoir sediments would not increase nickel concentrations in downstream reaches and the potential exposure to nickel in potential deposits of reservoir sediment in the Middle and Lower Klamath River and the Klamath River Estuary would likely be within background conditions.

However, in an abundance of caution, since land use along the Middle and Lower Klamath River floodplain includes residential or agricultural (i.e., row crop) land use or the potential for residential or agricultural (i.e., row crop) land use, where human soil exposure patterns may approach those specified by the USEPA and CalEPA residential screening levels, implementation of Mitigation Measure WQ-3 would be required to ensure that short-term and long-term human exposure to inorganic and organic contaminants due to release of sediments currently trapped behind the Lower Klamath Project dams to a less-than-significant impact.

Similar to the Hydroelectric Reach, there also is potential for human exposure to inorganic and organic contaminants in reservoir sediments from contact with river water during drawdown when reservoir sediments and associated inorganic and organic contaminants are being transported. Elutriate concentration results from 2009–2010 sediment testing along with an evaluation of the elutriate concentrations results with consideration of dilution in the Middle and Lower Klamath River and the Klamath River Estuary indicate the potential for human exposure to inorganic and organic contaminants greater than applicable human health drinking water standards that may cause substantial adverse impacts to human health. This would be a significant impact. As detailed above in the Hydroelectric Reach, the maximum potential human exposure exists immediately downstream of Iron Gate Dam during drawdown, where the maximum SSCs and the minimum dilution (48- to 66-fold) would occur. Additional tributary inflows to the Klamath River downstream of Iron Gate Dam would decrease the maximum SSCs and increase the dilution (see Potential Impact 3.2-3), so potential human exposure gradually decreases in the Middle and Lower Klamath River with distance downstream. In the Klamath River at Seiad Valley, the maximum modeled SSCs range from approximately 9,000–10,000 mg/L, so dilution is expected to range from approximately 65- to 72-fold in that section of the Middle Klamath River. The maximum modeled SSCs range from approximately 3,000–6,000 mg/L in the Klamath River at Orleans, resulting in dilution ranging from approximately 108- to 217-fold. In the Lower Klamath River at Klamath, the maximum modeled SSCs range from approximately 800–2,000 mg/L, so dilution ranges from 325- to 813-fold.

In the Middle Klamath River, the human exposure to inorganic and organic contaminants immediately downstream of Iron Gate Dam would be the same as analyzed above for the Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam. Before consideration of dilution, aluminum, arsenic, chromium, lead, and total PCB are the only chemicals present in elutriate sediment samples results at concentrations above applicable drinking water standards for samples from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs (CDM 2011). After consideration of the dilution immediately downstream of Iron Gate Dam (48- to 66-fold), only aluminum, arsenic, and total PCB concentrations would be greater than the most stringent human health drinking water standards, since the anticipated dilution immediately downstream of Iron Gate would be less the maximum dilution necessary for aluminum (219-fold), arsenic (13,635-fold), and total PCB (100-fold), but the dilution immediately downstream of Iron Gate Dam would be greater than the maximum dilution necessary for chromium (12-fold) and lead (0.3-fold) (CDM 2011). While the maximum dilution necessary to meet the most stringent applicable human health drinking water standards would be met further downstream in the Middle and Lower Klamath for aluminum and total PCB as the dilution in the river increases, the dilution for arsenic would not be met in the Middle and Lower Klamath River and the Klamath River Estuary.

Elutriate sediment samples results from the Klamath River Estuary also show aluminum, arsenic, and total PCB concentrations greater than the most stringent applicable human health drinking water standards, indicating elevated concentrations of these chemicals occur under existing conditions in the Middle and Lower Klamath River and the Klamath River Estuary. However, the concentrations of these chemicals in the elutriate sediment samples results from the Klamath River Estuary are less than those measured in reservoir sediments. Arsenic concentrations in estuary elutriate sediment samples require a 999- to 2,726-fold dilution to meet the most stringent applicable human health drinking water standards, while aluminum requires a 14-fold dilution and total PCB requires a 1.0- to 1.5-fold dilution. Overall, human exposure to concentrations of aluminum, arsenic, and total PCB greater than applicable human health drinking water standards and existing conditions would potentially occur if river water were to be used during drawdown as a drinking water supply in the Middle and Lower Klamath River and the Klamath River Estuary. This would be a significant impact.

Similar to the Hydroelectric Reach, the dilution in the Middle and Lower Klamath River and the Klamath River Estuary necessary to meet the most stringent applicable human health drinking water standards (i.e., 13,635-fold for arsenic) would occur once SSCs decrease below 47 mg/L. As described for the Hydroelectric Reach, modeled SSCs immediately downstream of Iron Gate Dam are greater than 47 mg/L for approximately six to ten consecutive months after drawdown begins (see Potential Impact 3.2-3). While increased dilution with distance downstream of Iron Gate Dam would likely reduce the duration that SSCs exceed 47 mg/L and the duration of human exposure to elevated contaminant concentrations, this analysis conservatively applies the modeled SSCs immediately downstream of Iron Gate Dam for the entire Middle and Lower Klamath River and Klamath River Estuary. As such, the exposure to inorganic and organic contaminants in reservoir sediments that would potentially cause substantial adverse impacts on human health would occur in the Middle and Lower Klamath River and the Klamath River Estuary for approximately six to ten months after drawdown begins. In dry water year types, there also would be potential human exposure to contaminant concentrations (i.e., arsenic) above the most stringent applicable human health drinking water standards for approximately five to six months during the winter and spring after dam removal, since modeled SSCs immediately downstream of Iron Gate Dam increase during this period due to high flows associated with storms (see Figure 3.2-15). This would be a significant impact. Implementation of Mitigation Measure WQ-2 would reduce this impact to a less than significant level. Modeled SSCs downstream of Iron Gate Dam are consistently below 47 mg/L after July of post-dam removal year 1, (see Figure 3.2-15 to 3.2-17), indicating potential human exposure to contaminant concentrations that could cause substantial adverse impacts would be negligible after July of post-dam removal year 1 and thus there would be no significant impact after this point in time.

Long-term human exposure to concentrations of aluminum, arsenic, and total PCB levels greater than applicable human health drinking water standards due to dam removal is unlikely since modeled SSCs would return to background levels (i.e., existing conditions) and fine reservoir sediments and associated inorganic and organic contaminants would be unlikely to form sediment deposits in the Middle and Lower Klamath River and the Klamath River Estuary (see Potential Impact 3.11-5). Potential human exposure to inorganic and organic contaminants is associated with elevated SSCs, thus modeling that indicates SSCs would return to background levels (i.e., existing conditions) by the end of post-dam removal year 1 under all water year types (see Potential Impact 3.2-3) also indicates that potential human exposure to contaminants would return to background levels in this time period. Additionally, sediment modeling indicates fine reservoir sediments would be unlikely to settle along the riverbed in the Klamath River in the Middle and Lower Klamath River and the Klamath River Estuary (Stillwater Sciences 2008; USBR 2012) (see Potential Impact 3.11-5). Coarser reservoir sediment would potentially deposit between Iron Gate Dam and Cottonwood Creek (USBR 2012), but these sediments are not typically associated with appreciable contaminant levels due to their lack of organic matter and chemical properties (i.e., lower cation exchange capacities) (CDM 2011). Thus, there would be little to no potential long-term potential for adverse impacts to human health from exposure to river water due the release of reservoir sediments and associated inorganic or organic contaminants trapped behind the Lower Klamath Project dams, and there would be no significant impact in the long term for human exposure to inorganic and organic contaminants in the Hydroelectric Reach.

Implementation of mitigation measures WQ-2 and WQ-3 would reduce the short-term significant impact of human exposure to inorganic and organic contaminants in the Middle and Lower Klamath River and the Klamath River Estuary to less than significant.

Mitigation Measure WQ-2 – Modifications and monitoring for transient non-community and community water systems using the Klamath River for their water supply.

The KRRC shall consult with community water systems, transient non-community water systems, or other drinking water providers that use Klamath River surface water for drinking water to identify appropriate measures to reduce impacts associated with the Proposed Project's impacts to their Klamath River water supply, such that Proposed Project implementation shall not result in service of water that fails to meet drinking water quality standards. At least two months prior to initiating drawdown, the KRRC shall submit to the State Water Board a report detailing drinking water mitigation measures for each potentially affected supply and demonstrating that such measures are sufficient to protect drinking water supplies. KRRC shall amend the measures if required to protect drinking water supplies and shall implement them sufficiently prior to reservoir sediment releases to ensure protection of water supplies. Potential measures shall include, as appropriate: (1) providing an alternative potable water supply; (2) providing technical assistance to assess whether existing treatment is adequate to treat the potential increase in sediments and sediment-associated contaminants so as to meet drinking water standards; (3) providing water treatment assistance to adequately treat Klamath River water to remove SSCs and associated constituents that may impact human health; 4) ensuring that transient, non-community supplies are temporarily shut off for drinking; or 5) ensuring that water not intended for drinking is clearly marked as non-potable

Mitigation Measure WQ-3 – Monitoring and potential remediation of reservoir sediments deposited along the Middle and Lower Klamath River floodplain.

By December of post-dam removal year 1, and upon notice from property owners, the KRRC shall assess visibly obvious sediment deposits along with Middle and Lower Klamath River that may have been deposited during reservoir drawdown activities in areas with a residential or agricultural (i.e., row crop) land use or the potential for residential or agricultural land use. Visibly obvious sediment deposits shall be assessed by the KRRC if they are consistent with physical sediment properties associated with Lower Klamath Project reservoir sediments (see Section 3.11.2.5 *Reservoir Sediment Storage and Composition*). Visibly obvious sediment deposits consistent with physical sediment properties associated with Lower Klamath Project reservoirs shall be tested for arsenic. Soil samples in the vicinity of the deposited reservoir sediments on the river bank and/or floodplain shall also be tested for arsenic to determine the local background concentrations of arsenic. No additional actions or remediation shall be required if the measured arsenic concentrations in the deposited reservoir sediments are less than or equal to measured local background soil arsenic concentrations. If the concentration of arsenic in deposited reservoir sediments on the river banks and floodplain in the Middle and Lower Klamath River exceed local background levels and USEPA or CalEPA human health residential screening levels, the deposited reservoir sediments shall be remediated to local background levels through removal of the deposited reservoir sediments or soil capping, if soil removal is infeasible or poses a greater risk than soil capping.

Significance

No significant impact with mitigation

Potential Impact 3.2-14 Freshwater and marine aquatic species exposure to inorganic and organic contaminants due to release of sediments currently trapped behind the dams.

This potential impact evaluates the potential for any inorganic and organic contaminants in reservoir sediments to result in a substantial adverse impact to aquatic organisms when the sediments are released downstream of the dams into the Klamath River. The release of reservoir sediments has the potential to increase the exposure of aquatic species to any harmful material in the sediment by moving the sediments and associated contaminants to new places in the river; mixing the sediments and associated contaminants into the water column where aquatic life may interact with them; and, for some materials, creating conditions where contaminants may enter the food chain. Sediment testing indicates that the amounts of contaminants in the sediments is not high, but this analysis evaluates the level of risk and potential impacts in more detail with consideration of the conditions in the Klamath River under the Proposed Project, especially during drawdown.

Hydroelectric Reach

Organic and inorganic contaminants have been identified in the sediment deposits currently trapped behind the dams (see Section 3.2.2.8 *Inorganic and Organic Contaminants*). Under the Proposed Project, the short-term pathway of contaminant exposure for freshwater aquatic species includes exposure during sediment transit through the Hydroelectric Reach ("Exposure Pathway 1" in CDM [2011]), while long-term pathways include exposure from river bed deposits ("Exposure Pathway 3" in CDM [2011]) (Figure 3.2-27). The CDM (2011) analysis of exposure pathways using the 2009 SEF screening levels has been updated based on 2018 SEF screening levels, as appropriate (Appendix C – *Section C.7*).

One path for short-term exposure to inorganic and organic contaminants for freshwater aquatic species would be associated with the transport of elevated suspended sediment concentrations (SSCs) through the Hydroelectric Reach during reservoir drawdown. Due to the relatively small volume of the sediment deposits behind J.C. Boyle Dam (approximately eight percent of total volume for the Lower Klamath Project, see also Tables 2.7-9 and 2.7-10), short-term SSCs in the Hydroelectric Reach between J.C. Boyle Dam and the upstream end of Copco No. 1 Reservoir would be considerably less than those anticipated to occur downstream of Iron Gate Reservoir (see Potential Impact 3.2-3). The ratio of the contaminant concentration to SSCs measured in laboratory tests is assumed to be equal to the ratio of the contaminant concentration to SSCs in the Klamath River during drawdown, so the amount of dilution necessary to meet water quality standards would vary based on changes in SSC during drawdown. Variations in flow and dilution downstream of the reservoirs during drawdown would be inherently included in the modeled SSCs since the model utilizes expected drawdown flows in its estimate of SSCs. Thus, the maximum dilution necessary to meet water quality standards for aquatic species would be calculated using the maximum SSCs.

In the Hydroelectric Reach downstream of J.C. Boyle to the upstream end of Copco No. 1 Reservoir, the maximum SSCs would range from 2,000–3,000 mg/L (see Potential Impact 3.2-3), so dilution of mobilized sediments with reservoir and river water is expected to range from 217- to 325-fold immediately downstream of J.C. Boyle during drawdown. Within the remainder of the Hydroelectric Reach from the upstream end of Copco No. 1 Reservoir through Iron Gate Reservoir, short-term SSC would be relatively greater than upstream of Copco No. 1 Reservoir, generally increasing in the downstream direction due to the larger sediment deposits in Copco No. 1 and Iron Gate reservoirs contributing to SSCs. The minimum dilution in the Klamath River would occur immediately downstream of Iron Gate Dam during drawdown, where higher peak SSCs from release of sediments in Copco No. 1 and Iron Gate reservoirs would result in dilution ranging from 48- to 66-fold. As a conservative estimate, this analysis uses the J.C. Boyle dilution only for the J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoirs portion of the Hydroelectric Reach and the dilution expected immediately downstream of Iron Gate Dam for the remainder of the Hydroelectric Reach when evaluating the dilution necessary to meet water quality standards for contaminant results. The actual SSCs in the Hydroelectric Reach in Copco No. 1 Reservoir to Iron Gate Dam potentially would be less than the maximum SSCs estimated below Iron Gate Dam based on modeled SSCs below the J.C. Boyle and Copco No. 1 dams (see Impact 3.2-3), so the inorganic and organic contaminant concentrations and the aquatic species exposure to those contaminants in the Hydroelectric Reach of the Klamath River would be less than those estimated using the maximum SSCs estimated below Iron Gate Dam.

Sediment chemistry data from 2006 collected from 25 cores representing both reservoir-deposited and pre-reservoir sediments within the historical Klamath River channel ("on-thalweg") and on historical riverbanks and terraces along the edge of the Klamath River ("off-thalweg") in J.C. Boyle, Copco No. 1, and Iron Gate reservoirs indicate generally low levels of metals, pesticides, chlorinated acid herbicides, PCBs, VOCs, SVOCs, cyanide, and dioxins (Shannon & Wilson, Inc. 2006; see also Section 3.2.2.8 *Inorganic and Organic Contaminants*). While two-dimensional sediment transport modeling of Copco No. 1 Dam and Reservoir during drawdown indicates that sediments would be mobilized from across the reservoir footprint, the sediments in the historical Klamath River channel would be the most likely to erode (USBR 2012) and thus the sediment chemistry of the on-thalweg sediment cores is more likely to be representative of eroded sediment conditions.

An additional 37 sediment cores were collected in 2009–2010 in the Lower Klamath Project reservoirs for the Klamath Dam Removal Secretarial Determination process to evaluate the sediment characteristics of reservoir-deposited and pre-reservoir sediments in the historical Klamath River channel ("on-thalweg") and terrace ("off-thalweg") locations at a finer spatial resolution. Testing results for the 2009–2010 cores indicate no exceedances of applicable screening levels, indicating a low risk of toxicity to freshwater sediment-dwelling organisms in the Hydroelectric Reach under the Proposed Project. Results from acute (10-day) sediment bioassays for exposure to undiluted reservoir sediments and elutriate samples for midges (*Chironomus dilutus*) and amphipods (*Hyalella azteca*), two national benchmark toxicity species, indicate generally equal survival in reservoir sediments as compared with laboratory control samples. The exception is J.C. Boyle Reservoir, which exhibited considerably lower survival for *Chironomus dilutus* in the on-thalweg sample as compared with the laboratory control (64 percent versus 95 percent) and somewhat lower survival for the off-thalweg sample (83 percent versus 95 percent) (CDM 2011).

While J.C. Boyle reservoir sediment results suggest potential toxicity to freshwater benthic organisms, the conditions in the bioassays would be very unlikely to occur during drawdown and dam removal in the Hydroelectric Reach downstream of J.C. Boyle Dam, so there is an overall low likelihood of acute toxicity to benthic organisms due to releases of reservoir sediments. The bioassays evaluated the survival of freshwater benthic organisms in composite[33] sediments from individual reservoirs, but undiluted composite sediments from the reservoirs would be very unlikely to occur outside of the reservoir footprints during drawdown and dam removal. Sediments from the reservoirs would mix with water and incoming suspended sediments from tributaries as they move downstream under the Proposed Project, exposing downstream aquatic biota to a diluted, "average" sediment composition rather than pure reservoir sediments. Under current conditions, the total volume of erodible sediments in Copco No. 1 and Iron Gate reservoirs (7.4 million and 4.7 million cubic yards, respectively; see also Tables 2.7-7 through 2.7-9) is considerably greater than that of J.C. Boyle Reservoir (1 million cubic yards; see also Tables 2.7-7 through 2.7-9), further diminishing the potential influence of J.C. Boyle Reservoir sediments on biota exposure. Additionally, fine sediments released during drawdown and dam removal would be transported by large water volumes, and sediment modeling indicates that fine sediments would be unlikely to settle along the riverbed in the Klamath River in the Hydroelectric Reach (Stillwater Sciences 2008; USBR 2012) and thus unlikely to result in riverine, floodplain, or estuarine sediment deposits that resemble existing conditions in the reservoirs.

More specifically, dilution would be expected to range from 217- to 325-fold downstream of J.C. Boyle Dam to the upstream end of Copco No. 1, so benthic organism exposure to inorganic and organic contaminants in J.C. Boyle Reservoir sediments would be much less during drawdown under the Proposed Project than in the bioassays. The intensity of exposure compared to the bioassays would be further reduced due to considerable additional mixing occurring within the Hydroelectric Reach from the current Copco No. 1 Reservoir to Iron Gate Dam. While dilution would decrease downstream of Copco No. 1 due to higher SSCs, the mixing of sediments from J.C. Boyle and Copco No. 1 along with additional mixing of water from Copco No. 1 would reduce the overall intensity of exposure to J.C. Boyle reservoir sediments. In the absence of undiluted sediment deposits from J.C. Boyle Reservoir, freshwater benthic organisms in the Hydroelectric Reach are unlikely to experience the same intensity of exposure to reservoir sediments as in the bioassays that suggested potential for toxicity (CDM 2011). Overall, the freshwater sediment bioassays indicate a low likelihood of acute toxicity to benthic organisms in the Hydroelectric Reach of the Klamath River due to sediment release under the Proposed Project.

Elutriate concentration results (representing the water between grains of sediment, which can also be referred to as pore water) from the 2009–2010 sediment testing also provide important context for evaluating the potential effects of in-water column exposure to inorganic and organic contaminants from reservoir sediments on aquatic freshwater species. Elutriate sediment sample chemistry results indicate that, before consideration of dilution, ammonia, aluminum, chromium, copper, lead, and mercury are the chemicals present at concentrations above Basin Plan, national priority, and national non-priority fresh water quality criteria for samples from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs (CDM 2011). Human health freshwater water quality criteria were also evaluated (CDM 2011) and those results are analyzed above in Potential Impact 3.2-13. Dilution of mobilized sediments with reservoir and river water is expected to range from 217- to 325-fold downstream of J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoir and 48- to 66-fold immediately downstream of Iron Gate during drawdown. Thus, the elutriate sediment sample concentrations for all the chemicals currently present at concentrations above water quality criteria (i.e., ammonia, aluminum, chromium, copper, lead and mercury) would be below the freshwater water quality criteria with dilution in the portion of the Hydroelectric Reach from J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoir. Inorganic and organic contaminants would be unlikely to cause adverse effects to freshwater aquatic species in the J.C. Boyle Dam to the upstream end of Copco No. 1 Reservoir portion of the Hydroelectric Reach since the dilution required to meet the most stringent criterion is 22-fold (i.e., the elutriate concentration would have to be 22 times higher than the water quality standard concentration to exceed criterion) for ammonia, 125-fold for aluminum, 0.2-fold for chromium, 2.3-fold for copper, 2.1-fold for lead, and 1.3-fold for mercury. However, the dilution in the Copco No. 1 Reservoir to Iron Gate Dam portion of the Hydroelectric Reach would be less than upstream, reaching a minimum of 48- to 66-fold at Iron Gate Dam due to release of additional sediment from Copco No. 1 and Iron Gate reservoirs and higher SSCs. Elutriate sediment sample concentrations in the Copco No. 1 Reservoir to Iron Gate Dam portion of the Hydroelectric Reach would be below the freshwater water quality criteria for ammonia, chromium, copper, lead, and mercury after consideration of dilution with no potential to cause substantial adverse impacts on freshwater aquatic species.

For aluminum, the expected dilution at Iron Gate Dam is less than the dilution required for three of the six elutriate sediment samples to meet the most stringent freshwater criterion (87 ug/L) with those three samples requiring a 50- to 125-fold dilution. While some inorganic forms of aluminum can be toxic to aquatic organisms at high and low pH, insoluble and nontoxic forms of aluminum prevail in the environment under typical conditions (pH ranging from six to eight s.u. and alkalinity greater than 100 mg/L). The pH conditions at drawdown are not anticipated to be in the range that would cause inorganic aluminum to become toxic. Thus, any residual free (toxic) aluminum present in reservoir waters during drawdown is likely to form compounds with the dissolved organic matter abundant in eutrophic (nutrient-rich) waters such as the Lower Klamath Project reservoirs, rendering the aluminum non-bioavailable and nontoxic. Thus, water column toxicity due to the concentration of inorganic or organic substances under the Proposed Project is unlikely (CDM 2011) and would not result in substantial adverse impacts on environmental receptors.

Elutriate sediment sample bioassay results for J.C. Boyle Reservoir indicate that no further dilution would be required to prevent water column toxicity to freshwater fish, even without considering the dilution that will take place during drawdown and dam removal (CDM 2011). Elutriate sediment sample bioassay results indicate no statistically significant reduction of mean 96-hour rainbow trout survival for exposure to samples from Copco No. 1 and Iron Gate reservoirs, tested at one percent and 10 percent elutriate concentrations, but a significant reduction from Copco No. 1 Reservoir at 100 percent elutriate concentrations and from Iron Gate Reservoir at 50 percent and 100 percent elutriate concentration. Of these, the one percent and 10 percent concentrations are considered to be most representative of field conditions upon reservoir drawdown due to the expectation of substantial mixing and dilution with river water and tributary inputs, even during dry water years (CDM 2011).

Long-term exposure to reservoir sediments that are mobilized as a result of dam removal would not result in substantial adverse impacts on aquatic species due to negligible deposition of these sediments in Hydroelectric Reach and the overall infrequency and low magnitude of exceedances of screening levels for inorganic and organic contaminants. Sediment modeling indicates that the fine grain nature of the sediments (i.e., silts and clays) and the generally high gradient river channel within the Hydroelectric Reach would result in little to no deposition of the fine or coarser (e.g., sand) sediments in the Hydroelectric Reach of the Klamath River (CDM 2011; USBR 2012).

Additionally, no consistent pattern of elevated chemical distribution was observed across the reservoir samples, with only eight chemicals detected in the 77 samples that exceeded one or more available screening level (see Section 3.2.2.8 *Inorganic and Organic Contaminants*). Nickel was the only one of those eight chemicals that exceeded both SEF screening levels in all three reservoirs. However, nickel is higher in Klamath River Estuary sediments (representing current Klamath Basin background conditions) than reservoir sediments, so reservoir sediments would not elevate nickel concentrations above background conditions. The absence of a consistent pattern of elevated chemical concentrations in reservoir sediment samples supports the conclusion that mixing and dilution of mobilized sediments during drawdown would reduce the overall chemical concentrations in the water column and any sediment deposits and further reduce exposure potential in the newly formed river channels of the Hydroelectric Reach (CDM 2011).

Combined, results from the Shannon & Wilson, Inc. (2006) study and the 2009–2010 Klamath Dam Removal Secretarial Determination study (CDM 2011) indicate that currently one or more chemicals are present in the Lower Klamath Project reservoir sediments at levels with potential to cause minor or limited adverse impacts on freshwater aquatic species. However, chemicals present in the Lower Klamath Project reservoir sediments are expected to be mixed and diluted below water quality standards reducing the likelihood of causing even minor or limited adverse impacts on freshwater aquatic species in the short term. In the long term, one or more chemicals are present, but at levels unlikely to cause substantial adverse impacts on environmental receptors. Therefore, under the Proposed Project, the short-term and long-term impacts on freshwater aquatic species from exposure to sediment-associated inorganic and organic contaminants during sediment release and transit, and from potential downstream river-channel deposition, in the Hydroelectric Reach, would be a less-than-significant impact.

Middle and Lower Klamath River

Organic and inorganic contaminants have been identified in the sediment deposits currently trapped behind the dams (see Section 3.2.2.8). Under the Proposed Project, the short-term pathway of contaminant exposure for freshwater aquatic species includes exposure during sediment transit through the Middle and Lower Klamath River ("Exposure Pathway 1" in CDM [2011]), while long-term pathways include exposure from river bed deposits ("Exposure Pathway 3" in CDM [2011]). The CDM (2011) analysis of exposure pathways using the 2009 SEF screening levels has been updated based on 2018 SEF screening levels, as appropriate (Appendix C – *Section C.7*).

As detailed above for the Hydroelectric Reach, sediment chemistry data from 25 cores collected from Lower Klamath Project reservoirs in 2006 and from an additional 37 sediment cores collected in 2009–2010 indicate generally low levels of metals, pesticides, chlorinated acid herbicides, PCBs, VOCs, SVOCs, cyanide, and dioxins (Shannon & Wilson, Inc. 2006; see also Section 3.2.2.8 *Inorganic and Organic Contaminants*) and no exceedances of applicable screening levels, indicating a low risk of toxicity to freshwater sediment-dwelling organisms in the Middle and Lower Klamath River under the Proposed Project. Acute (10-day) sediment bioassays for exposure to undiluted reservoir sediments and elutriate samples for midges (*Chironomus dilutus*) and amphipods (*Hyalella azteca*), two national benchmark toxicity species, indicate generally equal survival in reservoir sediments as compared with laboratory control samples, except for J.C. Boyle Reservoir sediments (see discussion in the Hydroelectric Reach above). Similar to the Hydroelectric Reach, the conditions in the bioassays would be very unlikely to occur during drawdown and dam removal in the Klamath River downstream of Iron Gate Dam because the downstream aquatic biota would be exposed to a diluted "average" sediment composition rather than pure reservoir sediments analyzed in the bioassays. As such, the potential toxicity of J.C. Boyle Reservoir sediments on downstream biota would be significantly reduced compared to the bioassays, especially downstream of Iron Gate Dam due to considerable mixing and dilution within the Hydroelectric Reach. Additionally, any natural background sediments or flows from tributaries (e.g., Bogus Creek, Shasta River) entering the Klamath River downstream of Iron Gate Dam would further mix and dilute sediments, reducing exposure relative to the bioassays. Fine sediments released during drawdown and dam removal would be transported and unlikely to settle along the riverbed in the Klamath River downstream of Iron Gate Dam (USBR 2012; Stillwater Sciences 2008), so any potential riverine, floodplain, or estuarine sediment deposits that resemble existing conditions in the reservoirs are very unlikely. In the absence of undiluted sediment deposits from J.C. Boyle Reservoir, freshwater benthic organisms downstream of Iron Gate Dam are unlikely to experience the same intensity of exposure to reservoir sediments as in the bioassays that suggested potential for toxicity (CDM 2011). Overall, the freshwater sediment bioassays indicate a low likelihood of acute toxicity to benthic organisms in the Middle and Lower Klamath River due to sediment release under the Proposed Project.

As previously discussed for the Hydroelectric Reach, elutriate concentration results from 2009-2010 also provide important context for evaluating the potential effects of in-water column exposure to inorganic and organic contaminants from reservoir sediments on aquatic freshwater species. Elutriate sediment sample chemistry results indicate that, before consideration of dilution, ammonia, aluminum, chromium, copper, lead, and mercury are the chemicals present at concentrations above Basin Plan, national priority, and national non-priority fresh water quality criteria for samples from J.C. Boyle, Copco No. 1, and Iron Gate reservoirs (CDM 2011). However, dilution of mobilized sediments with reservoir and river water is expected to range from 48- to 66-fold immediately downstream of Iron Gate during drawdown, with further dilution occurring downstream from Iron Gate Dam due to tributary inflows. Elutriate sediment sample concentrations of ammonia, chromium, copper, lead and mercury would be below the freshwater water quality criteria after consideration of dilution immediately downstream of Iron Gate Dam with no potential to cause substantial adverse impacts on freshwater aquatic species since the dilution required to meet the most stringent criterion is 22-fold for ammonia, 0.2-fold for chromium, 2.3-fold for copper, 2.1-fold for lead, and 1.3-fold for mercury.

For aluminum, the expected dilution downstream of Iron Gate Dam is less than the dilution required for three of the six elutriate sediment samples to meet the most stringent freshwater criterion (87 ug/L) with those three samples requiring a 50- to 125-

fold dilution. While some inorganic forms of aluminum can be toxic to aquatic organisms at high and low pH, insoluble and nontoxic forms of aluminum prevail in the environment under typical conditions (pH ranging from six to eight s.u. and alkalinity greater than 100 mg/L). The pH conditions at drawdown are not anticipated to be in the range that would cause inorganic aluminum to become toxic. Thus, any residual free (toxic) aluminum present in reservoir waters during drawdown is likely to form compounds with the dissolved organic matter abundant in eutrophic (nutrient-rich) waters such as the Lower Klamath Project reservoirs, rendering the aluminum non-bioavailable and nontoxic. Thus, water column toxicity due to the concentration of inorganic or organic substances under the Proposed Project is unlikely (CDM 2011).

Elutriate sediment sample bioassay results indicate no statistically significant reduction of mean 96-hour rainbow trout survival for exposure to samples from Copco No. 1 and Iron Gate reservoirs, tested at one percent and 10 percent elutriate concentrations, but a significant reduction from Copco No. 1 Reservoir at 100 percent elutriate concentrations and from Iron Gate Reservoir at 50 percent and 100 percent elutriate concentration. Of these, the one percent and 10 percent concentrations are considered to be most representative of field conditions upon reservoir drawdown due to the expectation of substantial mixing and dilution with river water and tributary inputs, even during dry water years (CDM 2011).

Long-term exposure to reservoir sediments that are mobilized as a result of dam removal downstream of Iron Gate Dam are similar to those analyzed in the Hydroelectric Reach and release of reservoir sediments is unlikely to result in substantial adverse impacts on aquatic species due to minimal deposition of these sediments in the downstream river channel and the overall infrequency and low magnitude of exceedances of screening levels for inorganic and organic contaminants. No consistent pattern of elevated chemical distribution was observed across the reservoir samples, with only eight chemicals detected in the 77 samples that exceeded one or more available screening level (see Section 3.2.2.8 *Inorganic and Organic Contaminants*). Nickel was the only one of those eight chemicals that exceeded both SEF screening levels in all three reservoirs. Nickel is higher in Klamath River Estuary sediments (representing current Klamath Basin background conditions) than reservoir sediments, so reservoir sediments would not elevate nickel concentrations above background conditions. The absence of a consistent pattern of elevated chemical concentrations in reservoir sediment samples supports the conclusion that mixing and dilution of mobilized sediments during drawdown would reduce that overall chemical concentrations in the water column and any sediment deposits and further reduce exposure potential in the Middle and Lower Klamath River (CDM 2011).

Overall, one or more chemicals are currently present in the Lower Klamath Project reservoir sediments at levels with potential to cause minor or limited adverse impacts on freshwater aquatic species in the short term, based results from the Shannon & Wilson, Inc. (2006) study and the 2009–2010 Klamath Dam Removal Secretarial Determination study (CDM 2011), but chemicals present in the Lower Klamath Project reservoir sediments are expected to be mixed and diluted below water quality standards, reducing the likelihood of any substantial adverse impacts on freshwater aquatic species in the short term. In the long term, one or more chemicals are present, but at levels unlikely to cause substantial adverse impacts based on available evidence. Therefore, under the Proposed Project, the short-term and long-term impacts on freshwater aquatic species from exposure to sediment-associated inorganic and organic contaminants during sediment release and transit, and from potential downstream river-channel deposition, in the Middle and Lower Klamath River, would be a less-than-significant impact.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Under the Proposed Project, pathways of contaminant exposure for estuarine and marine aquatic species include short-term exposure during sediment transport through the Klamath River Estuary and Pacific Ocean nearshore environment ("Exposure Pathway 1" in CDM [2011]), as well as the potential for long-term exposure following deposition in the Pacific Ocean nearshore environment ("Exposure Pathway 4" in CDM [2011]). See Potential Impact 3.11-6 for further discussion of sediment deposition patterns in the Pacific Ocean nearshore environment.

For the 2009–2010 Klamath Dam Removal Secretarial Determination study, there were no exceedances of the 64 applicable and available maximum marine screening levels (CDM 2011), with the exception of a small number of sediment samples from J.C. Boyle Reservoir, which exceeded the applicable marine screening level for dieldrin[67] and 2,3,4,7,8-PECDF[68] (CDM 2011). The concentrations of detected inorganic or organic contaminants in Lower Klamath Project reservoir sediments were below the concentrations measured in Klamath River Estuary sediments for chromium and nickel, so the release of reservoir sediments from behind the Lower Klamath Project dams would not elevate estuarine concentrations of these inorganic or organic contaminants or increase exposure for freshwater aquatic species relative to existing conditions. In reservoir sediments total chromium concentrations ranged from 18 to 48 mg/kg and total nickel concentrations ranged from 18 to 33 mg/kg, but in Klamath River Estuary sediments total chromium concentrations ranged from 96 to 97 mg/kg and total nickel concentrations were consistently 110 mg/kg. Marine screening levels are designed to be protective of direct toxicity to benthic and epibenthic organisms, corresponding to a "no adverse effects level," so the majority of sediment sample results from 2009 and 2010 indicate a low risk of toxicity to sediment-dwelling organisms. Additionally, the Proposed Project would result in substantial mixing and dilution during sediment release and transit through the Klamath River estuarine and/or Pacific Ocean nearshore environment, exposing downstream aquatic biota to an "average" water column concentration rather than a reservoir- or site-specific concentration, further reducing the potential for toxicity. The standard laboratory tests used could not measure whether 33 analytes were present above marine screening levels because the smallest amount the laboratory tests could detect (i.e., the reporting limit) for those analytes was greater than the marine screening level itself (CDM 2011). Because it is not possible to determine whether these analytes are present in reservoir sediments either above or below levels of concern, the Lower Klamath Project EIR analysis relies upon the results of integrative bioassays (described below) to determine the potential for short-term sediment toxicity to estuarine and marine aquatic species during sediment transport through the Klamath River Estuary and Pacific Ocean nearshore environment.

---

[67] Dieldrin is a pesticide developed in the 1940s as an alternative to DDT and widely used during the 1950s until early 1970s on crops such as corn and cotton. Its use on crops ceased in 1972 and its other use, killing termites, ceased in 1987, but it is still in the environment due to its past use and slow breakdown in soil (USDHHS 2002).

[68] 2,3,4,7,8-PECDF is a chlorodibenzofuran (i.e., dioxin-like) compound that can be released during burning of material, including wood, coal, and oil for home heating and production of electricity. It is also produced during the manufacture of some chlorinated chemicals and consumer products, such as wood treatment chemicals (e.g., creosote), some metals, and paper products (USDHHS 1994).

Sediment bioassays from a single upper Klamath River Estuary sample included in the 2009–2010 Klamath Dam Removal Secretarial Determination study indicate greater survival (89 to 99 percent survival) of national benchmark toxicity species (midge [*Chironomus dilutus*] and amphipod [*Hyalella azteca*]) in the estuary sediment sample as compared with the laboratory control samples (81 to 94 percent survival) (see CDM 2011). A simple comparison between the estuary area composite acute toxicity results and the reservoir super-composite results indicates similar survival for *Chironomus dilutus* (89 percent vs. 64 to 94 percent, respectively) and greater survival for *Hyalella azteca* (99 percent vs. 80 to 94 percent, respectively). The toxicity tests of estuary and reservoir sediments show the existing background toxicity of estuary sediments is similar to the toxicity of reservoir sediments, so under the Proposed Project, sediment transport during drawdown and potential exposure to inorganic and organic contaminants in the reservoir sediments are unlikely to cause acute toxicity relative to background conditions in the estuary. For the Pacific Ocean nearshore environment under the Proposed Project, a comparison of the applicable marine water and sediment screening levels for ocean conditions with elutriate chemistry results (prior to consideration for mixing and dilution) and sediment chemistry results does not indicate likely toxicity (CDM 2011).

With respect to bioaccumulation potential, there are no exceedances of applicable marine bioaccumulation screening levels (CDM 2011). Further, with the exception of four samples in J.C. Boyle Reservoir (CDM 2011), levels of other known bioaccumulative compounds did not exceed ODEQ bioaccumulation screening level values (SLVs) for marine fish. Note that ODEQ bioaccumulatory screening levels are not strictly applicable in the California marine offshore environment, but they are indicative of potentially bioaccumulative compounds.

Regarding analysis through the pathway of suspended sediment exposure, elutriate chemistry results indicate that several chemical concentrations in the elutriate samples from J.C. Boyle, Copco No. 1, Iron Gate reservoir sediments and Klamath River Estuary sediments exceed one or more water quality criteria for evaluation of surface water exposures for marine biota. Chemicals that exceed marine surface water criteria include those generally considered to be nontoxic (e.g., phosphorus) as well as those with substantial potential for contributing to adverse impacts (e.g., copper). Exposures to suspended sediment with elevated concentrations of potentially toxic chemicals are of lower concern for marine receptors than exposures to elevated concentrations of dissolved chemicals (CDM 2011). The chemicals with the greatest potential to cause adverse impacts due to their elutriate sample concentrations (e.g., copper) are, under field conditions associated with this exposure pathway, expected to bind to particulate matter and no longer be bioavailable, and therefore are unlikely to contribute substantially to elevated concentrations of dissolved forms in the water column. Further, 48- to 66-fold dilution of river water and associated suspended sediments is expected to occur immediately downstream of Iron Gate Dam with further dilution occurring downstream and in the marine environment. The dilution required to meet the most stringent marine water quality criteria for the detected elutriate chemicals ranges from 0.1- to 40-fold with the exception of phosphorus, so the expected dilution during dam removal would be greater than that required to meet marine water quality criteria. Phosphorous would require 1,299 to 5,399-fold dilution to meet the most stringent marine water quality criterion (0.1 ug/L[69]), but phosphorus is generally considered to be non-toxic (CDM 2011). Potential effects of elevated phosphorus concentrations in the estuarine and marine environment due to sediment releases during dam removal are discussed further under Potential Impact 3.2-7.

Although not conducted specifically for estuarine or marine organisms, additional lines of evidence from the 2009–2010 Klamath Dam Removal Secretarial Determination study support the conclusion that exposure to inorganic and organic compounds in sediments released from the reservoirs under the Proposed Project are unlikely to result in substantial long-term adverse impacts on estuarine and marine near shore aquatic species. These include the evaluation of elutriate toxicity bioassay results for rainbow trout, sediment toxicity bioassay results for benthic invertebrate national benchmark species, comparisons of tissue-based toxicity reference values (TRVs) to chemical concentrations in laboratory-reared freshwater clams and worms exposed to field collected sediments (see prior discussion of Proposed Project potential impacts on freshwater aquatic species), and comparisons of tissue-based TRVs and toxicity equivalent quotients (TEQs) to chemical concentrations in field-collected fish tissue.

Under the Proposed Project, the short-term and long-term impacts of sediment release, transit through the Klamath River Estuary, and deposition in the Pacific Ocean nearshore environment on aquatic species due to low-level exposure to sediment-associated inorganic and organic contaminants would be less-than-significant.

The Definite Plan (see Appendix B: *Definite Plan – Appendix M*) includes a Water Quality Monitoring Plan to assess the Proposed Project's impacts to water quality, and this plan includes potential toxicity monitoring, but no toxicity monitoring activities are currently included. The proposed Water Quality Monitoring Plan notes that the identified potential toxicity monitoring activities would only be performed if the additional testing is required by the State Water Board. The State Water Board has authority to review and approve any final Water Quality Monitoring Plan through its water quality certification under Clean Water Act Section 401. The State Water Board has issued a draft water quality certification which sets forth monitoring and adaptive management requirements for any Water Quality Monitoring Plan to meet, as Condition 1[70]. Additionally, the Oregon Department of Environmental Quality has issued a water quality certification[71] that sets forth water quality monitoring and adaptive management conditions for points upstream of California. The effect of the Proposed Project on inorganic and organic contaminants is anticipated to be less than significant in both the short and long term, and this analysis of Potential Impact 3.2-14 does not further discuss the water quality monitoring and adaptive management conditions.

Significance

No significant impact

Potential Impact 3.2-15 Short-term increases in inorganic and organic contaminants from hazardous materials associated with construction and restoration activities in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam.

Under the Proposed Project, pre-construction activities that would potentially affect water quality include canal and diversion tunnel modifications, road improvements, Iron Gate and Fall Creek hatchery modifications, Yreka pipeline modifications, and dam site preparation between June and November of dam removal year 1 (Table 2.7-1). Immediately following dam removal, non-natural fish barriers would be modified to enable volitional fish passage. Facility removal activities would begin in October of dam removal year 1 with removal of the Copco No. 1 Powerplant, including demolition of the dams and their associated structures, power generation facilities, and transmission lines, installation of temporary cofferdams, hauling, recreation facilities removal, regrading of recreation access roads and parking areas, and other activities (Table 2.7-1). Short-term restoration activities would include irrigation system installation and maintenance, as well as active seeding, planting, and weed management in the reservoir footprint and disturbed upland areas within the Limits of Work (Table 2.7-1). All of the aforementioned activities could result in the disturbance of reservoir sediment deposits remaining within the reservoir footprints and result in inorganic and organic contaminants in those sediments entering the Klamath River. Additionally, use of heavy construction equipment and construction-related vehicles involves gasoline, other petroleum fuels, hydraulic and lubricating fluids and other materials, which have the potential to contaminate waters should they be captured in site stormwater runoff or due to accidents. Please see Potential Impact 3.2-4 potential stormwater-related impacts to water quality and Potential Impact 3.22-2 for consideration of the accidental release of hazardous materials from construction equipment and/or vehicles under the Proposed Project.

As discussed in Potential Impact 3.2-4, the Proposed Project includes construction and other ground-disturbing BMPs to reduce potential impacts to water quality in wetlands and other surface waters during construction (Appendix B: *Definite Plan – Appendix J*). Those BMPs focus on general stormwater-related contamination as well as fuels, oils, and lubricants; however, their implementation would also minimize or eliminate the potential for increases in inorganic and organic contaminants that could enter wetlands and other surface waters located within the Limits of Work (Figures 2.2-5, 2.7-2, and 2.7-4), including the Hydroelectric Reach, tributaries of the Klamath River that enter this reach (as appropriate), or the Middle Klamath River immediately downstream of Iron Gate Dam due to construction and other ground-disturbing activities. However, the Proposed Project does not specify BMPs for pre-construction, reservoir restoration, or upland restoration activities. Further, the proposed BMPs are not sufficiently comprehensive to avoid all potential violations of water quality standards or otherwise degrade water quality in affected portions of the wetlands, Hydroelectric Reach, tributaries to the Klamath River that enter this reach (as appropriate), or the Middle Klamath River immediately downstream of Iron Gate Dam, during these other periods of Proposed Project activity. Thus, short-term increases in inorganic and organic contaminants from hazardous materials associated with construction and restoration activities would potentially result in substantial adverse impacts on human health or environmental receptors and there could be significant impacts without mitigation to water quality in the Hydroelectric Reach and the Middle Klamath River immediately downstream of Iron Gate Dam. Implementation of Mitigation Measures WQ-1, TER-1, and HZ-1 would reduce this impact to less than significant.

Significance

No significant impact with mitigation

Potential Impact 3.2-16 Short-term impacts to aquatic biota from herbicide application during restoration of the reservoir areas.

The Proposed Project Reservoir Restoration Plan includes active seeding and planting of vegetation in drained reservoir areas to stabilize the surface of the sediment and minimize erosion from exposed terrace surfaces following drawdown (Appendix B: *Definite Plan – Appendix H*). An invasive exotic vegetation (IEV) management plan would be implemented to control terrestrial invasive exotic plant species. As part of the management plan, IEV surveys would be undertaken prior to dam removal year 1 and year 2 and non-herbicide methods of integrative pest management (e.g., manual weed pulling, mowing or cutting, mechanical eradication by tilling in larger areas, grazing, shading, and solarization) would be used first to remove IEVs within the Limits of Work. As a last resort and only when other methods prove to be ineffective or potentially cause more harm than benefit within the environment, herbicides would be used to control the growth of invasive exotic vegetation species, with application by wicking or brushing occurring during dam removal year 2.

Herbicide use to control invasive exotic vegetation species has the potential to contaminate the Klamath River through runoff or drift without proper selection, handling, and application. KRRC has proposed to avoid this risk to the extent possible by only using herbicides after non-chemical control methods have proven ineffective or may cause more harm than benefit to the environment. The only herbicides used would be those approved for use by the Bureau of Land Management (BLM), California Department of Fish and Wildlife (CDFW), North Coast Regional Board, USFWS, and NMFS in California. If herbicide application becomes the necessary method for effective IEV control, the KRRC would consider only those application methods with the least side-effects to native vegetation and wildlife and would base application methods on plant reproduction, structure, and growth. Monitoring and management of invasive plant species would continue after dam removal year 2 with the potential for further herbicide application, if the latter offers the most effective methods for control and eradication of noxious weeds (Appendix B: *Definite Plan – Appendix H*).

While the Proposed Project includes strategies to avoid and minimize runoff that is toxic to aquatic biota from herbicide application, the Reservoir Restoration Plan included in the Definite Plan (see Appendix B: *Definite Plan – Appendix H*) lacks specificity regarding certain herbicide formulations and application practices that could result in short-term aquatic toxicity within the Hydroelectric Reach during reservoir restoration activities, which would constitute a substantial adverse impact on aquatic biota and thus would be a significant impact.

Under the Proposed Project, the Reservoir Restoration Plan would be further developed by KRRC working with the appropriate agencies through the FERC process, and it would be subject to State Water Board approval. In addition, it would also be appropriate for the Final Reservoir Restoration Plan to include Mitigation Measure WQ-4, which provides further protections for aquatic biota in relation to control of terrestrial invasive exotic plant species via herbicide application.

Mitigation Measure WQ-4 Herbicide Characteristics and Application Approach. Aquatic formulations of glyphosate (i.e., Glyfos Aquatic) are developed for use in sensitive protected environments such as habitat restoration sites and wetlands. If glyphosate is chosen as a suitable herbicide for IEV management, then an aquatic formulation shall be used and glyphosate formulations containing POEA or R-11 shall be avoided to reduce risks to amphibians and other aquatic organisms. Additionally, glyphosate shall not be applied when weather reports predict precipitation within 24 hours of application, before or after. If another herbicide is chosen, it shall meet the characteristics of low soil mobility and low toxicity to fish and aquatic organisms and shall be applied using low use rates (i.e., spot treatments), avoidance of application in the rain, avoidance of treatments during periods when fish are in life stages most sensitive to the herbicide(s) used, and adherence to appropriate buffer zones around stream channels as specified in BLM (2010).

Significance
No significant impact with mitigation

3.2.5.8 General Water Quality

Potential Impact 3.2-17 Short-term and long-term influence of changes in Iron Gate and Fall Creek hatchery production on Klamath River and Fall Creek water quality. Under the Proposed Project, the Iron Gate Hatchery facilities would be modified from existing conditions and the nearby Fall Creek Hatchery would be reopened (see Section 2.7.6 *Hatchery Operations* for more details). As part of the Proposed Project, the existing adult fish ladder and holding tanks at the base of Iron Gate Dam and the cold-water supply and aerator for the hatchery would be removed, while other hatchery features would remain in place and would be altered for limited operations during dam removal year 2 and the subsequent seven years post-dam removal (eight years total) (see Section 2.7.6.1 *Iron Gate Hatchery* for more details). Fall Creek Hatchery has not been used to produce fish since 2003, so existing facilities would be upgraded for raising coho salmon and Chinook salmon as part of reopening Fall Creek Hatchery, and new facilities (e.g., a settling pond, vehicle parking, pertinent buildings, tagging trailer, etc.) would be constructed (see Section 2.7.6.2 *Fall Creek Hatchery* for more details). As with Iron Gate Hatchery, it would operate for eight years in total, starting in dam removal year 2. As the hatchery facilities would operate for eight years and then close, for this potential impact, short-term is defined as through the eight-year period of operation, and long-term is defined as the period thereafter.

Total hatchery production under the Proposed Project would be reduced from current levels. Iron Gate Hatchery Chinook salmon smolt production goals would be reduced to 3,400,000 under the Proposed Project and fall-run Chinook and coho yearling salmon and steelhead production goals would be reduced to zero since they would no longer be produced at Iron Gate Hatchery (Table 2.7-13). In tandem with fish production decreases at Iron Gate Hatchery, production at Fall Creek Hatchery would increase from zero under existing conditions to 75,000 coho yearlings and 115,000 Chinook yearlings. No Chinook smolts and no steelhead would be produced at Fall Creek Hatchery (see also Section 2.7.6.2 *Fall Creek Hatchery*). While the hatchery production goals have been set, the ability to meet the production varies annually based on adult returns and hatchery performance. At Iron Gate Hatchery, the fall-run Chinook salmon yearling smolt goals and coho salmon yearling smolt goals have been achieved on average since

2005 but fall-run Chinook salmon age zero smolts are typically approximately one million smolts less than production goals (K. Pomeroy, CDFW, pers. comm., 2018) and no steelhead have been released since 2012 (NMFS and CDFW 2018). After considering the actual production achieved, hatchery operations under the Proposed Project would constitute a reduction in production from existing conditions of approximately 87 percent for yearling fall-run Chinook salmon smolts, 20 percent for fall-run Chinook salmon age zero smolts, 100 percent for steelhead, and zero percent for coho salmon smolts (see Section 3.3.5.6 *Fish Hatcheries* for more details).

Hatcheries potentially alter water temperature through increasing exposure to direct sunlight (e.g., in raceways or settling ponds) and ambient air temperatures. Hatcheries also potentially increase suspended material, turbidity, and nutrients in streams by discharging water containing organic solids from uneaten commercial pelletized feed and fish waste. Hatchery discharges may also alter dissolved oxygen, pH, and salinity in streams by discharging water with dissolved oxygen, pH, or salinity different than the streams into which the discharge is released. Differences in dissolved oxygen can be due to hatchery fish respiration, biochemical oxygen demand (BOD) from organic solids associated with fish feed, biological growth (e.g., algae and bacteria) in the hatchery and settling ponds or use of chemicals to manage hatchery conditions (e.g., fish disease). Use of water treatment chemicals, drugs, and/or vaccines to treat illnesses within hatchery fish or prevent detrimental fungal or bacterial conditions also has the potential to alter the inorganic and organic contaminants (ICF 2010). The impacts of hatchery operations and discharges of hatchery effluent on Klamath River water quality would be similar or would decrease under the Proposed Project compared to existing conditions, as current production goal would be reduced, resulting in an overall decrease in potential suspended material, nutrient, or water treatment chemical releases in the system as a whole.

Under the Proposed Project, water temperature effects from Iron Gate Hatchery would likely be similar to existing conditions since lower production and proposed modifications at the hatchery would not significantly alter the area of the raceways and settling tanks that are exposed to sunlight or air temperatures. However, suspended material, turbidity, nutrients, dissolved oxygen, pH, salinity, and inorganic and organic contaminants from the combined operation of Iron Gate Hatchery and Fall Creek in the Klamath River downstream of Iron Gate Hatchery would decrease under the Proposed Project compared to existing conditions since lower fish production would require less feed and less frequent use of chemicals to manage hatchery conditions.

Feed is a major source of organic material, nutrients, and BOD; therefore, reductions in fish production and feed at Iron Gate Hatchery under the Proposed Project also would correspond to a reduction in total nitrogen (TN), total phosphorus (TP), and carbonaceous biological oxygen demand (CBOD)[72] loads from the hatchery. Thus, while Iron Gate Hatchery currently exceeds its TMDL allocation of zero net discharge of nitrogen, phosphorous and biological oxygen demand, these existing exceedances to the Klamath River would be reduced under the Proposed Project for eight years of hatchery operations and would then be eliminated. Overall, the decrease in total hatchery fish production would maintain or improve return water quality conditions

[72] Carbonaceous biological oxygen demand (CBOD) is used instead of BOD to evaluate the organic matter loads in the Klamath River TMDL California Compliance Conditions. BOD is equal to the CBOD plus the nitrogenous biological oxygen demand (NBOD).

downstream of Iron Gate Hatchery as compared to existing conditions, so there would be no significant impact on water quality below Iron Gate Hatchery in the short term or long-term due to changes in fish production under the Proposed Project.

For the stretch of river that is between the Fall Creek Hatchery downstream to Iron Gate Hatchery, there would be a net increase in hatchery-related discharges as compared to the existing condition, because Fall Creek Hatchery is currently not operating. The reopening of Fall Creek Hatchery and production of fish at the hatchery for eight years (i.e., dam removal year 2 and the subsequent seven years post-dam removal) under the Proposed Project would potentially alter the short-term (dam removal year 2 through post-dam removal year 1) and long-term (after post-dam removal year 1) water quality conditions in Fall Creek downstream of the hatchery (Figure 2.7-15). The fish ladder would continuously discharge water from the rearing tanks, except during periods of cleaning, feeding, or chemical use to treat fish illnesses (i.e., therapeutics). The settling pond is proposed for construction on one of two potential nearby sites[73] and would discharge all water from the rearing ponds after cleaning, feeding, or therapeutic use along with all water from the incubation and spawning operations. Fall Creek water quality below Fall Creek Hatchery would be primarily influenced by the hatchery discharges downstream of the settling pond (maximum of approximately 0.35 mile upstream of Fall Creek's confluence with the Klamath River) but Fall Creek water quality potentially would also be influenced by hatchery discharges up to the adult fish ladder (approximately 0.87 mile upstream from Fall Creek's confluence with the Klamath River).

Fall Creek Hatchery operations and effluent discharge would potentially alter water temperature downstream of the hatchery discharge points, but the change in water temperature would be minimal. Water temperature data from 11 hatcheries and concurrent water temperature measurements upstream and downstream of the hatchery discharge indicate the average change in water temperature downstream of the hatchery discharge ranged from -0.5ºF to 2.2ºF, with a 0.1ºF or less change in water temperature downstream of more than half of the hatcheries (ICF 2010). While the water temperature impacts of most hatcheries were limited, there were three instances (i.e., 1 percent of all available data) where the water temperature downstream of a hatchery was 5ºF greater than the water temperature upstream, including one occasion at Iron Gate Hatchery in June 2008. In all three instances, hatchery discharge was warmer than the upstream water temperature, but it was less than the downstream water temperature, suggesting that factors in addition to hatchery operations may have influenced water temperature in the stream (ICF 2010). Fall Creek Hatchery is generally shady and therefore unlikely to have the same solar radiation impacts as Iron Gate Hatchery. However, there is the potential for the hatchery to elevate temperatures

Overall, Fall Creek Hatchery discharges potentially would alter water temperature between -0.5ºF to 2.2ºF, and there is significant potential that Fall Creek Hatchery discharges would result in exceedances of water quality standards for water temperature. Fall Creek is an interstate water originating in Oregon, so potential water temperature increases in the stream from hatchery discharges would result in an exceedance of the Thermal Plan water temperature water quality standard for interstate waters that prohibit the discharge of elevated temperature waters into **COLD** interstate

[73] Selection of the settling pond site is pending cultural resources investigations and consultation with tribes with historical and cultural connection to the area (see also Section 2.7.6.2 *Fall Creek Hatchery*).

waters (Table 3.2-4) and there would be a significant and unavoidable impact without mitigation to water temperature in Fall Creek due to Fall Creek Hatchery under the Proposed Project. While water temperature data in the Klamath River upstream and downstream of the confluence of Fall Creek is unavailable to determine the influence of Fall Creek water temperature on Klamath River water temperatures, the average monthly water temperature in Fall Creek is typically colder than the average monthly water temperature of the Klamath River upstream of Copco No. 1 during April through September (FERC 2007). Thus, Fall Creek would potentially be a source of cold water to the Klamath River during portions of the year and an increase in Fall Creek water temperature due to Fall Creek Hatchery discharges potentially would result in an increase in Klamath River water temperature. While the increase in Fall Creek water temperature and subsequent potential increase in Klamath River water temperature due to hatchery discharges would be small, any increase in water temperature would exceed Thermal Plan water temperature water quality standard for **COLD** interstate waters and there potentially would be a significant and unavoidable impact without mitigation on water temperature in the Hydroelectric Reach of the Klamath River due to Fall Creek Hatchery under the Proposed Project.

Fall Creek Hatchery discharges potentially would increase suspended material in Fall Creek by discharging water containing organic solids from uneaten commercial pelletized feed and fish waste, but those increases remain less than the suspended sediment thresholds of significance. The measured maximum net TSS resulting from the discharge of 19 existing CDFW hatcheries ranged from less than 5.0 mg/L to 25.6 mg/L, with TSS equal to or greater than 5 mg/L in hatchery discharges occurring at 12 of the 19 hatcheries (ICF 2010). At those 12 hatcheries, TSS was equal to or greater than 5 mg/L less than once a year (1 out of 57 measurements at Iron Gate Hatchery) to approximately twice per year (13 out of 120 measurements at Hot Creek Hatchery). Additionally, the TSS was measured directly in the hatchery discharge, so the TSS within the receiving waterbody (i.e., just downstream of the hatchery discharge point) would be less due to dilution (ICF 2010). The range of potential suspended material in Fall Creek Hatchery discharges would likely be similar to existing CDFW hatcheries, so the potential for hatchery discharges to cause nuisance or adversely affect beneficial uses by introducing suspended material, settleable material, or sediments in excess is based on data regarding existing hatcheries. In line with data from existing CDFW hatcheries and expected dilution in the receiving waterbodies, suspended material in hatchery discharges would remain below the numeric SSC[74] threshold of significance for suspended sediments. Thus, Fall Creek Hatchery discharges under the Proposed Project would have a less than significant impact on suspended sediments in the short term and long term in Fall Creek and in the Klamath River downstream of its confluence with Fall Creek.

Nutrient concentrations in hatchery discharges likely would increase nutrients in Fall Creek downstream of the settling ponds and to a lesser extent downstream of the adult fish ladder, based on nutrient data from existing CDFW hatcheries. In the six existing CDFW hatcheries with nutrient data, the measured nutrients ranged from 0.07 to 5.6 mg/L TN, 0.008 to 5.2 mg/L nitrate, 0.02 to 0.25 mg/L TP, and less than 0.01 to 0.28 mg/L orthophosphate (ICF 2010). The range of measured nitrate concentrations indicates that there is no potential for hatchery discharges to exceed nitrate primary

[74] For the purposes of this report, SSC is considered equivalent to TSS (see Section 3.2.3.1 *Thresholds of Significance* for additional details).

drinking water standards in streams. The existing CDFW hatchery data also documents that nutrient concentrations in hatchery discharges usually vary little from nutrient concentrations in the hatchery source water (i.e., upstream water not influenced by the hatchery), with higher nutrient concentrations in hatchery discharges occurring infrequently. Visual observations from 10 hatcheries that record potential nuisance growth conditions in receiving waters (i.e., streams) did not note nuisance biostimulatory responses, such as discoloration, bottom deposits, visible films/sheens, or objectionable growth (i.e., fungi or slimes) downstream of hatchery discharges (ICF 2010). Fall Creek Hatchery discharges likely would increase nutrient concentrations in Fall Creek[75] and in the Klamath River downstream of its confluence with Fall Creek, but those increases would not be expected to result in exceedances of North Coast Regional Board Basin Plan water quality objectives for biostimulatory substances.

Fall Creek Hatchery discharges may also alter dissolved oxygen in streams by discharging water with dissolved oxygen concentrations different than the receiving waters due to fish respiration or biochemical oxygen demand (BOD) from organic solids, discharging water with organic solids that contribute BOD to streams and reduces dissolved oxygen downstream of the hatchery, and biological growth (e.g., algae and bacteria) in the hatchery and settling ponds. The analysis of dissolved oxygen data from existing CDFW hatcheries, including Iron Gate Hatchery, does not present dissolved oxygen percent saturation in the hatchery discharges, so it is not possible to evaluate hatchery discharges relative to Basin Plan dissolved oxygen water quality objectives. Dissolved oxygen in existing CDFW hatchery discharges usually were greater than 7.0 mg/L, but eight hatcheries had at least one occurrence of dissolved oxygen less than 7.0 mg/L (ICF 2010). In two out of nine measurements, Iron Gate Hatchery discharge dissolved oxygen was less than 7.0 mg/L, with the minimum dissolved oxygen reaching 6.3 mg/L (ICF 2010). While hatcheries manage dissolved oxygen concentrations for fish using flow control, passive aeration devices, and mechanical aeration, there is a low potential for dissolved oxygen below 7.0 mg/L (ICF 2010) that may correspond to dissolved oxygen percent saturation being less than Basin Plan dissolved oxygen water quality objectives. Dissolved oxygen percent saturation varies with water temperature, so dissolved oxygen can be below 7.0 mg/L during peak summer water temperature conditions, yet still meet the Basin Plan dissolved oxygen water quality objectives of 85 percent saturation. Thus, Fall Creek Hatchery discharges would have a low potential for causing dissolved oxygen percent saturation to be less than Basin Plan dissolved oxygen water quality objectives in Fall Creek downstream of the hatchery or in the Klamath River downstream of the confluence with Fall Creek.

While Fall Creek Hatchery discharges would have a low potential for causing dissolved oxygen percent saturation to become less than Basin Plan dissolved oxygen water quality objectives, dissolved oxygen percent saturation in Fall Creek may infrequently decrease below Basin Plan dissolved oxygen water quality objectives and thus there would be significant impact without mitigation on dissolved oxygen in the short term and long term from hatchery discharges under the Proposed Project.

[75] One data point exists for nutrient concentrations in Fall Creek measured in October 1999 when the Fall Creek Hatchery was still in operation. However, due to the difference in production goals and proposed new facilities (i.e., settling ponds), it is likely this data would overestimate background nutrient conditions in Fall Creek and potentially overestimate nutrient conditions in Fall Creek upon the resuming of Fall Creek Hatchery operations.

Fall Creek Hatchery discharges are unlikely to alter pH in streams based on pH monitoring data from existing CDFW hatcheries. The incremental change in pH between upstream and downstream monitoring data was less than 0.5 s.u. downstream of all hatcheries where downstream pH data was available (ICF 2010). Hatchery discharges had pH greater than 8.5 s.u. or less than 6.5 s.u. in only four out of the 12 CDFW hatcheries, with no exceedances occurring at Iron Gate Hatchery (ICF 2010). Thus, Fall Creek Hatchery discharges under the Proposed Project would be unlikely to alter pH in Fall Creek or the Klamath River downstream of its confluence with Fall Creek by 0.5 s.u. or more or result in pH less than 6.5 units or greater than 8.5 units and there would be a less than significant impact without mitigation on pH in Fall Creek and the Klamath River due to Fall Creek Hatchery operations and discharges under the Proposed Project.

Fall Creek Hatchery discharges would potentially increase the concentration of inorganic and organic contaminants in Fall Creek downstream of the settling ponds due to the use of water treatment chemicals, drugs, and vaccines to treat illnesses within hatchery fish (i.e., therapeutics) or prevent detrimental fungal or bacterial conditions. Chemical use in hatcheries typically occurs for several hours using immersion bath or flushing water through one or more components of the hatchery facilities for general treatments, while therapeutics are usually applied in small water volumes or fish feed for a short duration of several minutes up to one hour (ICF 2010). All water from the rearing ponds after cleaning, feeding, or therapeutic use along with all water from the incubation and spawning operations would be discharged from the hatchery settling pond (Figure 2.7-15), so potential increases in inorganic and organic contaminants would be limited to downstream of the settling pond (maximum of approximately 0.35 miles upstream of Fall Creek's confluence with the Klamath River).

Potential chemicals used in CDFW hatcheries, the reason for their use, and the regulatory status of the chemicals are summarized in Table 3.2-15. Copper sulfate had been historically used in hatcheries for general treatments, but its use has been discontinued in all CDFW hatcheries (ICF 2010). All the chemicals currently used are Food and Drug Administration (FDA) Center Veterinary Medicine (CVM) approved, investigational new animal drugs (INAD), low regulatory priority (LRP) compounds, or deferred decision (DD) chemicals (Table 3.2-15). FDA approved drugs have been determined to be safe for the treated fish, humans who might consume the treated fish, and the environment when used in accordance with label instructions for proper usage. FDA INAD are used under exemption only, with annual renewals and numerous FDA requirements for their use. FDA LRP compounds are considered comparatively little risk to aquatic organisms, human consumers, or the environment, such that regulatory action is unlikely to occur as long as an appropriate grade of the compound is used for listed indications at the prescribed levels according to good management practices and local environmental requirements are met. FDA DD chemicals are those already approved by the USEPA in aquaculture settings (AFS FCS 2014).

Table 3.2-15. Potential General Treatment and Therapeutic Chemicals Used at California Department of Fish and Wildlife Hatcheries.

Chemical Name	Use	Regulatory Status
acetic acid	Control of external parasites	FDA LRP compound
carbon dioxide (gas)	Anesthetic	FDA LRP compound
sodium bicarbonate (baking soda)	Anesthetic	FDA LRP compound
formalin (formaldehyde)	Fungus and parasite treatment	FDA approved
povidone-iodine (PVP iodine)	Disinfectant for eggs	FDA LRP compound
potassium permanganate	Control of external parasites and bacteria	FDA DD chemical; USEPA registered pesticide with approved use in aquaculture
hydrogen peroxide	Control of fungal and bacterial infection	FDA approved
Chloramine-T (*N*-chloro tosylamide)	Control of external gill bacteria	FDA INAD
Terramycin (oxytetracycline)	Antibiotic	FDA approved
Aquaflor (florfenicol)	Antibiotic	FDA approved
penicillin G	Control and prevention bacterial infections	FDA approved
Romet-30 (sulfadimethoxine-ormetoprim)	Antibiotic	FDA approved
MS-222 (tricane mesylate)	Anesthetic	FDA approved

FDA = Food and Drug Administration
INAD = investigational new animal drugs
LRP = low regulatory priority
DD = deferred decision
USEPA = U.S. Environmental Protection Agency

The potential for chemical concentrations in hatchery discharges to exceed the Basin Plan narrative toxicity water quality objective (Table 3.2-4), drinking water criteria, including California Department of Public Health (DPH) maximum contaminant levels (MCLs), or otherwise degrade water quality in streams was evaluated for existing CDFW hatcheries by comparing chemical use concentrations and measurements of chemicals in undiluted hatchery discharge water with CDFW Pesticide Unit guidance aquatic toxicity values and a CDFW Pesticide Investigation Unit toxicity assessment that determined short-term acute test methods (i.e., lethality end point) and chronic test methods (i.e., growth and reproduction end point) (ICF 2010). The CDFW Pesticide Investigation Unit toxicity assessment has been used previously by Regional Water Quality Control Boards to develop NPDES permit numerical effluent limits considered protective of applicable narrative toxicity objectives. Based on the frequency and duration of use in hatcheries, the expected rate of dilution and degradation in the environment, and reported hatchery discharge concentrations, the ICF (2010) analysis concludes acetic acid, carbon dioxide, sodium bicarbonate, PVP iodine, oxytetracycline, florfenicol, penicillin G, Romet-30, and MS-222 all pose a low risk of exceeding CDFW guidance values that are protective of aquatic life, thus the potential for substantial adverse effects on human health or environmental receptors is very low. Available data indicates formalin, potassium permanganate, hydrogen peroxide, and Chloramine-T may exceed CDFW guidance values in undiluted hatchery water, but the analysis concludes the potential for substantial adverse effects from these chemicals on aquatic life-related beneficial uses and other less sensitive designated beneficial uses is very low since potentially elevated concentrations of the chemicals in undiluted hatchery discharges would be expected to rapidly degrade in the aquatic environment, or be diluted within the zone of complete mixing in the receiving waters (ICF 2010). As the discharge will be downstream of the City of Yreka's Fall Creek diversion for drinking water, the discharge should pose no risk to that water supply.

Fall Creek Hatchery operations and general treatment or therapeutic chemical use would be expected to be generally similar in the short term and long term to other CDFW hatcheries. Installation of an ultraviolet light (UV) treatment system for water used in egg incubation at Fall Creek Hatchery, as specified for the Proposed Project, would likely reduce chemical use relative to other CDFW hatcheries without UV treatment systems. Additionally, potential influences of hatchery discharges on Fall Creek and the Klamath River downstream of its confluence with Fall Creek would occur for eight years (i.e., dam removal year 2 and the subsequent seven years post-dam removal) since Fall Creek Hatchery is assumed to operate for only this duration under the Proposed Project. Thus, potential increases in inorganic and organic contaminants in Fall Creek and in the Klamath River downstream of its confluence with Fall Creek due to general treatment or therapeutic chemicals in Fall Creek Hatchery discharges also would have a low risk of substantially adversely impacting aquatic life or other designated beneficial uses in the short term and long term and there is a less than significant impact without mitigation on inorganic and organic contaminants in the short term and long term under the Proposed Project from Fall Creek Hatchery discharges.

In summary, the combined impact of Fall Creek and Iron Gate hatchery operations under the Proposed Project would have no significant impact below Iron Gate Hatchery's discharges, since production would be reduced, decreasing impacts on Klamath River water quality from hatchery operations relative to existing conditions. Fall Creek Hatchery would have a significant impact without mitigation on water temperature in Fall Creek and potentially the Klamath River as it would potentially alter water temperature by -0.5 to 2.2ºF and any increase in water temperature would exceed the Thermal Plan water temperature water quality standard for **COLD** interstate waters. Dissolved oxygen percent saturation in Fall Creek may infrequently occur at levels below Basin Plan dissolved oxygen water quality objectives due to Fall Creek Hatchery discharges and thus there would be significant impact without mitigation on dissolved oxygen in the short term and long term from hatchery discharges under the Proposed Project. While Fall Creek Hatchery operations and discharges would alter suspended materials, and inorganic and organic contaminant concentrations downstream of hatchery discharges, there would be no significant impact on suspended sediments, pH, chlorophyll-a and algal toxins, or inorganic or inorganic and organic contaminants in Fall Creek or the Klamath River downstream of Fall Creek in the short term or long-term under the Proposed Project.

In order to comply with Sections 301, 302, 303, 306, and 307 of the Clean Water Act (CWA), and with applicable requirements of California law, the Proposed Project would implement the conditions specified by the State Water Board in the Section 401 water quality certification. In addition to the Proposed Project Fish Hatchery Plan (see also Section 2.7.6; Appendix B: *Definite Plan – Section 7.8.3 Proposed Fish Hatchery Plan*), the draft water quality certification issued by the State Water Board specifies in

Condition 12 *Hatcheries* that, prior to operation of the Iron Gate and Fall Creek hatcheries, the Licensee shall, for each hatchery, obtain coverage under and comply with the *Cold Water Concentrated Aquatic Animal Production Facility Discharges to Surface Waters, National Pollutant Discharge Elimination System* permit (NPDES No. 135001) or subsequent NPDES permits issued by the North Coast Regional Board.

Several measures were considered to remediate water temperature increases in Fall Creek to avoid a significant impact. Fall Creek Hatchery settling pond and adult fish ladder discharges directly from Fall Creek diversion point could discharge to the Klamath River rather than Fall Creek. Fall Creek is typically cooler than the Klamath River, so Fall Creek Hatchery settling pond discharges would likely still be cooler than the Klamath River even with small amounts of warming of Fall Creek water through the hatchery. Thus, redirecting Fall Creek Hatchery settling pond discharges from Fall Creek to the Klamath River likely would not increase the temperature of interstate waters. Adult fish ladder discharges under the Proposed Project would have gone through the rearing ponds, so they may experience some warming and they may also increase the temperature of interstate waters. Thus, the adult fish ladder discharges would also need to be re-plumbed such that adult fish ladder discharges would be directly taken from the Fall Creek Hatchery diversion point on the Fall Creek powerhouse canal return flow to prevent warming. It is unclear given the available information about the plumbing of the Fall Creek Hatchery whether diverting flows from the Fall Creek Hatchery diversion point directly to the adult fish ladder and having all flows for the rearing tanks go to the settling pond for eventual discharge directly to the Klamath River is even generally feasible or cost-effective (i.e., this distance of pipe is unlikely to be cost effective for temporary hatchery modifications. Additionally, due to prolific tribal cultural resources in the vicinity of Fall Creek Hatchery this measure is likely infeasible. Furthermore, diverting flows from Fall Creek would reduce high-quality habitat for anadromous fish spawning for a longer stretch of the creek. Thus, this measure was not pursued as a feasible mitigation measure.

Chillers may also reduce water temperatures in Fall Creek Hatchery discharges so that water temperature in discharges is always less than the water temperature of receiving waters (in this case, Fall Creek). However, the temporary operations of the hatchery combined with the electricity cost of a chiller(s) was, like the distance for additional piping, found not to be feasible, and this mitigation measure was likewise not pursued.

Significance

No significant impact in the short term and long term for water quality in the Middle Klamath River downstream of Iron Gate Hatchery

Significant and unavoidable in the short term for water temperature and dissolved oxygen in Fall Creek downstream of Fall Creek Hatchery

No significant impact in the long term for water quality (except water temperature and dissolved oxygen) in Fall Creek downstream of Fall Creek Hatchery

Potential Impact 3.2-18 Impacts on water quality from construction activities on Parcel B lands.

As discussed in Section 2.7-10 *Land Disposition and Transfer*, as part of the Proposed Project, Parcel B lands would be transferred to the states (i.e., California and Oregon), as applicable, or to a designated third-party transferee, following dam removal. The outcome of the future Parcel B land transfer is speculative with regard to land use; while the lands would be managed for the public interest, this could include open space, active wetland and riverine restoration, river-based recreation, grazing, and potentially other uses.

It is likely that there would be at least some construction for recreation facilities, active restoration, fencing, trail-building, or other land management activities. To the extent there are construction activities, these could involve the same types of potential short-term impacts to water quality as described in Potential Impact 3.2-4, which would be a significant impact. Use of construction best management practices are feasible and implementation of these can reduce the erosion and sediment issues associated with construction to less than significant.

Therefore, the impact of minor construction on suspended sediments in the future associated the transfer of Parcel B lands and future land use on them would be less than significant with mitigation measures WQ-1, TER-1, and HZ-1, which include BMPs for the area. These measures represent protection under a broad range of construction projects, both in-water and in the dry, and are likely to cover the range of construction activities that would support the various public land uses anticipated under the KHSA. If implemented as part of construction activities under future land uses, these measures would avoid potential violations of water quality standards or other water quality degradation in affected portions of wetlands and other waterbodies and would reduce impacts to less than significant.

In the long term, if managed grazing activities were to occur beyond the level occurring under existing conditions, this could result in erosion-related significant impacts on water quality. However, managed grazing activities would incorporate project-specific measures to reduce potential water quality impacts, including storm water management, streambank setbacks, or exclusionary livestock fencing. Managed grazing activities are required to meet the requirements of the non-point source discharge policy, the prohibition against unpermitted discharges, and the North Coast Regional Water Quality Control Board's Agricultural Lands Discharge Program. These require compliance with BMPs designed to meet state water quality requirements (North Coast Regional Board 2018a). Managed grazing activities that implement such project-specific measures would be expected to have a less than significant impact on water quality in the long term. Future land use activities that involve active wetland and riverine restoration would be likely to result in long-term benefits to water quality.

Significance

No significant impact with mitigation in the short term or long term

3.3 Aquatic Resources

This section describes existing conditions of aquatic resources in the Klamath Basin; analyzes potential impacts that the Proposed Project would have on these aquatic resources and the recovery of listed fish species; and includes measures to avoid or mitigate any significant adverse impacts to fish, aquatic mammals, freshwater mussels, and aquatic macroinvertebrates. Commercial fisheries are discussed in Section 5.3.1 *Regional Economic Impacts*, and potential impacts to recreational fisheries opportunities are in discussed Section 3.20 *Recreation*. The tribal significance of fisheries and potential impacts are discussed in Section 3.12 *Historical Resources and Tribal Cultural Resources*. Floating and attached algae are addressed in Section 3.4 *Phytoplankton and Periphyton*, and wetlands and riparian vegetation and wildlife species (including amphibians and reptiles) are addressed in Section 3.5 *Terrestrial Resources*.

The objectives of the Proposed Project include advancing the long-term restoration of the natural fish populations in the Klamath Basin through water quality improvements, habitat expansion, and a reduction in existing disease rates among salmonids (Section 2.1 *Project Objectives*). Many comments were received by the State Water Board during the public scoping process relating to aquatic resources (see Appendix A), and several of the comment topics were controversial. Some commenters expressed concern that the Proposed Project will not, or is not likely to, meet the stated objectives, or that the costs of implementation (financial and otherwise) are too great to justify the potential for gain. Numerous commenters asserted that hundreds of miles of habitat would become available to salmonids should the dams be removed, and many commenters asserted evidence of historical salmon migrations to Upper Klamath Lake. In contrast, a number of comments identified potential fish passage obstructions located within the portion of the mainstem Klamath River that is currently inundated by the Lower Klamath Project reservoirs. Many comments further stated the belief that coho salmon were not historically found in the Klamath Basin, while others stated that coho salmon were not found in the mid- or upper Klamath Basin due to natural passage barriers. Numerous comments described the fishery benefits that could result from dam removal, including increased habitat access and reduced fish disease, while other comments described the fishery benefits that could result from leaving the dams in place and using fish ladders to support passage and hatchery operations to offset habitat losses. Many public comments contended that the Lower Klamath Project dams are responsible for the reduction in salmon populations in the Klamath Basin, while a roughly equal number of comments indicated that other factors are responsible for the observed population declines, including predation by sea lions, tribal harvest, and fishing pressure from foreign fishing fleets. Comments were also received regarding the relationship between marine mammals, such as Southern Resident Killer Whales and sea lions, and the Chinook salmon fishery in the Klamath watershed, including comments that dam removal could benefit the mammals by increasing abundance of their prey. Additional summary of the aquatic resource comments received during the public scoping process, as well as the individual comments, are presented in Appendix A.

3.3.1 Area of Analysis

The Area of Analysis for aquatic resources considers the range of environments that could be affected by the Proposed Project. The Area of Analysis includes most portions of the Klamath Basin, excluding the Lost River watershed, and most of the Trinity River.

Although the Area of Analysis for aquatic resources includes much of the Upper Klamath Basin in Oregon, these areas are included only to the extent to which they affect California aquatic resources. As the lower 1/4 to 1/2 mile of the Trinity River could be used as a refuge by Klamath River fish attempting to avoid exposure to sediment pulses associated with dam removal, this portion of the Trinity River is also considered in the analysis as part of the Klamath Basin, the Area of Analysis includes the Klamath River Estuary and the nearshore portions of the Pacific Ocean.

This aquatic resources analysis includes an assessment of potential impacts within and across five study reaches of the Klamath River separated by changes in basin physiography (e.g., Upper and Lower Klamath basins), the presence of Lower Klamath Project facilities, and the degree of marine influence (Figure 3.3-1). The five study reaches within the Area of Analysis for aquatic resources are as follows:

1. Upper Klamath River and Connected Waterbodies
    a. Tributaries to Upper Klamath Lake (Sprague, Wood, and Williamson rivers)
    b. Upper Klamath Lake and Agency Lake
    c. Keno Impoundment/Lake Ewauna
    d. Upper Klamath River upstream of the influence of J.C. Boyle Reservoir to Keno Dam
    e. Tule Lake and Lost River between Anderson Rose Dam and Tule Lake
2. Upper Klamath River − Hydroelectric Reach
    a. J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate reservoirs
    b. J.C. Boyle Bypass and Peaking reaches
    c. Copco No. 2 Bypass Channel
    d. Tributaries to the Upper Klamath River (e.g., Jenny, Spencer, Shovel, and Fall creeks)
3. Middle and Lower Klamath River
    a. Middle Klamath River from Iron Gate Dam downstream to the confluence with Trinity River
    b. Major tributaries to the Middle Klamath River (e.g., Shasta, Scott, and Salmon Rivers)
    c. Minor tributaries to the Middle Klamath River (e.g., Bogus, Beaver, Humbug, and Cottonwood creeks)
    d. Lower Klamath River from the confluence with the Trinity River to the estuary
    e. Lower portion of the Trinity River
4. Klamath River Estuary
5. Pacific Ocean Nearshore Environment
    a. California portion of the Klamath River Management Zone (KMZ, Oregon-California state line south to Horse Mountain [40° 05’ 00” N. latitude])

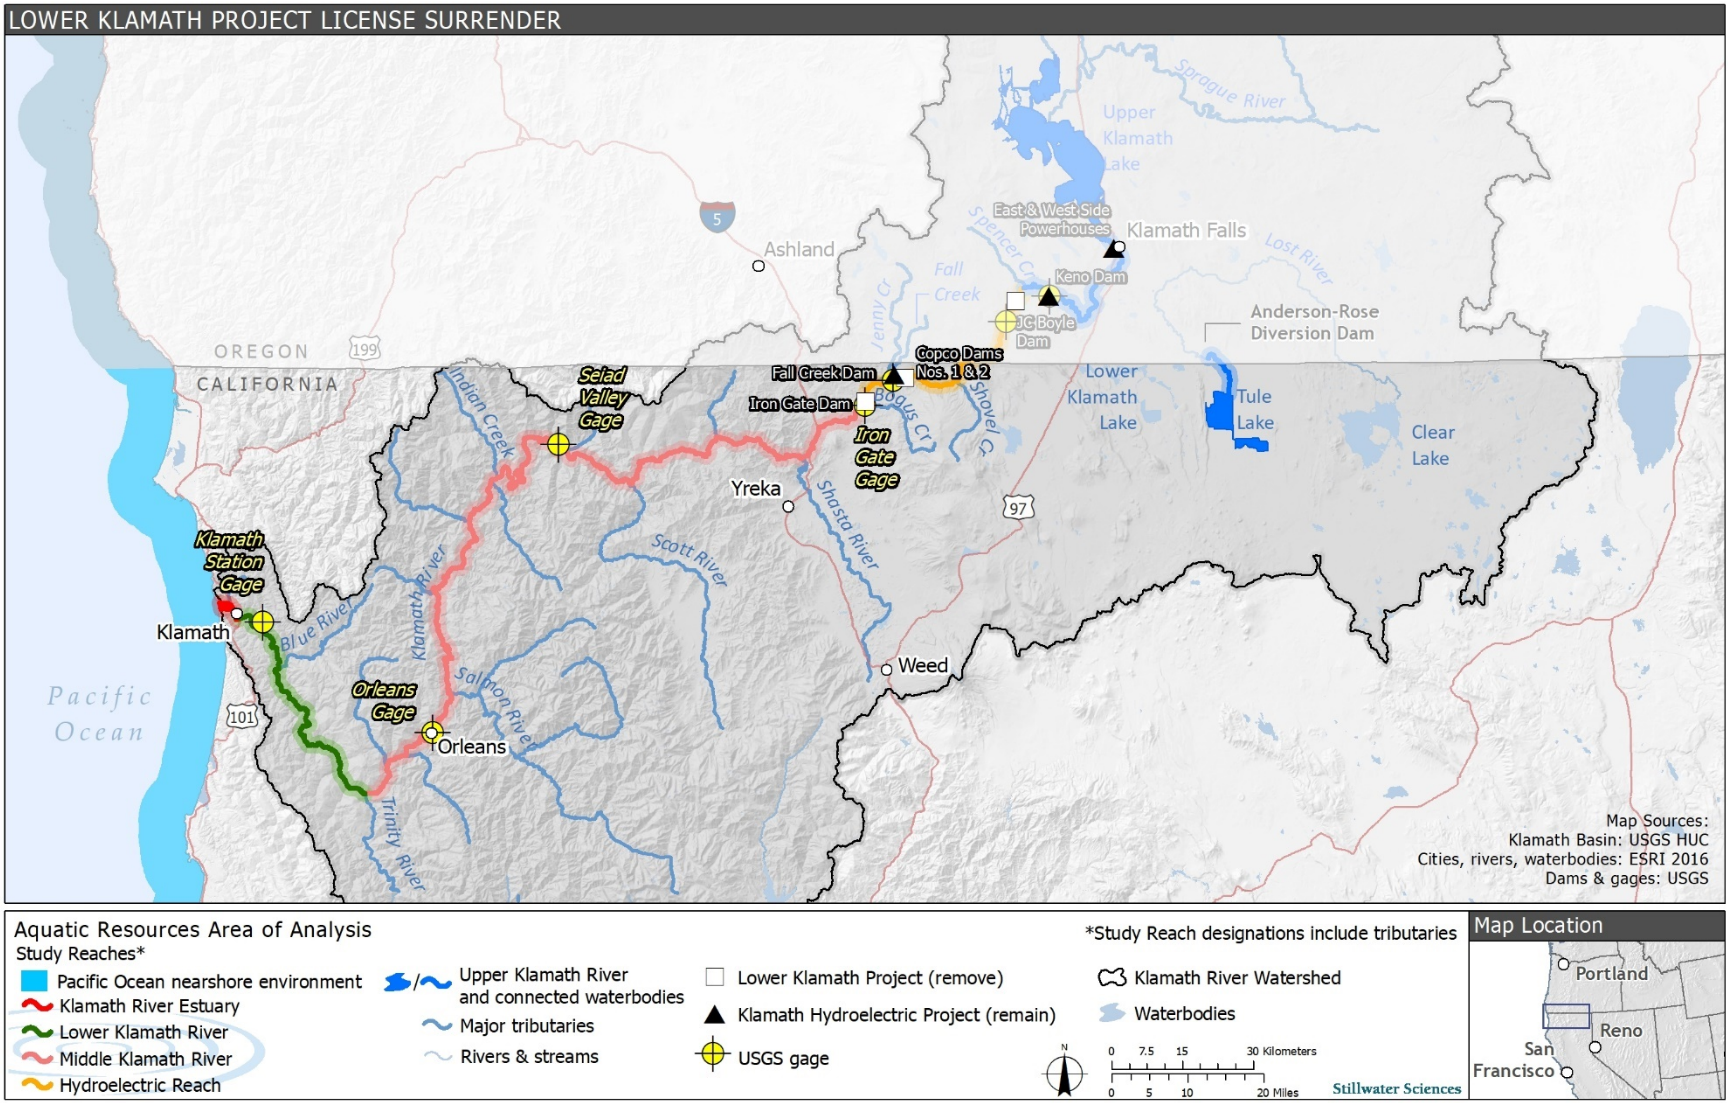

Figure 3.3-1. Study Reaches within the Area of Analysis for Aquatic Resources.

3.3.2 Environmental Setting

This section describes existing conditions in the Area of Analysis for aquatic resources, including discussion of aquatic species (Section 3.3.2.1 *Aquatic Species*); physical habitat in the waterbodies (Section 3.3.2.2 *Physical Habitat Descriptions*); and important factors affecting aquatic resources that the Proposed Project would influence, if implemented (Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*).

Each aquatic species description includes a brief summary of the current and historical distribution, life-history patterns, and habitat requirements. The narrative is subdivided into anadromous fish, resident riverine fish, non-native fish species, estuarine species, freshwater mollusks, benthic macroinvertebrates, and marine mammals.

The description of physical habitat contains a summary of water quality and other factors that may limit aquatic resource production in the waterbodies in the Area of Analysis, and it describes the species that occur in the California portion of these waterbodies. This section also describes designated critical habitat for species listed under the federal ESA and Essential Fish Habitat (EFH) managed under the Magnuson-Stevens Fishery Conservation and Management Act occurring within the California portion of the aquatic resources Area of Analysis.

Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project* provides a more detailed description of existing conditions for factors that potentially could have a major influence on aquatic resources. These factors form the basis for Section 3.3.5 *[Aquatic Resources] Potential Impacts and Mitigation*.

3.3.2.1 Aquatic Species

Numerous aquatic species use the California portion of the Klamath Basin during some or all of their lives. The large number of species prohibits an individual evaluation of each species. Instead, the assessment of potential impacts and/or benefits of the Proposed Project within California on aquatic species is based on an analysis of target species that possess a legal status or importance for tribal, commercial, or recreational fisheries, and for which there are sufficient data to support the analysis. Appendix J: *Special-status Plant, Fish, and Wildlife Scoping Lists* Table J-1 includes a summary of all special-status aquatic fish documented in the Project vicinity. Special status species included in the analysis are summarized in Table 3.3-1, and all the target species (including others without special status) selected for analysis are discussed below.

Table 3.3-1. Special-status Aquatic Species Documented in the Vicinity of the Proposed Project and Included in Aquatic Resources Analysis.

Common Name ***Scientific Name***	**Status[a] Federal/ State/Forest Service, Bureau of Land Management**	**Query Sources**	**Distribution**	**Habitat Association**
Fish				
Shortnose sucker *Chasmistes brevirostris*	FE/SE, SFP/-- Designated critical habitat	CNDDB USFWS	Resident fish observed in the Upper Klamath Basin. In California, they are found in the Klamath River downstream to Copco No. 1 Reservoir and Iron Gate Reservoir.	Warm slow-moving waters or lakes. Spawning occurs along shorelines of lakes or tributaries.
Lost River sucker *Deltistes luxatus*	FE/SE, SFP Designated critical habitat within Area of Analysis	CNDDB USFWS	Resident fish observed in the Upper Klamath Basin. In California, they are found in the Klamath River downstream to Copco No. 1 Reservoir and Iron Gate Reservoir.	Warm slow-moving waters or lakes. Spawning occurs along shorelines of lakes or tributaries.
Coho salmon, southern Oregon/northern California coasts ESU *Oncorhynchus kisutch*	FT/ST/-- Designated critical habitat within Area of Analysis	USFWS	Within the Area of Analysis anadromous fish occurring downstream in the mainstem Klamath River and tributaries downstream of Iron Gate Dam	Streams; spawns in gravel riffles
Chinook salmon - upper Klamath and Trinity Rivers ESU *Oncorhynchus tshawytscha*	--/SSC/FSS	CNDDB	Within the Area of Analysis anadromous fish occurring downstream in the mainstem Klamath River and tributaries downstream of Iron Gate Dam	Streams; spawns in gravel riffles
Coastal cutthroat trout *Oncorhynchus clarki*	--/SSC/FSS	CNDDB	Within the Area of Analysis coastal cutthroat trout are distributed primarily within smaller tributaries to the lower 22 miles of the Klamath River mainstem above the estuary, but also within tributaries to the Trinity River.	Shaded streams with water temperatures below 64.4˚F and small gravel for spawning
Summer-run steelhead trout *Oncorhynchus mykiss irideus*	--/SSC/--	CNDDB	Within the Area of Analysis anadromous fish distributed throughout the Klamath River and in its tributaries, downstream from Iron Gate Dam	Streams; spawns in gravel riffles
Longfin smelt *Spirinchus thaleichthys*	FC/ST, SSC/--	CNDDB	Within the Area of Analysis anadromous fish found in Klamath River Estuary	Adults in large bays, estuaries, and nearshore coastal areas; migrate into freshwater rivers to spawn; salinities of 15–30 ppt

Common Name *Scientific Name*	Status[a] Federal/ State/Forest Service, Bureau of Land Management	Query Sources	Distribution	Habitat Association
Eulachon *Thaleichthys pacificus*	FT/--/-- Designated critical habitat within Area of Analysis	CNDDB	Within the Area of Analysis anadromous fish found in Klamath River Estuary	Adults in large bays, estuaries, and nearshore coastal areas; migrate into freshwater rivers to spawn.
Aquatic Mollusks				
Montane peaclam *Pisidium ultramontanum*	–/–/FSS	CNDDB	Within the Area of Analysis, they have been found in Upper and Lower Klamath Basin	Mollusk found in spring-influenced streams, lakes, and pools and strongly associated with sands or small clean gravels
Mammals				
Killer whale *Orcinus orca* Southern Resident DPS	FE/– Critical habitat (Designated)	NMFS	Pacific Ocean	Coastal habitats of temperate waters, including bays

[a] Status codes:

Federal
FE = Listed as endangered under the federal Endangered Species Act
FT = Listed as threatened under the federal Endangered Species Act
FPE = Federally proposed as endangered
FPT = Federally proposed as threatened
FC = Federal candidate species
FD = Federally delisted
PD = Federally proposed for delisting
BGEPA = Federally protected under the Bald and Golden Eagle Protection Act
FSS = Forest Service Sensitive species
BLMS = Bureau of Land Management Sensitive Species

State
SE = Listed as Endangered under the California Endangered Species Act
ST = Listed as Threatened under the California Endangered Species Act
SCE = State Candidate Endangered
SD = State Delisted
SSC = CDFW Species of Special Concern
SFP = CDFW Fully Protected species
BOFS = Considered a sensitive species by the California Board of Forestry under the California Forest Practice Rules (14 CCR §895.1)

Fish

Numerous fish species use the California portion of the Klamath Basin during some portion or all of their lives. Native fishes found in riverine environments, some of which are listed under the federal or state ESAs, include salmonids, lamprey, sturgeon, suckers, minnows, dace, sculpin; and in the estuary, anchovy, gunnel, pipefish, eulachon, smelt, stickleback, and gobies occur. Species that have been introduced into the Klamath Basin include non-native yellow perch (*Perca flavescens*), largemouth bass (*Micropterus salmoides*), spotted bass (*Micropterus punctulatus*), sunfish (*Lepomis spp*), and catfish (*Siluriformes spp*).

Anadromous Fish Species

The Klamath Basin provides habitat for many species of anadromous fish – fish that migrate between salt and fresh water. Many Klamath River anadromous fish are salmonids, but there are also green sturgeon (*Acipenser medirostris*), Pacific lamprey (*Entosphenus tridentatus*), American shad (*Alosa sapidissima*) (discussed under *Non-native Fish Species* below), and eulachon (*Thaleichthys pacificus*) (discussed under *Estuarine Species* below). Additionally, CDFW operates the Iron Gate Hatchery directly downstream of Iron Gate Dam for salmonid production, as described in more detail in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project – Fish Hatcheries*.

Anadromous fish species within the Klamath Basin have nearly all declined compared to their historical abundance (Table 3.3-2). Although historical data are not available for green sturgeon, the population appears to be more stable than other fish species. Based on reports of green sturgeon captures in the Yurok Tribal Chinook salmon gill-net fishery, Van Eenennaam et al. (2006) conditionally suggests that the Klamath River green sturgeon population appears strong and stable but cautions against conclusions based on short time frames relative to the green sturgeon's long-life span.

Table 3.3-2. Historical and Recent Status of Klamath River Anadromous Fish.

Species	Historical Run Estimate[1]	Recent Run Size Estimate	Source
Pacific Lamprey

[5] Based on data from 2007–2012
[6] Based on data from 2006–2015
[7] Trinity River Hatchery steelhead includes hatchery returns and hatchery origin fish that spawn in the wild
[8] Based on data from 1999–2005
[9] Based on data from 2004–2012
[10] Run size includes hatchery returns
[11] Based on data from 2005–2015
[12] Klamath River has the largest spawning population in the ESU, but while harvest numbers are available, no populations estimates have been made.
[13] Coastal cutthroat are present in lower Klamath tributaries, but no population numbers are available.

Anadromous Salmonids

Anadromous salmonids in the Klamath River include fall-run[76] and spring-run Chinook salmon (*Oncorhynchus tshawytscha*); coho salmon (*Oncorhynchus kisutch*); fall-, winter-, and summer-run steelhead (*Oncorhynchus mykiss*); and coastal cutthroat trout (*Oncorhynchus clarki clarki)*. Anadromous salmonids share similar life-history traits, but the timing of their upstream migrations, timing of outmigration[77], habitat preferences, and distributions differ. All anadromous salmonids spawn in gravel or cobble substrates that are relatively free of fine sediment with suitable surface and subsurface flow to carry oxygen to the eggs and carry metabolic waste away from the eggs. Once suitable spawning habitat is found, the adult female digs one or more nests (called redds) and deposits up to 3,000 eggs per redd (depending on species). The larger the female, the greater the number of eggs she produces. Her mate, or mates, will simultaneously

[76] Run is a migration of salmon up a river from the sea.
[77] Outmigration is the migration of juvenile salmonids from rivers downstream to the estuary and ocean.

fertilize the eggs and fend off other males and egg-eating predators. The female continues digging upstream of the nest, which forms a distinctive pit just upstream from and a protective mound of gravel and cobble over the eggs. The female will continue the mound-building process and defend her nest location. Most anadromous male and female salmonids die after completing spawning, although steelhead and coastal cutthroat may survive spawning, re-enter the ocean, and return to spawn the following year(s).

The salmonid eggs hatch several weeks or months after spawning, depending on species and water temperature. The resulting yolk-sac fry, also referred to as alevins, reside in the gravel for several more weeks and feed off their yolk sac until it is depleted. Egg-to-emergence survival is related to fine sediment infiltration, water temperature, and the fitness of the eggs. The fry that survive to emerge from the redds seek slow shallow areas near shoreline or vegetative cover, feed on benthic macroinvertebrates, gradually moving into deeper and faster water as they grow. Anadromous salmonids are generally considered "juveniles" when they have grown to a fork length of approximately 55 millimeters (about 2.2 inches)[78].

Juveniles feed opportunistically on macroinvertebrates, crustaceans, and smaller fish, and grow on their way downstream. Downstream migration is increased during spring rain events. As discussed in detail in subsequent sections, survival of fry and juvenile life stages is related to disease, parasites, food availability, predation risk, water temperature, and habitat availability (e.g., refuge from high flows). Within the Klamath River juvenile salmonids seek refuge from high flows and turbidity during winter in off-channel features such as side-channels and ponds, and during summer locate thermal refuge within cool water at the confluence with tributaries (in addition to thermal relief during nighttime cooling). Juvenile salmonids may also rear for some time in the estuary feeding prior to entering the ocean. Before entering brackish or salt water, juveniles must undergo a physiological process called smoltification, which is the series of physiological changes allowing juveniles to adapt from living in fresh water to living in seawater. After entering the ocean, smolts range up and down the coast as they grow to adulthood.

Most adult salmonids return to spawn in the stream where they were born, although some straying to nearby waterbodies does occur. Different salmon species and populations (and even the same populations from year to year) have highly variable straying rates, with hatchery origin spawners straying at a higher rate (Lasko et al. 2014). Straying may be the result of a multitude of factors, including as a response to environmental conditions or disturbance events, or exploration of new habitats for suitability. Survival of adults in the marine environment is related to fishing pressure, food availability, and predation risk (e.g., marine mammals). When adults return to natal streams upstream migration success is related to availability of adequate instream flows, turbidity, water temperature (for spring- and summer-runs), disease and parasites, fishing pressure, and passage obstacles (both natural and man-made). Between 1998 and 2008, smolt-to-adult-return-ratios (SAR) for coho at Iron Gate Hatchery ranged from 0.04 percent to 2.66 percent with an average of 0.99 percent (CDFW 2014). From 1988 to 2003, the SAR for fall Chinook released from the Trinity River hatchery ranged from 0.12 percent to 3.19 percent with an average of 1.61 percent (California HSRG 2012).

[78] Fork length is the length of a fish measured from the tip of the snout to the end of the middle caudal fin rays.

For Trinity River Spring Chinook, Yearling releases have averaged just over twice the survival of smolt releases (0.54 percent vs. 1.11 percent). The range of SARs for smolts was from 0.004 percent in 1989 to 2.27 percent in 1999. The SAR range for yearlings was from 0.08 percent in 1990 to 3.30 percent in 1999.

Specific details of life history and distribution are described in the following sections for each anadromous salmonid species.

Chinook Salmon

Two Chinook salmon Evolutionarily Significant Units (ESUs) currently occur in the Klamath Basin downstream of Iron Gate Dam—the Southern Oregon and Northern California Coastal ESU, which includes all naturally spawned Chinook salmon in the Lower Klamath River downstream from its confluence with the Trinity River, and the Upper Klamath and Trinity Rivers ESU, which includes all naturally spawned populations of Chinook salmon in the Klamath and Trinity rivers upstream of the confluence of the two rivers. A status review in 1999 determined that neither ESU warranted listing under the federal ESA (NMFS 1999a). The Upper Klamath and Trinity Rivers ESU is listed as a CDFW Species of Special Concern and a USDA Forest Service Sensitive Species.

Another petition to list Chinook salmon in the Upper Klamath and Trinity Rivers ESU under the ESA was submitted to NMFS in January 2011 (CBD et al. 2011). In the petition, NMFS was asked to consider one of three alternatives for the listing of Chinook salmon in the Upper Klamath and Trinity River ESU: (1) list spring-run only as a separate ESU, (2) list spring-run as a distinct population segment (DPS) within the Upper Klamath and Trinity River Chinook Salmon ESU, or (3) list the entire Chinook salmon Upper Klamath and Trinity River ESU including both spring-run and fall-run populations. In April 2011, NMFS announced that the petition contained substantial scientific information warranting federal review as to whether Chinook salmon within the Upper Klamath and Trinity River ESU should be listed as threatened or endangered. As a result, NMFS formed a Biological Review Team (BRT) to assess the biological status of the species and determine if listing under the ESA is necessary. The BRT (Williams et al. 2011) found that recent spawner abundance estimates of both fall-run and spring-run Chinook salmon returning to spawn in natural areas are generally low compared to historical estimates of abundance; however, the majority of populations have not declined in spawner abundance over the past 30 years (i.e., from the late 1970s and early 1980s to 2016) except for the Scott and Shasta rivers where there have been modest declines (Williams et al. 2011). In addition, Williams et al. (2011) found that hatchery returns did not track escapement[79] to natural spawning areas and they concluded that there has been little change in the abundance levels, trends in abundance, or population growth rates since the review conducted by Myers et al. (1998). The BRT also noted that recent abundance levels of some populations are low, especially in the context of historical abundance estimates. This was most evident with two of the three spring-run population units that were evaluated (Salmon River and South Fork Trinity River). The BRT concluded that although current levels of abundance are low when compared to historical estimates of abundance, the current abundance levels did not constitute a major risk in terms of ESU extinction.

[79] Escapement is the portion of a salmon population that does not get caught by commercial or recreational fisheries and returns to their freshwater spawning habitat or hatchery of origin.

The BRT also concluded that spring-run Chinook salmon did not warrant designation as a separate ESU or DPS within the Upper Klamath and Trinity River ESU. This finding was based in part on genetic evidence that indicates that spring-run and fall-run life histories have evolved on multiple occasions across different coastal watersheds located north and south of the Klamath River. Kinziger et al. (2008) found that there are four genetically distinct and geographically separated groups of Chinook salmon populations in the Upper Klamath and Trinity River basins; and that spring-run and fall-run Chinook salmon life histories have evolved independently, but in parallel, within both the Salmon and Trinity rivers. In addition, spring-run and fall-run populations in the Salmon River were nearly genetically indistinguishable and spring-run and fall-run populations in the South Fork Trinity River were extremely similar to each other and to Trinity River hatchery stocks. Williams et al. (2011) concluded that spring-run and fall-run Chinook salmon within the Upper Klamath and Trinity River basins are genetically similar to each other and that the two runs are not substantially reproductively isolated from each other. In addition, ocean type (ocean entry in early spring within a few months of emergence) and stream type (ocean entry during spring of their second year of life) life history strategies are exhibited by both run types, further suggesting that spring-run Chinook salmon in the Upper Klamath and Trinity River basins do not represent an important component in the evolutionary legacy of the species.

However, recently published research by Prince et al. (2017) questions the basis of treating the fall-run and spring-run Chinook salmon in the Upper Klamath and Trinity River ESU as a single ESU, which was based on overall genetic structure that is primarily defined by geography. The genomic results of Price et al. indicate that premature migration observed in spring-run Chinook salmon is defined by a single genetic variation, questioning the basis of conventional ESU designations which assume that genetic structure is primarily defined by geography.

In response to new information from Prince et al. (2017), and the overall decline of spring-run Chinook salmon, in November 2017, the Karuk Tribe and the Salmon River Watershed Council submitted a petition to NMFS to list as threatened or endangered the Upper Klamath and Trinity Rivers ESU or, alternatively, create a new ESU to describe Klamath spring-run Chinook salmon and list the new ESU as threatened or endangered under the ESA. In February 2018, NMFS announced a 90-day finding on this petition (NMFS 2018a). NMFS found that the petition presents substantial scientific information indicating the petitioned actions may be warranted. NMFS will conduct a status review of the Chinook salmon in the Upper Klamath and Trinity rivers to determine if the petitioned actions are warranted. No final decision has been published to date.

Regardless of the status of a determination on whether spring-run and fall-run Chinook salmon comprise a single ESU, these two runs have different life history strategies (NRC 2004), and therefore are considered distinct in this analysis. A more detailed discussion of the two run types is described below.

Fall-Run Chinook Salmon

Fall-run Chinook salmon are currently distributed throughout the Klamath River downstream from Iron Gate Dam. Upstream adult migration through the estuary and Lower Klamath River peaks in early September and continues through late October (Moyle 2002, FERC 2007, Strange 2008) (Table 3.3-3). Spawning peaks in late October and early November, and fry begin emerging from early February through early April (Stillwater Sciences 2009a), although timing may vary somewhat depending on temperatures in different years and tributaries. Table 3.3-3 provides a generalized life history periodicity for fall-run Chinook salmon life stages, with additional timing provided in Appendix E.3.1.1.

Table 3.3-3. Life-history Timing of Fall-run Chinook Salmon in the Klamath River Basin Downstream of Iron Gate Dam. Peak activity is indicated in black.

Fall-run Chinook salmon in the Klamath Basin exhibit three juvenile life-history types: Type I (ocean entry at age 0[80] in early spring within a few months of emergence), Type II (ocean entry at age 0 in fall or early winter), and Type III (ocean entry at age 1 in spring) (Sullivan 1989) (Table 3.3-3). Based on outmigrant trapping at Big Bar on the Klamath River from 1997 to 2000, 63 percent of natural Chinook salmon outmigrants are Type I, 37 percent are Type II, and less than 1 percent are Type III (Scheiff et al. 2001). Although trapping efforts are not equal among seasons, the results are consistent with scale analysis of adult returns by Sullivan (1989).

Critical stressors on fall-run Chinook salmon in the basin include water quality and quantity in the mainstem and within spawning tributaries. Downstream from Iron Gate Dam, the mainstem Klamath River undergoes seasonal changes in flows, water temperature, dissolved oxygen, and nutrients, as well occasional blooms of *Microcystis aeruginosa* (a blue-green algae species that is potentially toxic to fish, as discussed in detail below and in Section 3.4 *Phytoplankton and Periphyton*). During outmigration, juvenile Chinook salmon are vulnerable to contracting disease from pathogens, including the bacterium *Flavobacterium columnare*, and myxozoan parasites *Parvicapsula minibicornis* and *Ceratomyxa shasta*.

Spring-Run Chinook Salmon

Spring-run Chinook salmon in the Klamath Basin are distributed mostly in the Salmon and Trinity rivers and in the mainstem Klamath River downstream from these tributaries during migratory periods, although a few fish are occasionally observed in other areas

[80] A fish emerging in spring is designated as age 0 until January 1st of the following year, when it is designated as age 1 until January 1st of the next year, when it is designated age 2.

(Stillwater Sciences 2009a). Based on data from 2005 to 2014 (CDFW 2015b), the Salmon River contributions to the overall escapement of spring-run Chinook salmon ranged from 1 to 12 percent of the total escapement, and from 1 to 20 percent of the natural escapement. To date, no spring-run Chinook salmon spawning has been observed in the mainstem Klamath River (Shaw et al. 1997). As described above, the BRT (Williams et al. 2011) concluded that while current abundance is low compared with historical abundance (Table 3.3-2), the Chinook salmon population (which includes hatchery fish) appears to have been fairly stable for the past 30 years. However, the BRT noted, as did Myers et al. (1998), that the recent spawner abundance levels of two of the three spring-run population components (Salmon River and South Fork Trinity River) are very low compared to historical abundance (less than 2,000 fish and 1,000 fish, respectively). The BRT was concerned about the relatively few populations of spring-run Chinook salmon and the low numbers of spawners within those populations (Williams et al. 2011).

The BRT (Williams et al. 2011) found the decline in spring-run salmon especially troubling given that historically the spring-run population may have been equal to, if not larger than the fall-run (Barnhart 1994). Huntington (2006) reasoned that spring-run Chinook salmon likely accounted for the majority of the Upper Klamath Basin's actual salmon production under historical conditions. Spring-run Chinook salmon spawned in the tributaries of the Upper Klamath Basin (Moyle 2002, Hamilton et al. 2005, Hamilton et al. 2016) with large numbers of spring-run Chinook salmon spawning in the basin upstream of Klamath Lake in the Williamson, Sprague, and Wood rivers (Snyder 1931). Large runs of spring-run Chinook salmon also historically returned to the Shasta, Scott, and Salmon rivers (Moyle et al. 1995). The runs in the Upper Klamath Basin are thought to have been in substantial decline by the early 1900s and were eliminated by the completion of Copco No. 1 Dam in 1917 (Snyder 1931). The cause of the decline of the Klamath River spring-run Chinook salmon prior to Copco No. 1 Dam has been attributed to dams, overfishing, irrigation, and largely to commercial hydraulic mining operations (Coots 1962, Snyder 1931). These large-scale mining operations occurred primarily in the late 1800's, and along with overfishing, left spring-run Chinook salmon little chance to recover prior to dam construction in the early 1900's. Dams (e.g., Link River Dam, Iron Gate Dam, Lewiston Dam, etc.) have eliminated access to much of the historical spring-run spawning and rearing habitat and are partly responsible for the extirpation of at least seven spring-run populations from the Klamath-Trinity River system (Myers et al. 1998). For example, the construction of Dwinnell Dam on the Shasta River in 1926 was soon followed by the disappearance of the spring-run Chinook salmon run in that tributary (Moyle et al. 1995).

Wild spring-run Chinook salmon from the Salmon River appear to primarily express a Type II life history, based on scale analyses of adults returning from 1990 to 1994 in the Salmon River (Olson 1996), as well as otolith analyses of Salmon River fry and adults (Sartori 2006). A small number of fish employ the Type III life history, although it does not appear to be nearly as prevalent as the Type II.

Spring-run Chinook salmon upstream migration is observed during two-time periods—spring (April through June) and summer (July through August) (Strange 2008) (Table 3.3-4). Snyder (1931) also describes a run of Chinook salmon occurring in the Klamath River during July and August under historical water quality and temperature conditions. Adults spawn from mid-September to late-October in the Salmon River and from September through early November in the South Fork Trinity River (Stillwater Sciences

2009a). Emergence begins in March and continues until early June (West et al. 1990). Age-0 juveniles rearing in the Salmon River emigrate at various times of the year, with one of the peaks of outmigration occurring in April through May (Olson 1996), which would be considered Type I life history. Based on outmigrant trapping from April to November in 1991 at three locations in the South Fork Salmon River, Olson (1996) reported that the greatest peak in outmigration of age-0 juveniles (69 percent) was in mid-October, which would be considered Type II life history. Sullivan (1989) reported that outmigration of Type II age-0 juveniles can occur as late in the year as early-winter. On the South Fork Trinity River outmigration occurs in late-April and May with a peak in May (Dean 1994, 1995), although it is not possible to differentiate between spring- and fall-run juveniles and so the spring-run may have different run timing. Age-1 juveniles (Type III) have been found to outmigrate from the South Fork Trinity River during the following spring (Dean 1994, 1995). Table 3.3-4 provides a generalized life history periodicity for spring-run Chinook salmon life stages, with additional timing provided in Appendix E.3.1.2.

Table 3.3-4. Life-history Timing of Spring-run Chinook Salmon in the Klamath River Basin Downstream of Iron Gate Dam. Peak Activity is Indicated in Black.

It is unclear how much time outmigrating age-0 juveniles spend in the Klamath River mainstem and estuary before entering the ocean. Sartori (2006) did identify a period of increased growth (an estimated mean of 24 days) just prior to reaching an estuarine environment based on otolith analyses of returning adults to the Salmon River, but this period was never clearly linked to mainstem residence. From March to May, there were fair numbers of age-1 juvenile outmigrants captured in the Klamath River Estuary (Wallace 2004). Approximately half were identified to be hatchery age-1 juvenile fall-run Chinook salmon, and the rest were identified to be of natural origin, based on tag expansions.

Stressors on spring-run Chinook salmon related to water quality and quantity are similar to those for fall-run Chinook salmon in the mainstem Klamath River. Although water quality tends to improve in the mainstem downstream from the confluence with the Salmon River (the upstream-most spawning tributary), degradation of water quality (especially temperature and dissolved oxygen) can create critically stressful conditions for spring-run Chinook salmon adults and juveniles for much of the summer (June through September). Production in the Salmon River is primarily controlled by high water temperatures that reduce adult holding and summer rearing habitat in the mainstem Salmon River, while increased fine sediment input within the watershed reduces spawning and rearing habitat quality in some locations (Elder et al. 2002).

Coho Salmon

Coho salmon within the Klamath Basin are included within the Southern Oregon/Northern California Coast (SONCC) coho salmon ESU, which is listed as federally threatened (NMFS 1997a). SONCC coho salmon designated critical habitat includes the Klamath River downstream of Iron Gate Dam, including the estuary (NMFS 1999b). This ESU includes all naturally spawning populations between Punta Gorda, California and Cape Blanco, Oregon, which encompasses the Trinity and Klamath basins (NMFS 1997a). In addition, coho salmon in the Klamath Basin have been listed by the California Fish and Game Commission as threatened under the California Endangered Species Act (CESA) (CDFG 2002a). The Pacific Fishery Management Council (PFMC) considers potential impacts from fishing when setting retention limits each year. The annual coho salmon exploitation rate (proportion of a population that is caught during a year) averaged approximately 5 percent from 2000 to 2013. California waters were open to coho salmon fishing prior to 1998, but currently, coho salmon fishing in California is restricted to tribal harvest under federal reserved fishing rights in the Klamath River. California's statewide prohibition of coho salmon fishing maintains consistently low impacts from freshwater recreational fisheries on SONCC coho salmon (NMFS 2014).

Coho salmon are native to the Klamath Basin. Williams et al. (2006) described nine historical coho salmon populations within the Klamath Basin: the Upper Klamath River, Shasta River, Scott River, Salmon River, Middle Klamath River, Lower Klamath River, and three population units within the Trinity River watershed (Upper Trinity River, Lower Trinity River, and South Fork Trinity River). Note that the designation of these population units varies from the Area of Analysis study reach designations used in this EIR.

Although coho salmon are native to the Klamath River, documentation of coho salmon in the Klamath River is scarce prior to the early 1900's due, in part, to the apparent difficulty of those providing written records in recognizing that there were different species of salmon inhabiting the rivers of the area (Snyder 1931). Snyder (1931) reported that coho salmon were said to migrate to the headwaters of the Klamath River to spawn, but that most people did not distinguish them from other salmon species. Available data suggests that coho salmon were in both mainstem and tributary reaches of the Klamath River upstream to and including Spencer Creek at RM 232.6 (NRC 2004, as cited in NMFS 2007a, Hamilton et al. 2005). While noting that the evidence of historic presence between Fall and Spencer creeks was not conclusive, the 2006 Administrative Law Judge trial-type hearing under Section 241 of the Energy Policy Act of 2005 (NMFS 2006a) determined that coho salmon were abundant at Fall Creek, and that suitable habitat in the Hydroelectric Reach included Spencer, Fall, Beaver, Deer, Shovel, Scotch and Jenny creeks, as well as the main stem of the Klamath River itself.

The final SONCC Coho Salmon Recovery Plan was published on September 9, 2014 (NMFS 2014). Estimated extinction risk is designated as high for the Lower and Upper Klamath River populations, and moderate for the Middle Klamath River population. Estimated extinction risks of the Shasta, Scott, and Salmon river populations are designated as high, moderate, and high, respectively. Extinction risks for the Lower and Upper Trinity River populations are designated as high and moderate, respectively, while the South Fork Trinity River population is designated as high. Williams et al. (2006) describes population units to support recovery planning for the listed SONCC ESU. Analysis of coho salmon in this EIR considers impacts and benefits for each of the nine population units in the Klamath Basin separately but makes a significance determination for all population units combined within the Klamath Basin to be consistent with the approach to assessing other aquatic species populations.

The 2016 five-year status review of SONCC coho salmon (NMFS 2016a) indicated that the ESU's extinction risk has increased since the last status review in 2011. Drought conditions had persisted in four of the prior five years and were ongoing. These conditions are unprecedented in the time since SONCC coho salmon have been listed and were found likely to have resulted in reduced juvenile survival and stressful rearing conditions in nearly all parts of the ESU's range. Those juveniles that survived the freshwater conditions were also found likely to have faced poor ocean conditions, the results of which would only be apparent after these year classes return as adults.

Coho salmon are currently widely distributed in the Klamath River downstream from Iron Gate Dam (RM 193.1), which blocks the upstream migration of coho salmon to historically available habitat in the upper watershed. To minimize and mitigate for adverse effects to coho salmon, PacifiCorp prepared a Habitat Conservation Plan (HCP) for its interim operations of the Klamath Hydroelectric Project (PacifiCorp 2012). This HCP underlines the conservation strategy and measures that PacifiCorp will undertake to address anticipated effects on SONCC coho salmon and their habitat in the Klamath Basin. Per the HCP, PacifiCorp provides funding for the California Klamath Restoration Fund/Coho Enhancement Fund as an Interim Measure (IM2). Between 2009 and 2014, NMFS and CDFW selected 24 projects to benefit coho salmon (PacifiCorp 2014). These projects have been conducted at the mouths of 72 tributaries as well as in Seiad Creek, Scott River, Denny Ditch, Shasta River, Huseman Ditch, McBravey Creek, Fort Goff Creek Stanshaw Creek and Lower Hoopaw Creek. PacifiCorp has developed a partnership with the National Fish and Wildlife Foundation (NFWF) to administer the fund, and this allows grant recipients to apply for additional funding from other grant programs. A Technical Review Team was formed in 2012 and meets annually to review existing projects funded under the Coho Enhancement Fund and to recommend possible adaptive management changes.

Coho salmon use the mainstem Klamath River for some or all of their life history stages (spawning, rearing and migration). However, the majority of returning adult coho salmon spawn in the tributaries to the mainstem (Magneson and Gough 2006, NMFS 2010a).

Adult coho salmon in the Klamath Basin migrate upstream from September through late December, with migration peaking in October and November (Table 3.3-5). Spawning occurs mainly in November and December, with fry emerging from the gravel in the spring, three to four months after spawning, depending on water temperature (Trihey and Associates 1996, NRC 2004) (Table 3.3.-5). Table 3.3-4 provides a generalized life history periodicity for spring-run Chinook salmon life stages, with additional timing provided in Appendix E.3.1.2.

Table 3.3-5. Life-history Timing of Coho Salmon in the Klamath River Basin Downstream of Iron Gate Dam. Peak Activity is Indicated in Black.

Some fry and age-0 juveniles enter the mainstem in the spring and summer following emergence (Chesney et al. 2009). Large numbers of age-0 juveniles from tributaries in the mid-Klamath River move into the mainstem in the fall (October through November) (Soto et al. 2008, Hillemeier et al. 2009). Juvenile coho salmon have been observed to move into off-channel ponds, non-natal tributaries to the Klamath River, downstream portions of the Lower Klamath River, and the estuary for overwintering (Soto et al. 2008, Hillemeier et al. 2009). Some proportion of juveniles generally remain in their natal tributaries to rear.

Age-1 coho salmon migrate downstream from tributaries into the mainstem Klamath River as smolts from February through mid-June with a peak in April and May, which often coincides with the descending limb of the spring hydrograph (NRC 2004, Chesney and Yokel 2003, Scheiff et al. 2001). Once in the mainstem, smolts appear to move downstream rather quickly; Wallace (2004) reported that numbers of coho salmon smolts in the Klamath River Estuary peaked in May, the same month as peak outmigration from the tributaries.

The major activities identified as responsible for the decline of SONCC coho salmon and degradation of their habitat include logging, road building, grazing, mining, urbanization, stream channelization, dams, wetland loss, beaver trapping, artificial propagation, overfishing, water withdrawals, and unscreened diversions for irrigation (NMFS 1997a). In 2007, NMFS published a Klamath River Coho Salmon Recovery Plan to comply with the Magnuson-Stevens Fishery Conservation and Management Reauthorization Act of 2006. This level of recovery planning is not as intensive or thorough as the recovery planning process required under the ESA (which to date had not been completed). The 2007 plan includes the following actions identified as high priority for recovery:

- Restore access for coho salmon to the Upper Klamath Basin by providing passage upstream of existing mainstem dams.
- Fully implement the Trinity River Restoration Program.
- Provide incentives for private landowners and water users to cooperate in (1) restoring access to tributary streams that are important for coho spawning and rearing, and (2) enhancing mainstem and tributary flows to improve instream habitat conditions.

- Continue to improve the protective measures already in place to address forestry practices and road building/maintenance activities that compromise the quality of coho salmon habitat.
- Implement restorative measures identified through fish disease research results to improve the health of Klamath River coho salmon populations.

Many of the actions identified in the 2007 plan have been, or are in the process of being, addressed: the Proposed Project in this EIR would address restoration of access for coho salmon; the Trinity River Restoration Program is currently being implemented; and, many private landowners and water users are restoring coho access and habitat to stream reaches and they are addressing forestry practices that could harm fish. Fish disease issues are being researched and addressed, most recently in 2013 when the NMFS and USFWS issued a joint Biological Opinion (2013 BiOp; NMFS, and USFWS 2013) for the USBR's Klamath Irrigation Project operations, as described in detail in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*. While the 2013 BiOp is for operations upstream of the Lower Klamath Project, the conditions of the 2013 BiOp form an important part of the existing condition for coho salmon downstream of Iron Gate Dam, and, as discussed below, are intended to reduce coho disease rates. In this joint BiOp, NMFS consulted on coho salmon, while USFWS consulted on listed suckers (discussed below under *Lost River and Shortnose Suckers*).

In the 2013 BiOp, NMFS concluded that the effect of proposed USBR Klamath Irrigation Project operations on flows would result in habitat reductions for coho salmon juveniles in the mainstem Klamath River. To offset these negative effects, the 2013 BiOp includes flow release requirements to reduce disease incidence for coho salmon in the Klamath River downstream of Iron Gate Dam. The formulaic approach to flow releases designed to benefit coho salmon, as described in the 2013 BiOp, prioritizes a volume of water set-aside in an Environmental Water Account (EWA) for releases in the spring, and minimum daily flow targets in April through June to meet Hardy et al. (2006) recommended ecological base flows (discussed further in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*). The 2013 BiOp found that Klamath Irrigation Project operations were not likely to diminish habitat for coho salmon fry and juveniles in the Upper Klamath, Middle Klamath, Shasta, and Scott river populations to an extent that would reduce life history diversity.

In their 2013 BiOp analysis of the Klamath Irrigation Project operations, NMFS concluded that the proposed flow releases would result in coho salmon disease risks that are lower than observed period of record conditions, yet higher than under natural flow conditions (NMFS and USFWS 2013). Of all the adverse effects of the proposed Klamath Irrigation Project operations, NMFS concluded that risk of fish disease due to the myxozoan parasite *Ceratomyxa shasta* (*C. shasta*) is the most significant for coho salmon, since *C. shasta* is a key factor limiting salmon recovery in the Klamath River (e.g., Foott et al. 2009). The adaptive management element of the USBR's Klamath Irrigation Project proposed operations was intended to minimize disease risks to coho salmon during average to below average water years if EWA surplus volume is available. Lastly, NMFS concluded that the proposed minimum daily flows below Iron Gate Dam in April to June would limit the increase in disease risks posed to coho salmon from Klamath Irrigation Project operations. The Klamath Irrigation Project directs flow requirements in the Klamath River below Iron Gate Dam by releases from the Lower Klamath Project's Iron Gate Dam consistent with the 2013 BiOp issued on the Klamath

Irrigation Project. By lowering the disease risk, NMFS asserted that coho salmon abundance would likely improve over the next ten years for the Upper Klamath, Middle Klamath, Shasta, and Scott river populations.

However, the first years of 2013 BiOp implementation included severe drought conditions, and although the USBR was operating the Klamath Irrigation Project in accordance with the 2013 BiOp, the infection rate for *C. shasta* in the Klamath River downstream of Iron Gate Dam greatly exceeded the incidental take maximum (U.S. District Court 2017a). As described in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*, this led to a court order requiring USBR to implement three specific flows in the Klamath River, as measured immediately downstream of Iron Gate Dam: annual winter-spring surface flushing flows, biennial winter-spring deep flushing flows, and spring-summer emergency dilution flows (U.S. District Court 2017a–c). The court also required that USBR re-initiate consultation with NMFS and the USFWS regarding the effects of the Klamath Irrigation Project operations on coho salmon in the Klamath River and Lost River and shortnose suckers in the Upper Klamath Basin (U.S. District Court 2017a–c). The court-ordered flushing flows and emergency dilution flows are not part of existing conditions for the Proposed Project, because they went into effect after the Notice of Preparation was filed by the State Water Board in December 2016, and because the data evaluating the effectiveness of the flows and their potential impacts is not yet robust. The flushing and emergency dilution flows are detailed in Section 4.2.1.1 *[Alternative Description] Summary of Available Hydrology Information for the No Project Alternative* as part of the No Project Alternative because they would likely only apply if Iron Gate Dam were to remain in place or the disease nidus remains. These flows are also discussed in Section 4.4 *Continued Operations with Fish Passage Alternative*.

Steelhead

Steelhead are highly adaptive salmonids, with multiple life histories (Hodge et al. 2016). Klamath Basin summer steelhead and winter steelhead populations both belong to the Klamath Mountain Province ESU, which is not listed under the ESA. The NMFS (2001) status review found that this ESU was not in danger of extinction or likely to become so in the foreseeable future, based on estimated populations for the ESU and lower estimates of genetic risk from naturally spawning hatchery fish than estimated in previous reviews, and consideration of existing conservation efforts that are benefiting steelhead in the ESU.

Summer Steelhead

The Klamath Mountain Province ESU of summer steelhead is a CDFW Species of Special Concern and is distributed throughout the Klamath River downstream from Iron Gate Dam and in its tributaries. This species historically used habitat upstream of Upper Klamath Lake prior to the construction of Copco No. 1 Dam (Hamilton et al. 2005). However, some populations such as the Salmon River summer steelhead have declined significantly in the past several decades (Quiñones et al. 2013), and in general summer steelhead populations in the ESU are currently in low abundance (Moyle et al. 2017). Based on available escapement data from summer direct observation surveys, approximately 55 percent of summer steelhead spawn in the Trinity River and other lower-elevation tributaries (CDFW and USDA Forest Service 2002, unpubl. data). Most remaining summer steelhead are believed to spawn in tributaries between the Trinity River (RM 43.3) and Seiad Creek (RM 132.7), with high water temperatures limiting their use of tributaries to the Klamath River farther upstream (NRC 2004). Adult summer steelhead use the mainstem Klamath River primarily as a migration corridor to access holding and spawning habitat in tributaries.

Summer steelhead adults enter and migrate up the Klamath River from March through June while sexually immature (Hopelain 1998), then hold in cooler tributary habitat until spawning begins in December (USFWS 1998) (Table 3.3-6). Forty to 64 percent of summer steelhead in the Klamath River exhibit repeat spawning, with adults observed to migrate downstream to the ocean after spawning (also known as "runbacks") (Hopelain 1998). Summer steelhead in the basin also have a "half-pounder" life-history pattern, in which an immature fish emigrates to the ocean in the spring, returns to the river in the fall, spends the winter in the river, then emigrates to the ocean again the following spring (Busby et al. 1994, Moyle 2002). Table 3.3-6 provides a generalized life history periodicity for summer steelhead life stages, with additional timing provided in Appendix E.3.1.4.

Table 3.3-6. Life-history Timing of Summer Steelhead in the Klamath River Basin Downstream of Iron Gate Dam. Peak Life-history Periods are Shown in Black.

Juvenile summer steelhead in the Klamath Basin may rear in freshwater for up to three years before outmigrating. Although many juveniles migrate downstream at age-1 (Scheiff et al. 2001), those that outmigrate to the ocean at age 2 appear to have the highest survival (Hopelain 1998). Juveniles outmigrating from tributaries at age-0 and age-1 may rear in the mainstem or in non-natal[81] tributaries (particularly during periods of poor water quality) for one or more years before reaching an appropriate size for smolting. Age-0 juvenile steelhead have been observed migrating upstream into tributaries, off-channel ponds, and other winter refuge habitat in the Lower Klamath River (Stillwater Sciences 2010). Juvenile outmigration occurs primarily during spring. Smolts are captured in the mainstem and estuary throughout the fall and winter (Wallace 2004), but peak smolt outmigration normally occurs from April through June, based on estuary captures (Wallace 2004). Temperatures in the mainstem are generally suitable for juvenile steelhead, except during periods of the summer, especially upstream of Seiad Valley (for more species information see USFWS 1998, Moyle 2002, NRC 2004, and Stillwater Sciences 2009a). Critical limiting factors for summer steelhead include degraded habitats, passage impediments, predation, and competition (Moyle et al. 2008).

Winter Steelhead

[81] Tributary other than the one in which it was born.

Moyle (2002) describes steelhead in the Klamath Basin as having a summer- and winter-run. Some divide the winter-run into fall and winter-runs (Barnhart 1994, Hopelain 1998, USFWS 1998, Papa et al. 2007). In this section, "winter steelhead" refers to both fall- and winter-runs except in cases when the distinction is pertinent to the discussion, and wherever data was sufficient to analyze them separately.

Winter steelhead are widely distributed throughout the Klamath River and its tributaries downstream from Iron Gate Dam, and historically used habitat upstream of Upper Klamath Lake (Hamilton et al. 2005). Butler et al. (2010) found that 93 percent of the 41 *Oncorhynchus mykiss* specimens excavated from archeological sites above Upper Klamath Lake were anadromous (indicating occurrence of steelhead historically upstream of Upper Klamath Lake). Winter steelhead adults generally enter the Klamath River from July through October (fall-run) and from November through March (winter-run) (USFWS 1998, Stillwater Sciences 2010). They spawn mainly in tributaries throughout the Klamath River Basin downstream of Iron Gate Dam, and occasionally within the mainstem (NRC 2004). Winter steelhead migrate upstream primarily from January through April (USFWS 1998), with peak spawn timing in February and March (ranging from January to April) (NRC 2004) (Table 3.3-7). Adults may repeat spawning in subsequent years after returning to the ocean in the spring following spawning. Immature "half-pounders" return after a short (<1 year) ocean residence each year in September through March and typically use the mainstem Klamath River to feed until returning to the ocean (NRC 2004), although they also use larger tributaries such as the Trinity River (Dean 1994, 1995). Table 3.3-7 provides a generalized life history periodicity for spring-run Chinook salmon life stages, with additional timing provided in Appendix E.3.1.4.

Table 3.3-7. Life-history Timing of Fall-and Winter-run Steelhead and Rainbow Trout in the Klamath River Basin Downstream of Iron Gate Dam. Peak Life-history Periods are Shown in Black.

Fry emerge in spring (NRC 2004), with fry observed in outmigrant traps in Bogus Creek and Shasta River from March through mid-June (Dean 1994). Age-0 and age-1 juveniles have been captured in outmigrant traps in spring and summer in tributaries to the Klamath River upstream of Seiad Creek (CDFG 1990a, b). These fish are likely rearing in the mainstem or non-natal tributaries before outmigrating to the ocean as age-2 outmigrants.

Juvenile outmigration appears to primarily occur between May and September with peaks between April and June, although smolts are captured in the estuary as early as

March and as late as October (Wallace 2004). Most adult returns originate from fish that smolt at age-2, representing 86 percent of adult returns; in comparison with only 10 percent for age-1 juveniles and 4 percent for age 3+ juveniles (Hopelain 1998).

Similar limiting factors listed for summer steelhead also affect winter steelhead populations, including degraded habitats, decreased habitat access, fish passage, predation, and competition (for more species information see USFWS 1998, NRC 2004, Wallace 2004, and Stillwater Sciences 2009a).

Coastal Cutthroat Trout

Klamath River coastal cutthroat trout belong to the Southern Oregon/California Coasts ESU. Coastal cutthroat trout within the Area of Analysis for aquatic resources is listed as a CDFW Species of Special Concern and a USDA Forest Service Sensitive Species. In a 1999 status review, NMFS determined that the Southern Oregon/California Coasts ESU did not warrant ESA listing (Johnson et al. 1999). Coastal cutthroat trout are distributed primarily within smaller tributaries to the 22 miles of the Klamath River mainstem upstream of the estuary (NRC 2004), but also within tributaries to the Trinity River (Moyle et al. 1995).

Coastal cutthroat trout have not been extensively studied in the Klamath Basin, but it has been noted that their life history is similar to fall- and winter-run steelhead in the Klamath River (NRC 2004). Both resident and anadromous life histories are observed in coastal cutthroat trout in the Klamath Basin. Anadromous adults enter the river to spawn in the fall. Moyle (2002) noted that upstream migration in northern California spawning streams tends to occur from August to October after the first substantial rain. Generally, spawning of anadromous and resident coastal cutthroat trout may occur from September to April (Moyle 2002). “Sea-run” adults spend some time in the ocean without fully adopting a fixed anadromous life history may either return to rivers in summer to feed or return in September or October to spawn and/or possibly overwinter (NRC 2004). Cutthroat with a resident life history remain in freshwater for their entire lives and may use mainstem and/or tributary habitats.

Juvenile coastal cutthroat trout may spend anywhere from one to three years in freshwater to rear. Anadromous or sea-run juveniles outmigrate during April through June, at the same time as Chinook salmon juvenile downstream migration (Moyle 2002, NRC 2004). These juveniles also appear to spend at least some time rearing in the estuary. Wallace (2004) found that estuary residence time ranged from 5 to 89 days, with a mean of 27 days, based on a mark-recapture study.

Pacific Lamprey

Pacific lamprey are the only anadromous lamprey species in the Klamath Basin. Pacific lamprey, along with three other lamprey species found in California, Oregon, Washington and Idaho, were petitioned for ESA listing in 2003 (Nawa 2003). Although the USFWS halted species status review in December 2004 due to inadequate information (USFWS 2004), efforts to resume the review Pacific lamprey are anticipated as more information is obtained. Although no historical abundance data are available, recent estimates are that there are annual runs of over 4,000 Pacific lamprey in the Klamath Basin (Goodman and Reid 2012, Table 3.3-2).

Pacific lamprey are found in Pacific Ocean coast streams from Alaska to Baja California. They occur throughout the mainstem Klamath River downstream from Iron Gate Dam and its major tributaries including: Trinity, Salmon, Shasta, and Scott River basins (Stillwater Sciences 2009a). Although the evidence is inconclusive as to whether Pacific lamprey were historically present upstream of Iron Gate Dam, the record of evidence shows that access to habitat would benefit Pacific lamprey by providing additional spawning and rearing grounds (NMFS 2006a). Pacific lamprey are capable of migrating long distances and show similar distributions to anadromous salmon and steelhead (Hamilton et al. 2005).

Pacific lamprey are anadromous nest builders that die shortly after spawning. They enter the Klamath River on their own volition during all months of the year, with peak upstream migration occurring from December through June (Stillwater Sciences 2009a) (Table 3.3-8, life history timing detailed in Appendix E.3.1.5). As adults, Pacific lamprey do not feed in freshwater. Spawning occurs at the upstream edge of riffles in sandy gravel from mid-March through mid-June (Stillwater Sciences 2009a). After lamprey eggs hatch, the larvae (ammocoetes) drift downstream to backwater areas and burrow into the substrate, feeding on algae and detritus (FERC 2007). Based on observations and available habitat, most ammocoete rearing likely occurs in the Salmon, Scott, and Trinity rivers, as well as throughout the mainstem Klamath River from Iron Gate downstream to the estuary (FERC 2007). The Klamath River upstream of the Shasta River appears to have less available spawning and rearing habitat, and Pacific lamprey are not regularly observed there (FERC 2007). Juveniles remain in freshwater for five to seven years (with slower growing individuals leaving at older ages) before they migrate to the ocean and transform into adults (Moyle 2002). Pacific lamprey spend one to three years in the marine environment (with no documented cause of variability in marine residency), where they parasitize a wide variety of ocean fishes, including Pacific salmon, flatfish, rockfish, and pollock (Close et al. 2010). For more species information see Close et al. (2010), Stillwater Sciences (2009a), and PacifiCorp (2004a).

Major factors believed to be affecting their populations include barriers to upstream migration at dams, dewatering of larval habitat through flow regulation, stranding due to rapid downramping, reduced larval habitat by increasing water velocity and/or reducing sediment deposition areas when sediment is trapped at dams, and mortality due to exposure to contaminants in the larval stage (Close et al. 2002, as cited in Hamilton et al. 2011).

<u>Green Sturgeon</u>

Green sturgeon are an anadromous species that occurs in coastal marine waters from Mexico to the Bering Sea. NMFS has identified two DPSs: (1) the Northern Green Sturgeon DPS, which is not listed as threatened or endangered but is on NMFS' Species of Concern list and which includes populations spawning in coastal watersheds from the

Eel River north, and (2) the Southern Green Sturgeon DPS, listed as threatened under the federal ESA and encompassing coastal or Central Valley populations spawning in watersheds south of the Eel River (NMFS 2006b). Although the Southern Green Sturgeon DPS is considered a separate population from the Northern Green Sturgeon DPS based on genetic data and spawning locations, their ranges outside of the spawning season tend to overlap (CDFG 2002b, Israel et al. 2004, Moser and Lindley 2007). The Klamath Basin may support most of the spawning population of Northern Green Sturgeon DPS (Adams et al. 2002). Although Southern Green Sturgeon DPS may enter other west coast estuaries to feed in the summer and fall, there has been no documentation of them entering the Klamath River or its estuary (USBR 2010). No Northern Green Sturgeon DPS tagged by the Yurok Tribe within the Klamath River have ever been detected in the range of Southern Green Sturgeon DPS (primarily San Francisco Bay) despite the presence of numerous receivers that would have detected tagged Klamath River fish if they had ventured there (McCovey 2011a). No Southern Green Sturgeon DPS tagged in the Sacramento/San Joaquin and/or San Francisco Bay region have ever been detected in the Klamath River. Southern Green Sturgeon DPS have been detected immediately offshore of the Klamath River, but have not been detected in the Klamath River Estuary or mainstem despite the presence of functioning acoustic receivers in the Klamath River Estuary (McCovey 2011a). Based on the available evidence it appears unlikely that sturgeon from the Southern Green Sturgeon DPS currently occur within the Klamath River or nearshore environment. Therefore, the rest of this section pertains only to the Northern Green Sturgeon DPS.

Northern Green Sturgeon DPS in the Klamath River sampled during their spawning migration ranged in age from 16 to 40 years (Van Eenennaam et al. 2006). It is believed that in general green sturgeon have a life span of at least 50 years, and spawn every four years on average after around age-16, for approximately eight spawning efforts in a lifetime (Klimley et al 2007). Green sturgeon enter the Klamath River to spawn from March through July (Table 3.3-9). Green sturgeon spawn primarily in the lower 67 miles of the mainstem Klamath River (downstream from Ishi Pishi Falls, directly upstream of the confluence with the Salmon River), in the Trinity River, and occasionally in the lower Salmon River (KRBFTF 1991, Adams et al. 2002, Benson et al. 2007). Most green sturgeon spawning occurs from the middle of April to the middle of June (NRC 2004). After spawning, approximately 25 percent of green sturgeon migrate directly back to the ocean (Benson et al. 2007), and the remainder hold in mainstem pools in the Klamath River between RM 13 and RM 66.3 through November prior to migrating downstream to the ocean. Table 3.3-9 illustrates the periodicity of green sturgeon in the Klamath River. Additional timing detail is provided in Appendix E.3.1.6.

Table 3.3-9. Life-history Timing of Green Sturgeon in the Klamath River Basin Downstream of Iron Gate Dam. Peak Activity is Indicated in Black.

Life Stage	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Incubation/emergence												
Rearing												
Juvenile outmigration												
Adult migration												
Spawning												
Post-spawning adult holding												

During the onset of fall rainstorms and increased river flow, adult sturgeon move downstream and leave the river system (Benson et al. 2007). Juvenile green sturgeon may rear for one to three years in the Klamath River Basin before they migrate to the estuary and ocean (NRC 2004, FERC 2007, CALFED 2007), usually during summer and fall (Emmett et al. 1991, as cited in CALFED 2007, CH2M Hill 1985, Hardy and Addley 2001).

Adult green sturgeon that have held over the summer in the Klamath River after spawning appear to migrate downstream to the ocean in conjunction with increases in discharge in the fall. Attenuation of high flows downstream from Iron Gate Dam as a result of USBR Klamath Irrigation Project operations may affect a key environmental cue used to stimulate the fall outmigration of adult green sturgeon that have remained in holding pools over the summer (Benson et al. 2007). Historically Klamath River below Iron Gate Dam was relatively responsive to discharge increases related to rainfall events, and the timing of peak flows changed significantly following implementation of USBR Klamath Irrigation Project operations on the Klamath River (Balance Hydrologics, Inc. 1996). When compared to pre- Klamath Irrigation Project operations, existing flows in October are higher and flows in late spring and summer are lower (Balance Hydrologics, Inc. 1996).

Resident Riverine Fish Species

<u>Rainbow and Redband Trout</u>

Rainbow trout exhibit a wide range of life-history strategies, including anadromous forms (steelhead, described above) and resident forms, described here. The Klamath Basin has two subspecies of rainbow trout. Behnke (1992) identifies the inland form as the Upper Klamath redband trout, *Oncorhynchus mykiss newberrii*, but considers steelhead and resident rainbow trout downstream from Upper Klamath Lake to be primarily coastal rainbow trout, *Oncorhynchus mykiss irideus*. Since construction of Copco No. 1 Dam and Iron Gate Dam, resident trout upstream of Iron Gate Dam are considered redband trout, and resident trout downstream from Iron Gate Dam are considered coastal rainbow trout (FERC 2007). Coastal rainbow trout are widely distributed downstream of Iron Gate Dam, including occasionally within the mainstem Klamath River, and predominately within every major tributary and most smaller tributaries with perennial flow as well. Their habitat requirements, sensitivities to disease and water quality are the same as those described above for steelhead. Rainbow trout are distinguished from steelhead by a life history that is limited to freshwater. Juveniles rear in mainstem and tributary habitat from two to three years before reaching sexual maturity (with faster growing individuals maturing sooner), and adults spawn in tributaries.

Behnke (2002) indicates that two distinct groups of redband trout may be in the Upper Klamath Basin: one that is adapted to lakes and another that is adapted to streams. These fish are a popular recreational fishery. The Upper Klamath Basin supports the largest and most functional adfluvial[82] redband trout population of Oregon's interior basins (Hamilton et al. 2011). In the Hydroelectric Reach, most redband trout spawning is thought to occur in Spencer and Shovel creeks. Redband trout need to migrate among habitats, mainstem, tributaries, and reservoirs to meet their life-history requirements. Redband trout are considered resistant to *C. shasta* or other diseases potentially brought upstream by anadromous fishes (Hamilton et al. 2011).

For more information on rainbow and redband trout, see USFWS (1998); USFWS (2000); Behnke (2002); Moyle (2002); NRC (2004); PacifiCorp (2004a); Starcevich et al. (2006); and Messmer and Smith (2007).

Resident Lampreys

In addition to the anadromous Pacific lamprey, described above, at least three resident species are present in the California portion of the Klamath Basin (PacifiCorp 2006, Hamilton et al. 2011):

- Northern California brook lamprey (*Entosphenus folletti*);
- Western brook lamprey (*Lampetra richardsoni*); and
- Klamath River lamprey (*Lampetra similis*).

No lamprey species are listed as threatened or endangered on either the California or Federal ESA lists (CDFW 2018a). However, all three resident species are listed in California as Species of Special Concern (Moyle et al. 2015). All resident lamprey species have a similar early life history where ammocoetes drift downstream to areas of low velocity with silt or sand substrate and proceed to burrow into the stream bottom and live as filter feeders for two to seven years (USFWS 2004). After they transform into adults, the non-parasitic species (Northern California brook lamprey, western brook lamprey) do not feed, while the parasitic Klamath River lamprey feed on a variety of fish species (FERC 2007).

Klamath River lamprey are found both upstream and downstream from Iron Gate Dam, from Spencer Creek downstream, and are common in the Lower Klamath River and the low-gradient tributaries there (NRC 2004). They are also found in the Trinity River, and in the Link River of the Upper Klamath Basin (Lorion et al. 2000, as cited in Close et al. 2010).

In the Klamath River Basin, Western brook lamprey are known to occur only in Hunter and McGarvey creeks, near the mouth of the Klamath River (Close et al. 2010). Early studies of Western brook lamprey were conducted outside of California (Moyle et al. 2015), and therefore there is no information on the life history, distribution, or abundance of this species in the Klamath River Basin prior to the construction of the Lower Klamath Project. Because they are known to occur only in streams near the mouth of the Klamath River, the effects from the existing dams would be confined to flow alteration in the mainstem, to the extent that Western brook lamprey use the mainstem for dispersal or other life history events.

[82] Life history strategy in which adult fish spawn and juveniles subsequently rear in streams but migrate to lakes for feeding as subadults and adults.

Northern California brook lamprey (also known as the Modoc brook lamprey) are found upstream of Iron Gate Dam (Close et al. 2010). They have been reported from a tributary to the Lost River in the Clear Lake Basin and are potentially also found in Fall Creek (Close et al. 2010). Moyle et al. (2015) report that Northern California brook lamprey are known to occur in Willow and Boles creeks above Clear Lake Reservoir. Northern California brook lamprey was not described as a separate species until 1976 (based on museum specimens) and was not recognized as a species by the American Fisheries Society until 2013 (Moyle et al. 2015). Therefore, there is no information on the life history, distribution, or abundance of this species prior to the construction of the Lower Klamath Project. Moyle et al. (2015) states that the only known populations are above large reservoirs, which suggests that they are isolated from other populations. Moyle et al. (2015) reports that dams and diversions on the upper Klamath River and Lost River alter downstream flows and habitats, potentially negatively affecting the downstream populations.

Cyprinids

The native blue chub (*Gila coerulea)* and tui chub (*Gila bicolor*) are both found in the Klamath Basin, including Lost River, Lower Klamath Lake, Tule Lake, and Iron Gate and Copco No. 1 reservoirs (CH2M Hill 2003). These species prefer habitat with quiet water, well-developed beds of aquatic plants, and fine sediment or sand bottoms. Although blue and tui chubs can withstand a variety of conditions including cold, clear lake water, and can also tolerate low dissolved oxygen levels, they are most often found in habitats with summer water temperatures higher than 68°F. These fish are omnivores, they feed on sediment detritus, and can play an important role in nutrient cycling through the excretion of nutrients into the water column in forms available to primary producers (e.g., phytoplankton). Both species of chub found in the Klamath Basin spawn from April through July, in shallow rocky areas in temperatures of 59 to 64.4°F (Moyle 2002). Presumably dams and diversions have benefitted both of these species by increasing the availability of its preferred warmer, low-velocity habitat.

Sculpin

Several sculpin species are found in coastal streams and rivers from Alaska to southern California. Several species of sculpin are known to occur in the California portion of Klamath River and its estuary, including Pacific staghorn (*Leptocottus armatus*), prickly (*Cottus asper*), slender (*Cottus tenuis*), sharpnose (*Clinocottus acuticeps*), coastrange (*Cottus aleuticus*), and marbled (*Cottus klamathensis*). Of these, only the marbled and slender sculpins are known to occur upstream of Iron Gate Dam (Carter and Kirk 2008). Mainstem Klamath River habitat may be important to sculpin populations as it can provide an important migration corridor from the estuary to upstream riverine reaches (White and Harvey 1999). Pacific staghorn sculpin are found predominantly in brackish waters of the estuary. Coastal populations of prickly and coastrange sculpin are generally assumed to be dependent on the estuary for part of their early life history (White and Harvey 1999). The marbled sculpin is a relatively wide-ranging species found in a variety of habitats in northern California and southern Oregon (Daniels and Moyle 1984). Marbled sculpin are found mainly in low gradient, spring-fed streams and rivers where the water temperature is less than 68°F in the summer and in habitat with fine substrate that can support beds of aquatic plants. They are typically found in 60 to 70 centimeters of water and in velocities around 23 centimeters per second (approximately 0.36 gallons per minute) (Moyle 2002). Slender sculpin were likely historically common in the Williamson, Sprague, Sycan, and Lost rivers and in Upper

Klamath Lake (Bentivoglio 1998, cited in NRC 2004). Bentivoglio (1998) collected sculpins throughout the upper basin in 1995–1996 and found slender sculpins only in the lower Williamson River and a few in Upper Klamath Lake. Little is known about the species' biological requirements (NRC 2004). Sharpnose sculpin are primarily found in marine and brackish conditions, although they can tolerate freshwater (Love 2011). As such, they are likely restricted to the Klamath River Estuary and possibly the lower mainstem Klamath River.

Lost River and Shortnose Suckers

The Lost River sucker (*Deltistes luxatus*) and shortnose sucker (*Chasmistes brevirostris*) are endemic to the Upper Klamath Basin of southern Oregon and northern California (Moyle 2002). These species share similar distribution and habitat requirements, and thus are typically managed together. The Lost River sucker and the shortnose sucker are listed as endangered under the ESA (USFWS 1988) and are endangered under CESA. A Revised Recovery Plan for the Lost River sucker and Shortnose sucker (revised recovery plan) was published in 2013 (USFWS 2013a). The final designation of critical habitat for both species was published by the USFWS on December 11, 2012 (USFWS 2012). Both species are also fully protected species under California Fish and Game Code Section 5515(a)(3)(b)(4) and (6), respectively. Under Fish and Game Code section 2081.11, take of the Lost River and shortnose suckers may be authorized for Klamath River dam removal, so long as the take will not result in jeopardy for the species, is minimized, and mitigation incorporates information from sampling efforts.

The 2013 revised recovery plan (USFWS 2013a) identifies a recovery unit for both of these species within the California portion of the Area of Analysis: the reservoirs along the Klamath River downstream of Keno Dam (including Iron Gate and Copco reservoirs), known as the Klamath River Management Unit. Populations in the Klamath River Management Unit are comprised mostly of adults (USFWS 2013a). The USFWS (2013a) recovery plan considers these populations as "sink populations", as they are not likely self-sustaining because of low recruitment due to the lack of access to spawning habitats, citing Moyle (2002), and NRC (2004). Extensive sampling was conducted by Oregon State University (Desjardins and Markle 1999) in J.C. Boyle, Copco No. 1 and Iron Gate reservoirs during 1998 and 1999 using multiple gear types (trammel nets, beach seines, cast nets, trap nets, backpack electrofishing, and otter trawls). Sampling gears, seasons and locations were selected to maximize the collection of suckers and different sucker life stages, and thus the results may not be representative of the larger fish community. Adult suckers were sampled for in 1997, 1998 and 1999 (with trammel nets), while larval and juvenile suckers were only sampled in 1998 and 1999. Over three years of study, a total of 50 shortnose sucker adults were collected in J.C. Boyle Reservoir, 165 in Copco No. 1 Reservoir and 22 in Iron Gate Reservoir. Lost River suckers were present in J.C. Boyle Reservoir and Copco No. 1 Reservoir, but at much lower numbers, with just one collected in Copco No.1 Reservoir and two in J.C. Boyle Reservoir. Larval suckers (species unknown) were more abundant with 275 collected over two years in J.C. Boyle Reservoir, 8,729 in Copco No. 1 Reservoir, and 1,177 in Iron Gate Reservoir. A total of 23 juveniles were collected in J.C. Boyle Reservoir and 3 in Copco No.1 Reservoir. In all, shortnose sucker represented 1 percent (1998) and 2 percent (1999) of the trammel net catch in J.C. Boyle Reservoir, 12 percent (1998) and 14 percent (1999) in Copco No.1 Reservoir and 0.3 percent (1998) and 2 percent (1999) in Iron Gate Reservoir. Juveniles were only a significant portion of the seine net catch in J.C Boyle Reservoir, representing 17 percent of the catch in 1998 and 9 percent in 1999. In larval trawls, sucker larvae represented only 0.2 to 5 percent of the catch in all reservoirs in 1998, but those percentages increase to 27 percent (J.C. Boyle Reservoir), 44 percent (Copco No.1 Reservoir) and 30 percent (Iron Gate Reservoir) in 1999.

To minimize and mitigate for adverse effects to both sucker species, PacifiCorp prepared an HCP for its interim operations of the Klamath Hydroelectric Project (i.e., prior to dam removal) (PacifiCorp 2013). This HCP includes the conservation strategy and measures that PacifiCorp would undertake to address anticipated effects on suckers and their habitat in the Klamath Basin. The conservation measures outlined follow a two-pronged approach: (1) manage the shutdown of East- and West-side powerhouses (which are part of the Klamath Hydroelectric Project in Oregon, see Figure 3.3-1) in such a way as to minimize effects on listed suckers, resulting in additional benefits by reducing possible entrainment, ramping events, and false attraction to powerhouse tailraces; and (2) improve habitat conditions for listed suckers by facilitating/funding specific enhancement projects, a sucker conservation fund, and the Nature Conservancy's (TNC) Williamson River Delta Restoration Project.

In the 2013 BiOp (NMFS and USFWS 2013), USFWS consulted on both sucker species. USFWS concluded that the proposed USBR Klamath Irrigation Project operations affects both Lost River and shortnose suckers. In the Klamath River Management Unit, USFWS concluded that effects of the proposed operations on both species are likely small in comparison to other effects because there are fewer suckers present in the reservoirs, so effects are primarily limited to changes in water quality (USFWS 2007).

Existing threats to the sucker populations include: the damming of rivers, instream flow diversions, hybridization (e.g., between shortnose sucker and Klamath largescale suckers [*Catostomus snyderi*]), competition and predation by exotic species, dredging and draining of marshes, water quality problems associated with timber harvest, the removal of riparian vegetation, livestock grazing, agricultural practices, and low lake elevations, particularly in drought years (USFWS 1993). Reduction and degradation of lake and stream habitats in the Upper Klamath Basin is considered by USFWS to be the most important factor in the decline of both species (USFWS 1993).

Miller and Smith (1981) claimed that sucker hybridization was most pronounced in the Lower Klamath Project reservoirs, and Markle et al. (2005) reported hybridization between small scale sucker and both Lost River and shortnose suckers in the Hydroelectric Reach. Hybridization prompted Buettner et al. (2006) and others to caution against supporting migration of individuals from Iron Gate and Copco reservoirs into the Upper Klamath Lake population.

The Lost River sucker historically occurred in Upper Klamath Lake (Williams et al. 1985) and its tributaries and the Lost River watershed, Tule Lake, Lower Klamath Lake, and Sheepy Lake (Moyle 1976). Shortnose suckers historically occurred throughout Upper Klamath Lake and its tributaries (Williams et al. 1985, Miller and Smith 1981). The present distribution of both species includes Upper Klamath Lake and its tributaries (Buettner and Scoppettone 1990), Clear Lake Reservoir and its tributaries (USFWS 1993), Tule Lake and Lost River up to Anderson-Rose Dam (USFWS 1993), and the Klamath River downstream of Iron Gate Reservoir (USFWS 1993). Shortnose suckers occur in Gerber Reservoir and its tributaries, but Lost River suckers do not.

Lost River and shortnose suckers are lake-dwelling, but spawn in tributary streams or springs (USFWS 1988). They spawn from February through May, depending on water depth and stream temperature (Buettner and Scoppettone 1990, Andreasen 1975, USFWS 2008). Spawning locations appear to be both substrate and flow dependent (although specific preferred flow velocities are unknown), with an apparent preference for gravel substrates (where eggs incubate in the interstices). When spawning occurs over cobble and armored substrate, eggs fall between crevices or are swept downstream and lost (Buettner and Scoppettone 1990). Larval Lost River and shortnose suckers spend relatively little time in tributary streams, migrating to lake habitat shortly after emergence, typically in May and early June (Buettner and Scoppettone 1990). Adults return to Upper Klamath Lake soon after spawning. Lake fringe emergent vegetation is the primary habitat used by larval suckers (Cooperman and Markle 2004). Juvenile suckers use a wide variety of habitat including near-shore areas with or without emergent vegetation and off-shore habitat (Hamilton et al. 2011).

Smallscale Sucker

The Klamath smallscale sucker (*Catostomus rimiculus*) is common and widely distributed in the Klamath River and its tributaries downstream from the city of Klamath Falls, Oregon, and in the Rogue River (Moyle 2002). They tend to inhabit deep, quiet pools in mainstem rivers and slower-moving reaches in tributaries; however, they can be found in faster-flowing habitats when feeding or breeding (Moyle 2002). McGinnis (1984) reported that this species spawns in small tributaries to the Klamath and Trinity rivers. Spawning in tributaries to has been observed from mid-March to late April (Moyle 2002). Juveniles are most commonly found in the streams that are used for spawning. The larger adults observed have been from fish measuring 18 in, and have been aged through scale analysis as being approximately 15 years old (Scoppetone 1988, as cited in Moyle (2002). Moyle (2002) speculated that dams and diversions have benefitted this species by increasing the availability of its preferred warmer, low-velocity habitat.

Electrofishing conducted by PacifiCorp and ODFW in the J.C. Boyle Peaking Reach revealed the existence of a population of smallscale suckers in moderate velocity habitat, and they were the most prevalent species in the majority of the collected samples (W. Tinniswood, pers. comm., June 2011). J.C. Boyle Dam blocks the migration of smallscale suckers to potential spawning habitat in Spencer Creek. Currently, spawning occurs in the mainstem of the Klamath River where smallscale suckers are subject to flow fluctuations that can displace their broadcast spawning[83] or strand and dry the eggs during power peaking[84] operations (Dunsmoor 2006). Electrofishing in Jenny Creek revealed adult smallscale suckers occupying deep, moderate-velocity habitat among boulders (W. Tinniswood, pers. comm., June 2011).

Non-native Fish Species

Introduced non-native fish species threaten the diversity and abundance of native fish species through competition for resources, predation, interbreeding with native populations, and causing potential physical changes to the invaded habitat (Moyle 2002). Non-native fish species occurring within the Area of Analysis are described below, including descriptions of interactions with native fish species.

[83] Broadcast spawning takes place when suckers release their eggs and sperm into the water, where fertilization occurs externally.
[84] Power peaking is rapid changes in flow associated with hydropower generation.

Yellow Perch

Yellow perch (*Perca flavescens*) prefer weedy rivers and shallow lakes. They are found in reservoirs and ponds along the Klamath River, and are a popular recreational fishery. Optimal temperature for growth is between 71.6 and 80.6°F but yellow perch can survive in temperatures up to 86 to 89.6°F. They can also survive low levels of dissolved oxygen (less than one milligram per liter [mg/L]) but are most abundant in areas with low turbidity, as they are visual feeders. Larval and juvenile yellow perch feed on zooplankton; adults are opportunistic predators that may feed on larger invertebrates and small fish, including younger yellow perch, white bass, and smelt (Knight et al. 1984); and may also prey on larval suckers (USFWS 1993). The preferred habitat of the yellow perch includes large beds of aquatic plants for spawning and foraging; habitat that is common in Lower Klamath Project reservoirs. Their spawning takes place in 44.6 to 66.2°F water in April and May and usually occurs in their second year (Moyle 2002).

Bass and Sunfish

Several species of bass (*Micropterus* spp.) and sunfish (*Lepomis* spp.) have been introduced into the Klamath Basin, including largemouth bass, white and black crappie, bluegill, pumpkinseed, and green sunfish. All are a popular recreational fishery, especially the bass species. Largemouth bass and sunfish prefer lakes, ponds, or low-velocity habitat in rivers, and are mostly found in Lower Klamath Project reservoirs upstream of Iron Gate Dam. They prefer habitats with aquatic vegetation and will spawn in a variety of substrates. They prefer water temperatures above 80.6ºF. Juvenile and adult largemouth bass tend to feed on larger invertebrates and fish (Moyle 2002), potentially including suckers (USFWS 1993). Smaller members of the family, such as sunfish, are opportunistic feeders and eat a variety of aquatic insects, fish eggs, and planktonic crustaceans (Moyle 2002).

Catfish

Several species of catfish have been introduced into the Klamath Basin, including channel catfish (*Ictalurus punctatus*), black bullhead (*Ameiurus melas*), brown bullhead (*Ameiurus nebulosus*), and yellow bullhead (*Ameiurus natalis*) (NRC 2004). Catfish prefer slow moving, warm water habitat. Brown bullhead (*Ameiurus nebulosus*) can tolerate a wide range of salinities and live at temperatures of 32 to 98.6°F, but their optimum temperature range is 68 to 91.4°F. Brown bullhead are most active at night and form feeding aggregations. Catfish are opportunistic omnivores and scavenge off the bottom of their habitat (Moyle 2002).

Trout

Brook trout (*Salvelinus fontinalis)* is an introduced species in the Upper Klamath Basin within the California portion of the Area of Analysis (FERC 2007) found in clear, cold lake and stream habitats. They prefer temperatures between 57.2 and 66.2°F but can survive in temperatures ranging from 33.8 to 78.8°F. Brook trout feed predominantly on terrestrial insects and aquatic insect larvae, though they may also opportunistically feed on other types of prey such as crustaceans, mollusks, and other small fish. Brook trout spawn in the fall and prefer habitats with small-sized gravel and nearby cover (Moyle 2002).

Brown trout (*Salmo trutta*) have also been introduced to the Klamath River and are found in both the Upper and Lower Klamath Basin. Brown trout prefer clear, cold water and can utilize both lake and stream habitats. Like brook trout, they spawn in the fall in streams with areas of clean gravel. Brown trout become piscivorous (fish eaters) once they reach a size where their gape can accommodate small fish available as prey.

American Shad

American shad are an introduced, anadromous fish species found in the Klamath River downstream of Ishi Pishi Falls, and are a popular sport fish. They feed primarily on plankton, mostly mysids and copepods, and occasionally on small fishes such as smelt. Adult American shad spend three to six years in the ocean before returning to spawn in the Klamath River (Pearcy and Fisher 2011). The preferred spawning habitat of the American shad includes sandy or pebbly substrate, water temperatures between 59 and 64.4°F, and where water velocities are less than 0.7 m/s (approximately 2.3 feet per second) (Moyle 2002).

Estuarine Species

The estuary is the mixing zone for freshwater and saltwater from the ocean. The balance of freshwater to saltwater changes over the course of the day with tides and is also strongly influenced by river flows. Due to this, both marine and freshwater species can often be found in different portions of the estuary at various times. All anadromous fish pass through the estuary during their migrations from freshwater to the ocean and back again, and salmonid smolts may rear in the estuary for varying periods of time, prior to moving into the ocean. Surveys in the freshwater portion of the estuary commonly find Klamath speckled dace (*Rhinichthys osculus klamathensis*), Klamath smallscale sucker (*Catostomus rimiculus*), prickly sculpin, and Pacific staghorn sculpin. Other fairly common species include northern anchovy (*Engraulis mordax*), saddleback gunnel (*Pholis ornate*), and bay pipefish (*Syngnathus leptorhyncus*). Other species in the estuary include federally-listed eulachon, state-listed longfin smelt (*Spirinchus thaleichthys*) (described below), non-native Mississippi silversides (*Menidia beryllina*), surf smelt (*Hypomesus pretiosus*), three-spined stickleback (*Gasterosteus aculeatus*), and several species of gobies. Impacts to the estuarine species were assessed based on effects on specific sensitive species such as eulachon and EFH for groundfish and pelagic fish, as described in the Essential Fish Habitat subsection of Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*.

Eulachon

Eulachon is an anadromous fish that occurs in the lower portions of certain rivers draining into the northeastern Pacific Ocean, ranging from northern California to the southeastern Bering Sea in Bristol Bay, Alaska (McAllister 1963, Scott and Crossman 1973, Willson et al. 2006, as cited in NMFS 2010b). The Yurok Tribe consider eulachon a “Tribal Trust Species,” and the fish has major cultural significance (Larson and Belchik 1998). The southern population of Pacific eulachon consists of populations spawning in rivers south of the Nass River in British Columbia, Canada, to and including the Mad River in California (NMFS 2009a). On March 18, 2010, NMFS listed the southern DPS of eulachon as threatened under the ESA (NMFS 2010b). Final critical habitat was designated in October of 2011 and includes the Klamath River Estuary (NMFS 2011). NMFS has issued a draft recovery plan (NMFS 2016b) and has formed a Eulachon Recovery Team to support recovery planning.

Historically, the Klamath River was described as the southern limit of the range of eulachon (Gustafson et al. 2010). Other accounts have described large spawning aggregations of eulachon occurring regularly in the Klamath River (Fry 1979, Moyle et al. 1995, Larson and Belchik 1998, Moyle 2002, Hamilton et al. 2005), and occasionally in the Mad River (Moyle et al. 1995, Moyle 2002) and Redwood Creek in Humboldt County (Moyle et al. 1995). In addition, small numbers of eulachon have been reported from the Smith River (Moyle 2002). The only reported commercial catch of eulachon in northern California occurred in 1963 when a combined total of 25 metric tons (56,000 lbs) was caught from the Klamath River, the Mad River, and Redwood Creek (Odemar 1964). Since 1963, the run size has declined to the point that only a few individual fish have been caught in recent years. Moyle (2002) indicates that eulachon have been scarce in the Klamath River since the 1970s, with the exception of three years: they were plentiful in 1988, 1989, and 1998. After 1998, eulachon were thought to be extinct in the Klamath Basin until a small run was observed in the estuary in 2004. According to accounts of Yurok Tribal elders, the last noticeable runs of eulachon were observed in the Klamath River in 1988 and 1989 by Tribal fishermen (Larson and Belchik 1998).

Larson and Belchik (1998) reported that eulachon have not been of commercial importance in the Klamath since the 1980's. However, in January 2007, six eulachon were reportedly caught by tribal fishermen on the Klamath River. Another seven were captured between January and April of 2011 at the mouth of the Klamath River (McCovey 2011b). More recently, 40 adult eulachon were captured in spring 2012 (McCovey 2012), and 112 in spring 2012 (McCovey and Walker 2013) by Yurok Indian tribal biologists in presence/absence surveys, using seines and dip nets in the Klamath River.

According to the 2016 status review update of southern DPS eulachon (Gustafson et al. 2016), adult spawning abundance of the southern DPS of eulachon has increased since the listing occurred in 2010. A number of data sources indicate that eulachon abundance in some subpopulations within the southern DPS was substantially higher in 2011 through 2015 compared to indications of very low abundance in 2005 through 2010. The improvement in estimated abundance in the Columbia, Naselle, Chehalis, Elwha, and Klamath rivers, relative to the time of listing, reflects both changes in biological status and improved monitoring (Gustafson et al. 2016).

Historically, eulachon runs in northern California were said to start as early as December and January and peak in abundance during March and April. Large numbers of eulachon migrated upstream in March and April to spawn, but they rarely moved more than eight miles inland (NRC 2004). Eulachon spawn at an age of three to five years, and usually die after spawning (Larson and Belchik 1998). Spawning occurs in gravel riffles, with hatching about a month later. The larvae generally move downstream to the estuary following hatching (Larson and Belchik 1998).

Longfin Smelt

Longfin smelt are a state-listed threatened species and a CDFW Species of Special Concern throughout their range in California. The USFWS denied the petition for federal listing because the population in California (and specifically San Francisco Bay) was not believed to be sufficiently genetically isolated from other populations (USFWS 2009). This species generally has a two-year lifespan, although three-year-old fish have been observed (Moyle 2002). They typically live in bays and estuaries and have sometimes been observed in the nearshore ocean from San Francisco Bay to Prince William Sound, Alaska, including the Klamath River. Longfin smelt prefer salinities of 15 to 30 parts per thousand (ppt), although they can tolerate salinities from freshwater to full seawater. They prefer temperatures of 60.8 to 64.4°F and generally avoid temperatures higher than 68°F. Longfin smelt may occur in the Klamath River throughout the year. They would only be expected to use the estuary, the lowest reaches of the river, and infrequently in the Pacific Ocean nearshore. Longfin smelt spawning occurs primarily from January to March, but may extend from November into June, in fresh or slightly brackish water over sandy or gravel substrates. Temperatures during spawning in the San Francisco estuary are 44.6 to 58.1°F. Embryos hatch in approximately 40 days in 44.6°F water temperature (approximately 25 days in 51°F water) and are quickly swept downstream by the current to more brackish areas. The importance of ocean rearing is unknown. Longfin smelt were common in the Klamath River Estuary during 1978–1989, but the population has significantly declined since. In 1992, two were found in the Klamath River Estuary, and in 2001 only one adult longfin smelt was collected (CDFG 2009).

Freshwater Mollusks

While life history traits of individual species of freshwater mussels have not been fully studied, the general life cycle is as follows. Eggs within female freshwater mussels are fertilized by sperm that is brought into the body cavity. From April through July thousands of tiny larvae, called glochidia, are released into the water where they must encounter a host fish for attachment within hours, otherwise they perish (Haley et al. 2007). Most juvenile freshwater mussels from these species drop off the fish hosts to settle from June to early August. The juvenile freshwater mussels spend an undetermined amount of time buried in the sediment where they grow to the point where they can maintain themselves at or below the substrate surface in conditions that are optimal for filter feeding (Nedeau et al. 2009). Freshwater mussels are fed upon by muskrats, river otters, and sturgeon (Nedeau et al. 2009). They are also a food of cultural significance for the Karuk Tribe (Westover 2010) and The Klamath Tribes. Adult freshwater mussels are generally found wedged into gravel rock substrate or partially buried in finer substrates, using a muscular foot to maintain position. Freshwater mussels filter feed on plankton and other organic material suspended in the water column.

Four species of native freshwater mussels have been observed within the Klamath Basin (FERC 2007, Westover 2010). PacifiCorp surveys conducted in 2002 and 2003 found Oregon floater (*Anodonta oregonensis*), California floater (*Anodonta californiensis*) and western ridged mussel (*Gonidia angulata*) along Klamath River reaches from the Keno Impoundment/Lake Ewauna to the confluence of the Klamath and Shasta rivers. Westover (2010) also found western pearlshell mussel (*Margaritifera falcata*) in addition to these species along the Klamath River from Iron Gate Dam to the confluence of the Klamath and Trinity rivers. Byron and Tupen (2017) surveys also conducted during in 2002 and 2003 upstream of Iron Gate Dam documented Oregon floater and western ridged mussel in the Keno Reach, Oregon floater in the J.C. Boyle Peaking Reach, and both species in the mainstem Klamath River between Copco No. 2 Reservoir and J.C. Boyle Dam.

Downstream of Iron Gate Dam, Davis et al. (2013) found that *Anodonta sp.* occurred only in the farthest upstream survey sites; western ridged mussel was present in most reaches and often at high densities, and western pearlshell mussel was present in high numbers downstream of the confluence with the Salmon River. All surveyed mussel populations declined in abundance with increasing distance downstream of Iron Gate Dam, due to more mobile substrate. The Shasta River was the only tributary to the Klamath River with Oregon floater, California floater, and western ridged mussel all detected. Western ridged mussel and western pearlshell mussel were more common in reaches farther downstream in the Klamath River from Iron Gate Dam, probably due to thicker shells which allow them to withstand scouring in high flow events.

A full understanding of western ridged mussels former and current distribution is difficult to assemble due to the lack of data, but it is believed to have been extirpated in central and southern California and has probably declined in many other watersheds, including the Columbia and Snake River basins (Jepsen et al. 2010). The Klamath River appears unusual in that western ridged mussels dominates its mussel community, unlike other rivers in the Pacific Northwest (Westover 2010).

Western pearlshell mussels have also been observed within the Klamath Basin downstream from Iron Gate Dam, though in lesser abundance than other mussel species (Westover 2010). Western pearlshell mussels occupies habitats with low water velocity (e.g., pools and near banks) and pockets within bedrock and cobble (Howard and Cuffey 2003).

Anodonta spp. (commonly referred to as “floaters”) are more tolerant of lake conditions than other native mussel species (Nedeau et al. 2005), and have been observed in Lower Klamath Project reservoirs. Floaters are also more tolerant of siltier substrates, as their thin shells allow individuals to “float,” or rest on top of silt-dominated streambeds. Byron and Tupen (2017) found that low-energy areas where finer sediments accumulate and where hydrology is consistent were most suitable for *Anodonta spp.*

Western ridged mussels are the largest and most common type of freshwater mussel found within the Klamath Basin (Nedeau et al. 2005). They are known to prefer cold, clean water, but can tolerate seasonal turbidity, and can be found in aggrading, or depositional areas as it can partially bury itself within bed sediments without affecting filter feeding (Vannote and Minshall 1982, Westover 2010). Byron and Tupen (2017) found that they appeared to prefer faster waters and, consequently, coarser substrates such as medium- and coarse sands. Even areas with boulder and bedrock substrates had pockets of finer materials in which *G. angulata* were aggregated. Commonly, *G. angulata* were found buried to depths of 15 centimeters and often stacked atop one another. In general, *G. angulata* were always buried at least 80 percent, with only the tops of shells visible (Byron and Tupen 2017). Known fish hosts of juvenile *G angulata* include hardhead (*Mylopharodon conocephalus*), Pit sculpin (*Cottus pitensis*), and tule perch (*Hysterocarpus traski*), but a full list of host fish species for western ridged mussels are unknown (Jepsen et al. 2010). However, Mageroy (2016) found that *G. angulata* hosts in Canada included primarily sculpin species (*Cottus* spp.) but that northern pikeminnow (*Ptychocheilus oregonensis*), leopard dace (*Rhinichthys falcatus*), and longnose dace (*Rhinichthys cataractae*) are potential hosts as well. Therefore, it appears that the species has significant range of hosts.

Seven to eight species of fingernail clams and peaclams (Family: Sphaeriidae) were also found in the Hydroelectric Reach and from Iron Gate Dam to Shasta River during re-licensing surveys (FERC 2007). One of the clam species, the montane peaclam (*Pisidium ultramontanum)*, has special status as a federal species of concern and a USDA Forest Service Sensitive Species. The montane peaclam is generally found on sand-gravel substrates in spring-influenced streams and lakes, and occasionally in large spring pools. The historic range included the Klamath and Pit rivers in Oregon and California, as well as some of the larger lakes (Upper Klamath, Tule, Eagle, and possibly, Lower Klamath lakes) (FERC 2007). On USDA Forest Service lands they are currently present or suspected in streams and lakes of Lassen and Shasta-Trinity National Forests. Fingernail clams and peaclams are relatively short-lived (one to three years) compared to freshwater mussels (typically 10 to 15 years although in some cases 100 or more years for some species). These small clams live on the surface or buried in the substrate in lakes, ponds or streams. They bear small numbers of live young several times throughout the spring and summer (Thorp and Covich 2001).

There are also many species of freshwater snails, some of which are endemic to the Klamath Basin and have restricted ranges, often associated with cold-water springs. Several of these have recently been petitioned for listing. Based on their restricted distribution to areas outside of Klamath River reaches that could be affected by the Proposed Project, no further analysis was undertaken for freshwater snails for this EIR.

Benthic Macroinvertebrates

Benthic macroinvertebrates (BMI) are small aquatic animals and the aquatic larval stages of insects. They lack a backbone, are visible with the naked eye and are found in and around water bodies during some period of their lives. BMI include immature, aquatic stages of insects such as midges, mayflies, caddisflies, stoneflies, dragonflies, and damselflies. They also include immature and adult stages of aquatic beetles; crustaceans such as crayfish, amphipods and isopods ; clams and snails; aquatic worms; and other major invertebrate groups. Many BMI are the primary consumers in riverine food webs, feeding on primary producers—algae, aquatic plants, phytoplankton, bacteria, as well as leaves and other organic materials from terrestrial plants, and detritus. By converting organic material into biomass available to a wide variety of consumers, these organisms form an important component of the aquatic food web. Some BMI are secondary consumers, feeding on the primary consumers. BMI are the primary food source for most freshwater fish species, and therefore, changes in abundance, distribution, or community structure can affect fish populations. BMI are also used as general indicators of water quality. This is assessed based upon the relative abundance or diversity of each group (taxa) and their tolerance of water quality impairment or habitat degradation. BMI are also particularly sensitive to changes in fine and coarse sediment, which would occur during the Proposed Project. A diminished food supply can limit growth of salmonids, and this is especially true at higher temperatures because as water warms, a fish’s metabolic rate increases and it needs more food to sustain growth (Brett 1971, McCullough 1999). Growth is critical to juvenile salmonids because a larger size fish often has a survival advantage during the overwintering period, smolt outmigration, and ocean residence. If fish are chronically exposed to warm water temperatures and food availability is low, growth rates are reduced and fish experience physiological stress, often resulting in increased mortality from disease, parasites, and predation. However, in a productive system with high densities of BMI or forage fish, a high rate of growth can be sustained at temperatures higher than would be considered optimal under conditions where food is limiting.

Relicensing studies for PacifiCorp’s Klamath Hydroelectric Project evaluated BMI populations in the Klamath River from Link River Dam to the Shasta River and within Fall Creek in 2002 and 2003 (FERC 2007). These studies show that BMI are abundant, with typical densities of 4,000 to 8,000 individuals per square meter. BMI densities in the fall of 2002 ranged from approximately 2,200 per square meter in the Copco No. 2 Bypass Reach of the Klamath River to approximately 21,600 per square meter below Keno Dam (FERC 2007). Abundance of BMI in both the J.C. Boyle Peaking Reach of the

Hydroelectric Reach and the Middle Klamath River downstream of Iron Gate Dam was as low as approximately 500 per square meter in the spring of 2003. The Lower Klamath Project reservoirs had high abundance of BMI, but low diversity, and were dominated by species tolerant of impaired water quality conditions.

The Yurok Tribe conducted studies in 2005 and 2008 (Burks and Cowan 2007) evaluating the biological community of the Klamath River within the Yurok Indian Reservation (RM 0 to RM 43.3) through BMI surveys. Data collected during these studies were used to calculate an Index of Biological Integrity (IBI)—composite scores generated by assigning values to variables, such as species richness, percent intolerant individuals, percent predator individuals, and others.

The Index of Biological Integrity values generated in 2005 indicated that two of the nine sites on the Klamath River within the Yurok Indian Reservation were in the “impaired” range (i.e., score of 52 or below), and the majority of the other sites were in “fair” condition (i.e., score of 53 to 60) (Burks and Cowan 2007). In 2008, the Index of Biological Integrity values suggested a slight improvement in stream health, with the majority of sites scoring in the “good” range (i.e., score of 61 to 80) (Sinnott and Hanington 2008).

Marine Mammals

Pinnipeds (seals and sea lions), and Southern Resident Killer Whales potentially occur within the Pacific Ocean nearshore environment, off Northern California. Redwood National Park lists harbor seals (*Phoca vitulina richardsi*), California sea lions (*Zalophus californianus*), Steller sea lions (*Eumetopias jubatus*), and Northern elephant seals (*Mirounga angustirostris*) as occurring at least seasonally in the vicinity of the Klamath River Estuary. Elephant seal diets consist primarily of rays, sharks, pelagic squid, ratfish, and Pacific hake, and are not expected to consume salmonids, but other pinnipeds and Southern Resident Killer Whales may feed on adult salmon from the Area of Analysis. In particular, pinnipeds are a documented predator within the Klamath River Estuary and nearshore environment. During radio telemetry studies, Strange (2007a, 2007b, 2008) found that between 14 and 33 percent of tagged Chinook salmon were consumed by pinnipeds (primarily California sea lions). However, the Chinook salmon tagged in those studies were disoriented and potentially fatigued as a result of being captured, anesthetized, and handled, and were therefore more vulnerable to predation. In these studies, most of the observed predation occurred within minutes to hours of release.

In a study of pinniped predation in the Klamath River Estuary using visual observations in August through mid-November 1998 (Williamson and Hillemeir 2001), approximately 3,077 adult salmon were consumed (including fall-run Chinook salmon, spring-run Chinook salmon, coho salmon, and steelhead). Most predation was on fall-run Chinook salmon (2,559 consumed) and was equivalent to 2.6 percent of the estimated fall-run Chinook salmon run that year. An estimated 438 spring-run Chinook, 63 coho salmon, and 110 steelhead were also consumed. California sea lions were the primary predator, and Pacific harbor seals, and Steller sea lions were also observed feeding upon salmonids. Efforts such as “seal bombs” have been used to reduce pinniped predation on salmonids in the estuary, but have not been observed to be effective (Strange 2008).

Southern Resident Killer Whale

The Southern Resident Killer Whale (*Orcinus orca*) DPS is listed as endangered under the ESA (NMFS 2005). This DPS primarily occurs in the inland waters of Washington State and southern Vancouver Island, although individuals from this population have been observed off coastal California in Monterey Bay, near the Farallon Islands, and off Point Reyes (Heimlich-Boran 1988, Felleman et al. 1991, Olson 1998, Osborne 1999, NMFS 2005). Survival and fecundity of Southern Resident Killer Whales are correlated with Chinook salmon abundance (Ward et al. 2009, Ford et al. 2009). Hanson et al. (2010) found that Southern Resident Killer Whale stomach contents included several different ESUs of salmon, including Central Valley fall-run Chinook salmon, but none from the Klamath River Basin. More recent studies have confirmed that salmon from the Klamath River are consumed, although in small numbers (Hanson 2015). During most of the year Southern Resident Killer Whale are present in Washington inland waters where their diet consists primarily of Chinook salmon. During occasional and short-duration winter visits to the California Coast their diet is primarily chum, Chinook and coho salmon, augmented with smaller numbers of steelhead and sockeye (Hanson 2015). No data are available to determine the contribution of salmon from the Klamath River Basin to their overall diet, but it is believed to be small (<1 percent) on an annual basis given the work of Hanson et al. (2010) and Hanson (2015).

3.3.2.2 Physical Habitat Descriptions

Upper Klamath River and Connected Waterbodies

Aquatic habitat in the Upper Klamath Basin includes both lacustrine (lake) and riverine (river) habitats and large thermally stable coldwater springs. The Upper Klamath River upstream of Iron Gate Dam once supported large populations of anadromous salmon and steelhead by providing spawning and rearing habitat (Hamilton et al. 2005, Butler et al. 2010, Hamilton et al. 2016), as discussed in detail in Section 3.3.5.8 *Aquatic Habitat*.

Upper Klamath Lake is the most prominent feature in this part of the basin, although other lakes and reservoirs are also present. Lake Ewauna, another lake on the Klamath River mainstem, is formed by Keno Dam, which regulates water surface elevations in the impoundment to facilitate agricultural diversions. Lake Ewauna connects to Upper Klamath Lake via the Link River.

Upper Klamath Lake and Lake Ewauna are affected by poor water quality conditions. During the summer months, these waterbodies exhibit episodic high pH, broad daily shifts in dissolved oxygen, and elevated ammonia concentrations (Hamilton et al. 2011). In Upper Klamath Lake several incidents of mass adult mortality of shortnose and Lost River sucker have been associated with low dissolved oxygen levels (Perkins et al. 2000, Banish et al. 2009). Instances of pH levels above 10 and extended periods of pH levels greater than nine lasting for several weeks are associated with large algal blooms occurring in the lake (Kann 2010). On a diel (i.e., 24-hour) basis, algal photosynthesis can elevate pH levels during the day, with changes exceeding two pH units over a 24-hour period. During November through April, pH levels in Upper Klamath Lake are near neutral (Aquatic Scientific Resources 2005).

Implementation of the Proposed Project would result in the reintroduction of anadromous fish into Upper Klamath Lake and Lake Ewauna and their tributary streams. Fish passage over Link Dam is provided by a ladder. This ladder is designed to modern standards to allow the passage of shortnose and Lost River suckers and other migratory fish, including resident and anadromous salmonids and Pacific lamprey, if present. Keno Dam is equipped with a 24-pool weir and orifice type fish ladder, which rises 19 feet over a distance of 350 feet, designed to pass trout and other resident fish species (FERC 2007). The fishway at Keno Dam currently complies with passage criteria for salmonid fish. Although Lost River and shortnose suckers (in addition to other sucker species), have been observed to use the Keno Dam fish ladder, the ladder was not designed for sucker passage and is considered generally inadequate for sucker passage (USBR 2002). Plans are being developed to have the fishway rebuilt to criteria for suckers, lamprey, and for larger anadromous salmonid runs (T. Reaves Gilmore, USBR, pers. comm., October 2018).

The Williamson and Wood rivers are the largest and second largest tributaries to Upper Klamath Lake, respectively. The Sprague River is tributary to the Williamson River, and the Sycan River is tributary to the Sprague River (Hamilton et al. 2011). These tributaries currently provide habitat for redband trout, bull trout, shortnose sucker and Lost River sucker, as well as other species. Historically these tributaries provided substantial habitat for Chinook salmon and steelhead (Hamilton et al. 2005, 2016). Important flow contributions from springs into these tributaries provide cool summer baseflows with water temperatures and dissolved oxygen levels generally adequate to support coldwater fish habitat requirements (Hamilton et al. 2011).

Upper Klamath River – Hydroelectric Reach

The Hydroelectric Reach, from the upstream extent of J.C. Boyle Reservoir to Iron Gate Dam, includes four reservoirs (J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate) and two riverine reaches. Several coldwater tributaries enter the Klamath River and reservoirs in this reach. The reservoirs are productive and nutrient rich and tend to have warm surface waters during the summer months, with mean daily temperatures sometimes reaching 73ºF (FERC 2007). During the late spring/early summer, water quality in Copco No. 1 and Iron Gate reservoirs declines, becoming quite poor due to warm surface waters and annual blooms of the blue-green algae species *Aphanizomenon flow-aquae, Anabaena flos-aquae,* and *Microcystis aeruginosa* (see also Section 3.4 *Phytoplankton and Periphyton*). *Microcystis aeruginosa,* and to an unknown extent *Anabaena flos-aquae,* produce toxins that can be harmful to fish and other animals and humans. Routine sampling from areas frequented by recreational users of the reservoirs has documented cell counts up to 4,000 times greater than what the World Health Organization considers a moderate health risk (see Section 3.4 *Phytoplankton and Periphyton*). This has resulted in Copco No. 1 and Iron Gate reservoirs being posted with health advisory warnings against human and animal contact with the water by local health officials every summer since 2005.

The 21-mile long riverine reach between J.C. Boyle and Copco No. 1 reservoirs is divided into two reaches: the 4.6-mile long J.C. Boyle Bypass Reach, which receives bypass flows from J.C. Boyle Dam, and the 17-mile long Peaking Reach, which receives variable flow from hydroelectric operations (see also Section 2.3.1 *J.C. Boyle Dam and Associated Facilities*). The downstream 6.2 miles in California is designated by CDFW as a Wild Trout Area with the whole reach managed by CDFW for wild trout, including angling restrictions and reduced stocking, and habitat enhancements targeted for native trout (CDFG 2005). The reach from the J.C. Boyle Powerhouse to the Oregon-California state line is designated as a National Wild and Scenic River. Approximately 100 cubic feet per second (cfs) is released from J.C. Boyle Dam to the Bypass Reach through a minimum flow outlet and the fish ladder. This is augmented by inflows from Big Springs of about 220 to 250 cfs (FERC 2007). In the Peaking Reach, this flow is added to flows from the powerhouse, which can range from zero to over 3,000 cfs, depending on operations (FERC 2007). Peaking operations can occur daily, or cycles may extend over several days, depending on water availability, power demands, and whitewater boating needs. The 1.4-mile Copco No. 2 Bypass Reach has flows of about 5 cfs provided by Copco No. 2 Dam. Both of these riverine reaches provide complex physical habitat suitable for salmonid spawning and rearing.

A number of tributary streams join the Klamath River in this reach, including Spencer, Shovel, Fall, Spring, and Camp creeks. These streams provide suitable coldwater spawning and rearing habitat for fish (including potentially salmon and steelhead).

As described in detail in Section 3.20.2.3 *Lower Klamath Project Reservoir-Based Recreation*, the reservoirs currently provide a recreational fishery for non-native fishes including largemouth bass, trout, catfish, crappie, and sunfish (Hamilton et al. 2011). Fishing is popular in Copco No. 1 and Iron Gate reservoirs, especially for yellow perch (Hamilton et al. 2011). These reservoirs also support small numbers of native shortnose and Lost River suckers that are believed to be individuals that have migrated down from the upstream reservoirs and that are thought to not be self-sustaining populations or to be contributing to populations in upstream areas (Hamilton et al. 2011). Riverine sections between reservoirs support populations of speckled dace, marbled sculpin, tui chub, and rainbow and redband trout. This area historically supported anadromous fish populations, including Chinook and coho salmon, steelhead, and Pacific lamprey. These fish can no longer access this area because of the lack of adequate facilities for fish passage at the dams (Hamilton et al. 2011).

Middle and Lower Klamath River

The Klamath River flows unobstructed for 190 river miles downstream from Iron Gate Dam before entering the Pacific Ocean. Downstream from Iron Gate Dam, the Klamath River has a gradient of approximately 0.25 percent and four major tributaries enter this reach: Shasta, Scott, Salmon, and Trinity rivers.

The Klamath Basin downstream from Iron Gate Dam provides hundreds of miles of suitable habitat for anadromous and resident fish. Recreational fishing within this area is popular for steelhead and Chinook salmon, and tribal fishing is common for Chinook salmon with gillnets, and Pacific lamprey with basket traps. Freshwater mussels are also common in this reach. Most of the anadromous salmonid species spawn primarily in the tributary streams, although fall-run Chinook salmon and coho salmon do spawn in the mainstem. The mainstem also serves as a migratory corridor and as rearing habitat for juveniles of many salmonid species (FERC 2007). The ability of the mainstem Klamath River to support the rearing and migration of anadromous species is reduced by periodic high water temperatures during summer, poor water quality (low dissolved oxygen and high pH; see Sections 3.2.2.5 *Dissolved Oxygen* and 3.2.2.6 *pH*), and disease outbreaks during spring. Aquatic habitat quality in the tributaries is also affected by high temperatures. The Shasta and Scott Rivers also are impaired by low flows, high water temperatures, stream diversions, non-native species, and degraded spawning habitat (Hardy and Addley 2001, FERC 2007, North Coast Regional Board 2010). In the Salmon River, past and present high severity fires and logging roads in the watershed contribute to high sediment yields, and continued placer mining has disturbed spawning and holding habitat (NRC 2004).

Klamath River Estuary

Wallace (1998) surveyed the Klamath River Estuary and noted formation of a sand berm at the river mouth each year in the late summer or early fall, raising the water level in the estuary, reducing tidal fluctuation, and restricting saltwater inflow. The surveys found a brackish water layer along the bottom of the estuary may be extremely important to rearing juvenile salmonids, as they appeared to be more abundant near the freshwater/saltwater interface. Juvenile Chinook salmon may also use the cooler brackish water layer as a thermal refuge.

The Klamath River Estuary supports a wide array of fish species and also serves as breeding and foraging habitat for marine and estuarine species. These species include, but are not limited to Pacific herring (*Clupea pallasii*), surf smelt, longfin smelt, eulachon, top smelt, starry flounder (*Platichthys stellatus*) and other flatfish, Klamath speckled dace, Klamath smallscale sucker, prickly sculpin, Pacific staghorn sculpin, northern anchovy, saddleback gunnel, and bay pipefish. Recreational fishing for Chinook salmon is popular in the estuary, as well as tribal fishing for Chinook salmon with gillnets and Pacific lamprey with hooks.

Pacific Ocean Nearshore Environment

The Pacific Ocean nearshore environment includes the Klamath River Management Zone (KMZ), the California portion of which extends from the Oregon-California state line south to Horse Mountain (40° 05' 00" N. latitude) and out three nautical miles from the coast. Physical habitat within this environment includes sandy beach, rocky intertidal, and a sand-dominated seafloor at depths less than 200 ft within one mile of the coast, ranging to depths greater than 500 ft on the continental shelf. During winter high flows fine sediment deposits on the seafloor shoreward of the 196-feet isobath along the coast, with greater quantities depositing in close proximity to the mouth of the Klamath River. After fine sediment loading onto the continental shelf during river floods, fluid-mud gravity flows typically transport fine sediment offshore. Summer coastal upwelling naturally resuspends some of the river sediments that are transported to the nearshore environment and deposited on the continental shelf, especially those deposited during the previous winter (Ryan et al. 2005, Chase et al. 2007; see Potential Impact 3.2-8).

The Pacific Ocean nearshore environment supports a wide array of fish species and serves mostly as foraging habitat for marine and anadromous species. These species include, but are not limited to all of the anadromous fish listed previously, as well as federally threatened Southern DPS green sturgeon, Pacific halibut (*Hippoglossus stenolepis*), Pacific herring, surf smelt, longfin smelt, eulachon, top smelt, starry flounder and other flatfish, northern anchovy, saddleback gunnel, lingcod (*Ophiodon elongates*), rockfish species (*Sebastes spp.*). Within the Pacific Ocean nearshore, recreational and commercial fishing for Chinook salmon, halibut, lingcod, and rockfish species is common.

3.3.2.3 Habitat Attributes Expected to be Affected by the Proposed Project

The Proposed Project would affect the physical, chemical, and biological components of aquatic habitat within portions of the Klamath Basin. These effects would result from changes in suspended sediment, bedload sediment, water quality, water temperature, disease and parasites, habitat availability, and flow-related habitat. As described in the following sections, these changes would act in both beneficial and harmful ways on species, critical habitat, and EFH. Some of the changes would be short-term, and others permanent. The overarching long-term effect would be to bring the habitat closer to a more natural riverine system, from the current reservoir and reservoir-influenced baseline.

Appendices E and F provide more detailed technical descriptions of suspended sediment and bedload sediment under existing conditions. Anticipated changes in water quality under the Proposed Project are discussed in greater detail in Section 3.2 *Water Quality*, and a description of the effects of implementing the Proposed Project on algae is found in Section 3.4 *Phytoplankton and Periphyton*.

Suspended Sediment

Suspended sediment dynamics would be altered by the Proposed Project within the Hydroelectric Reach and reaches downstream of Iron Gate Dam. Existing conditions with respect to algal-derived (organic) suspended material and mineral (inorganic) suspended material in the Klamath River upstream and downstream from Iron Gate Dam are summarized in Section 3.2.2.3 *Suspended Sediments* and in Appendix C.

Hydroelectric Reach

Organic suspended material originating from Upper Klamath Lake (in Oregon) is the predominant form of suspended material entering the Hydroelectric Reach. Interception, decomposition, and retention of suspended materials in the Lower Klamath Project reservoirs, as well as dilution from coldwater springs downstream of J.C. Boyle Dam, can decrease organic suspended material concentrations in this reach; however, seasonal increases in organic suspended material also occur in Copco No. 1 and Iron Gate reservoirs due to large summertime phytoplankton blooms (see Section 3.2.2.3 *Suspended Sediments* and Appendix C – *Section C.2.1* for more detail). In the winter months, suspended material in the Hydroelectric Reach is dominated by mineral sediment loads from several tributaries that join the river in this reach (primarily Shovel Creek, Spencer Creek, Jenny Creek, and Fall Creek), which are primarily transported during high flow events and generally settle out in the Lower Klamath Project reservoirs. On the scale of the entire Klamath Basin, the trapping of fine sediments and suspended materials does not appear to be a critical function of the Lower Klamath Project reservoirs with respect to the overall cumulative sediment delivery including downstream tributaries (see also Section 3.11.2.4 *Sediment Load*), since a relatively small percentage (3.4 percent) of total sediment supplied to the Klamath River on an annual basis originates from the Upper and Middle Klamath River (i.e., from J.C. Boyle Dam to the confluence with the Shasta River).

Middle and Lower Klamath River

In general, available data (existing conditions) (detailed in Appendix C.2.2.1) indicate that suspended sediment concentrations (SSCs) downstream from Iron Gate Dam range from less than 5 mg/L during summer low flows to greater than 5,000 mg/L during winter high flows. During large winter storms or following landslides in the Klamath Basin, extremely high SSCs have been observed in the Klamath River mainstem and tributaries (M. Belchik, Fisheries Biologist, Yurok Tribe, pers. comm., August 2008). Large rivers such as the Klamath River, Columbia River, and Sacramento River have large fluctuations in SSCs even under unimpaired conditions, and aquatic species have adapted to survive in this environment. Appendix E provides a detailed analysis of the effects of suspended sediment on aquatic species downstream from Iron Gate Dam under existing conditions.

During all water year types, SSCs of the magnitude and duration modeled under existing conditions (multiple months with concentrations over 50 mg/L) are expected to cause major stress to migrating adult and juvenile salmonids primarily during winter and early spring (Newcombe and Jenson 1996, see also Appendix E). Under existing conditions, Iron Gate Dam traps most suspended sediment from upstream sources, and downstream of Iron Gate Dam SSCs generally increase in a downstream direction from the contribution of tributaries (Appendix C.2).

Klamath River Estuary
Under existing conditions, SSCs within the Klamath River Estuary (modeled at Klamath Station at RM 5; Figure 3.3-1) are relatively high compared to SSCs observed farther upstream due to SSC contribution of major tributaries downstream of Iron Gate Dam (Appendix E). The Lower Klamath River downstream from the Trinity River confluence to the estuary is currently listed as sediment-impaired under Section 303(d) of the Clean Water Act (CWA) (North Coast Regional Board 2010). Modeling in the Klamath River (from Seiad Valley at approximately RM 132.7 downstream to the Klamath Station at RM 5) indicates that under normal conditions SSCs are relatively high during winter and spring (typically 50 to 100 mg/L), and lower (less than 10 mg/L) during summer. Under existing extreme conditions (wet water year) SSCs are generally 10 to 100 mg/L in summer and fall, with peaks between 100 and 1,000 mg/L during winter and spring.

Pacific Ocean Nearshore Environment
Under existing conditions, a plume of Klamath River water extends into the Pacific Ocean nearshore environment in the Klamath River vicinity that is subject to strong land runoff effects following winter rainfall events. The plume can create areas of low-salinity, high levels of suspended particles, high sedimentation, and low light, and potential exposure to land-derived contaminants (Farnsworth and Warrick 2007). The extent and shape of the plume is variable, and influenced by wind patterns, upwelling effects, shoreline topography (especially Point Saint George), and longshore currents. High riverine SSC events contribute to the plume, especially during floods. In northern California, plume zones are primarily north of river mouths because longshore currents and prevailing winds are northward during periods of strong runoff (Geyer et al. 2000, Pullen and Allen 2000). River plumes and the associated habitat conditions they create support areas of high productivity for marine organisms (Grimes and Finucane 1991, Morgan et al. 2005), and create abrupt changes in marine water quality conditions (e.g., water temperature, salinity, sediment) that support salmonids (Schabetsberger et al. 2003, De Robertis et al. 2005).

Bed Elevation and Grain Size Distribution
Section 3.11.2.4 *Sediment Load* and Appendix F of this EIR describe sediment dynamics and channel conditions in the Area of Analysis and assess changes in channel bed elevation and sediment grain size in response to increased bedload supply and transport for existing conditions and under the Proposed Project. The sections below provide a brief summary of the analyses of bedload supply, transport, and channel change provided elsewhere. Bedload supply and transport are vital to the creation and maintenance of functional aquatic habitat. Natural river dynamics include transportation of coarse sediment (e.g., sand, gravel, cobble, and boulder) downstream. Natural sediment pulses that result from heavy rainfall and snowmelt events are incorporated by stream and river processes into spawning beds, gravel bars, side channels, pools, riffles, and floodplains that provide habitat and support food chains of aquatic species. These periodic inputs and movement of coarse sediment are necessary for the long-term

maintenance of aquatic habitats. Salmonids evolved to depend on continued sediment delivery to provide substrate suitable for spawning and early rearing in streams and rivers. These natural processes have been disrupted in the Klamath River since the construction of dams.

Under existing conditions, dams have disrupted geomorphic and vegetative processes that can form channels and create spawning grounds downstream from Iron Gate Dam, by trapping sediment and preventing its transport downstream (Buer 1981, PacifiCorp 2004a, KRBFTF 1991). Since the construction of the Lower Klamath Project, sediment and gravel have been intercepted by Lower Klamath Project reservoirs, with Iron Gate Dam cutting off sediment supply from the Upper Klamath Basin. The resultant reduction in spawning gravels downstream of Iron Gate Dam has been identified as one of the causes of the decline in salmonid fry production in this reach of the Klamath River (Buer 1981). In response to this recognized limiting factor, the California Department of Water Resources developed (but never implemented) gravel augmentation programs for spawning gravel downstream from Iron Gate Dam (Buer 1981). Per the interim operations of the Klamath Hydroelectric Project HCP (PacifiCorp 2012), PacifiCorp developed and implemented a plan to augment gravel immediately downstream of Iron Gate Dam beginning in 2014 (PacifiCorp 2014). Per the interim operations of the Klamath Hydroelectric Project HCP (PacifiCorp 2012), PacifiCorp developed and implemented a plan to augment gravel immediately downstream of Iron Gate Dam beginning in 2014 (PacifiCorp 2014). Gravel augmentation occurred immediately downstream of Iron Gate Dam in 2014, 2016, and 2017, with approximately 4,600 cubic yards total placed downstream of the dam as of December 2017 (PacifiCorp 2018). The placed gravel has been moved downstream by high flows (PacifiCorp 2018), although additional details on the extent of downstream movement have not been reported.

Water Quality

Section 3.2.2 *[Water Quality] Environmental Setting* provides information regarding existing conditions for water quality from J.C. Boyle Reservoir to the Klamath River Estuary, including those parameters that can directly affect beneficial uses for aquatic species (i.e., water temperature, suspended sediments, dissolved oxygen, pH, and algal toxins such as microcystin). Multiple waterbodies in the Area of Analysis, including the mainstem of the Klamath River, are listed under section 303(d) of the CWA for a variety of water quality parameters such as water temperature, sediment, nutrients, dissolved oxygen, pH, ammonia, chlorophyll-*a*, and microcystin (North Coast Regional Board 2011). Existing conditions for water temperature and algal toxins are evaluated in greater detail below with respect to implications on fish health and survival in the Klamath Basin. Microcystin toxin concentrations are also addressed in Section 3.2 *Water Quality* and Section 3.4 *Phytoplankton and Periphyton*.

Water Temperature

The Klamath River, from Keno Dam to the Klamath River Estuary, has been listed as impaired for water temperature (North Coast Regional Board 2011; see Section 3.2 *Water Quality* and Appendix C.1 of this EIR for discussion of existing water temperature conditions). Water temperatures in the Klamath River are of special concern as they are elevated with a greater frequency and remain elevated for longer periods of time than temperatures in adjacent coastal anadromous streams, and they are unsuitable in the lower mainstem for anadromous salmonids at times during the summer (Bartholow 2005). Acute thermal effects for salmonids are expected to occur as mean daily water temperatures begin to exceed 68°F (Bartholow 2005). These elevated temperatures are especially detrimental to anadromous species during the warmer portions of the year (ODEQ 2002). Bartholow (2005) expressed concern that if observed increases in water temperature over the last several decades in the mainstem Klamath River downstream from Iron Gate Dam, which may be related to the cyclic Pacific Decadal Oscillation, continue, some stocks may decline to levels insufficient to ensure survival of the population. Klamath River salmonids are generally more tolerant of high water temperatures than salmonids from other basins (FERC 2007, Foott et al. 2012). Moreover, NMFS (2006a) concluded that available evidence indicates that juvenile steelhead can withstand incrementally higher temperatures exceeding 71.6°F provided food is abundant and by finding thermal refuge or by living in areas where nocturnal temperatures drop below the thermal threshold. Elevated temperatures can affect the timing of different life-history events, altering migration patterns, delaying and shortening the spawning season, impairing reproductive success, reducing growth, and resulting in a reduction of the diversity in the timing of migration (Hamilton et al. 2011). High water temperatures can contribute to low dissolved oxygen events by reducing dissolved oxygen solubility and accelerating oxygen-demanding processes, and can facilitate the spread of disease (Wood et al. 2006). Stress associated with high water temperatures can make cold water species more vulnerable to disease and parasites, and have been associated with fish kills in the Klamath River downstream from Iron Gate Dam during low flow periods in late summer (Hardy and Addley 2001).

Upper Klamath River and Connected Waterbodies

Both Upper Klamath Lake and the Keno Impoundment/Lake Ewauna are relatively shallow and temperatures in both are generally warm during the late spring through early fall (FERC 2007). In the summer, instantaneous maximum water temperatures of 71.6 to 75.2°F are common in the upper three to six feet of Upper Klamath Lake, and temperatures can approach a maximum of 86°F near the surface (PacifiCorp 2004c). Although prolonged exposure to these high temperatures could be lethal for some species, the water temperature remains within tolerance criteria for migrating adult anadromous salmonids during migratory periods (i.e., not during summer) (Dunsmoor and Huntington 2006, Hamilton et al. 2011). Anadromous salmonids successfully navigated through Upper Klamath Lake to spawn in the Upper Klamath Basin prior to their access being blocked by the Lower Klamath Project. Temperatures in Upper Klamath Lake are cooler than those in the Klamath River downstream from Iron Gate Dam in the late summer and early fall when fall-run Chinook salmon are migrating. In addition, thermal refugia are available in this reach where fish can avoid high water temperatures. Upper Klamath Lake supports a population of redband trout that moves into cooler tributary habitats during the summer, but which have high growth rates while in the lake. Those in the lake over the summer can find thermal refuge in Pelican Bay, which is fed by springs and remains cool (Dunsmoor and Huntington 2006). Wetlands surround this bay and would be expected to provide juvenile salmonids with suitable rearing habitat (Dunsmoor and Huntington 2006).

The Keno Impoundment/Lake Ewauna has generally poor water quality in the summer, with instantaneous maximum water temperatures exceeding 77°F and low dissolved oxygen (Hamilton et al. 2011). These warm temperatures are also present downstream from Keno Dam. However, from November through mid-June, the reach from Link River Dam to Keno Dam is cooler (below 68°F) and meets criteria for migrating adult anadromous salmonids (Hamilton et al. 2011). Temperatures in the Link River and the Keno Impoundment/Lake Ewauna tend to increase in the summer; however, maximum water temperatures (71.6 to 77°F) are still within the preferred range for warm- and some cold-water species found in the Upper Klamath Basin (yellow perch, catfish, sunfish, largemouth bass, and spotted bass).

Upper Klamath River – Hydroelectric Reach
Water temperatures in the Hydroelectric Reach are generally warm in the Lower Klamath Project reservoirs from late spring through early fall, but tributaries in this reach are generally cool. In addition, numerous cold-water springs contribute flows to both Copco No. 1 and Iron Gate reservoirs. Average monthly water temperatures within reservoirs from 2001 to 2004 ranged from just over 41°F in November to more than 71.6°F in June through August (FERC 2007), with thermal stratification in Copco No. 1 and Iron Gate reservoirs resulting in relatively warm discharge waters during summer months. Water temperatures at the downstream end of the J.C. Boyle Bypass Reach and in the Klamath River upstream of Shovel Creek are consistently cooler than other sites sampled between Link Dam and the Shasta River (PacifiCorp 2004b). Temperatures in the J.C. Boyle Bypass Reach are cooled by the contribution of 200 to 250 cfs of groundwater at a relatively constant 51.8 to 53.6°F within the reach (PacifiCorp 2006, Kirk et al. 2010). The input from the Bypass Reach during the summer results in a relatively lower daily water temperature range in the Klamath River in the J.C. Boyle Peaking Reach (FERC 2007).

Further downstream in the Peaking Reach, near the confluence of the Klamath River and Shovel Creek (Figure 3.3-1), there are natural hot springs that contribute flows to the mainstem river. The natural hot springs were not found to result in consistent substantial warming of the Klamath River based on two sets of measurements made in November and December 2017 (KRRC 2018). Water temperature data collected upstream and downstream of the confluence of the Klamath River and Shovel Creek showed a 1.4˚F increase in the downstream direction during the November 2017 measurement, but a 0.2˚F decrease during the December 2017 measurement (KRRC 2018). Water temperatures in Shovel Creek itself are generally low year-round, with reported values consistently below 59°F in the summer (PacifiCorp 2004a). Water temperatures recorded in Shovel Creek in late fall/early winter 2017 were 46°F (on November 1) and 39.9°F (December 5) (KRRC 2018).

Temperature data for other tributaries entering the Hydroelectric Reach are based on a limited study period (between 2001 and 2003) (PacifiCorp 2004c). Fall Creek, which flows into Iron Gate Reservoir, is generally cold year-round and does not exceed 57.2°F during the summer (PacifiCorp 2004c). Temperatures in Jenny Creek, which also flows into Iron Gate Reservoir, vary seasonally, ranging from less than 50°F in the spring to more than 71.6°F in July and August (PacifiCorp 2004c). As noted above, temperatures in Shovel Creek are generally low year-round and do not exceed 59°F in the summer (PacifiCorp 2004c). Spencer Creek temperatures are low during spring (<59°F) and are generally below 64.4°F, but can exceed 68°F for short durations (PacifiCorp 2004c).

Iron Gate and Copco No. 1 reservoirs are the two deepest reservoirs in the Hydroelectric Reach. These reservoirs thermally stratify each year beginning in April/May and the warmer (64.4°F to 73.4°F) surface and colder (46.4°F to 62.6°F) bottom waters do not mix again until October/November (see also Section 3.2.2.2 *Water Temperature*). Surface waters in these reservoirs reach maximum temperatures exceeding 77°F during the summer (PacifiCorp 2004c). Colder water temperatures occur at depths greater than six to ten meters below the reservoir surfaces during periods when the reservoirs are stratified (see Appendix C, Section C.1.1.1 and Figure C-1) (PacifiCorp 2004c, Asarian and Kann 2011). The powerplant intakes in both reservoirs are relatively shallow, at approximately nine to ten meters below the surface, such most of the reservoirs' discharge waters are from the warmer surface waters. Consequently, discharges from Copco No. 1 and Iron Gate reservoirs increase late summer/fall water temperatures downstream of Iron Gate Dam by approximately 4°F to 18°F (approximately 2°C to 10°C) (see also *Middle and Lower Klamath River*). Further, even though Copco No. 1 and Iron Gate reservoirs retain large volumes (approximately 9,000 acre-feet and 23,000 acre-feet, respectively) of colder bottom waters during periods of stratification, these waters are typically hypoxic (dissolved oxygen less than 2 mg/L), particularly in Copco No. 1 Reservoir (Appendix C, Section C.4.1.1). Although summertime water temperatures documented in the Hydroelectric Reach are within the tolerance ranges of the species observed there (e.g., perch, bass), these temperatures regularly exceed the range of chronic effects temperature thresholds (approximately 55 to 68°F [13 to 20°C]) for full salmonid support in California (North Coast Regional Board 2010).

Middle and Lower Klamath River

The large thermal mass of the stored water in Copco No. 1 and Iron Gate reservoirs delays the natural warming and cooling of riverine water temperatures on a seasonal basis such that spring water temperatures in the Middle Klamath River immediately downstream of Iron Gate Dam are generally cooler than would be expected under natural conditions, and summer and fall water temperatures are generally warmer (Figure 3.2-3; see also Section 3.2.2.2 *Water Temperature*). This "thermal lag" diminishes downstream from Iron Gate Dam, and there is no noticeable alteration in water temperatures by just upstream of the Salmon River confluence. Summer weather conditions can be very hot from June through September and rising ambient air temperatures can lead to increased water temperatures (Hamilton et al. 2011). Downstream from Iron Gate Dam, monthly mean temperatures in the river are 37.4 to 42.8°F in January and 68 to 72.5°F in July and August (Bartholow 2005). Substantial losses of juvenile salmonids have occurred during their migration through the Lower Klamath River, and losses were especially severe during low-water years with periods of sustained high-water temperatures. Exposure to high water temperature reduces the resistance of these fish to disease and other stressors (Scheiff et al. 2001, Ray et al. 2014). Consequently, during periods of high water temperature juvenile salmonids have been observed to crowd into areas with suitable water temperature such as at tributary confluences (thermal refugia). Summary statistics compiled by the United States Environmental Protection Agency (USEPA) indicate that water temperatures at locations between Iron Gate Dam and the Klamath River's confluence with the Scott River range from about 60.8 to 71.6°F in June, and from 60.8 to 78.8°F in July (FERC 2007). From May through September (peaking in June–August) summer water temperatures in the Lower Klamath Basin begin to warm to stressful levels for cold water species such as salmon, steelhead, and Pacific lamprey.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Water temperatures in the estuary range from 41 to 53.6°F from December through April (Hiner 2006). Warmer air temperatures and lower flows in summer and fall months result in increased water temperatures ranging from 68 to 75.2°F (Wallace 1998) or greater than 75.2°F (Hiner 2006). When flows become low during some summer conditions, water temperatures in the Klamath River Estuary sometimes exceed criteria for optimal growth, and occasionally are warm enough to result in potential mortality for Chinook salmon, coho salmon, and steelhead (Stillwater Sciences 2009a). However, observed warm water conditions in the Klamath River Estuary are typically short in duration, due to input of cool ocean water and a high prevalence of coastal fog. Water temperatures in the Pacific Ocean nearshore environment are moderated by the Pacific Ocean currents and patterns that appear unrelated to the contribution of the Klamath River.

Disease and Parasites

Fish diseases, specifically the myxozoan parasites *Ceratomyxa shasta* (*C. shasta*) and *Parvicapsula minibicornis (P. minibicornis),* regularly result in substantial mortality of Klamath River salmon (Fujiwara et al. 2011, True et al. 2013); however, steelhead are generally resistant to *C. shasta*. Additional diseases that may affect fish in the Klamath Basin include *Ichthyophthirius multifis* (Ich) and *Flavobacterium columnare* (columnaris). These parasites and diseases occur throughout the watershed but appear to cause the most severe mortality in the mainstem Klamath River downstream from Iron Gate Dam where *C. shasta* has been observed to result in high rates of mortality in salmon (True et al. 2013). Ich and columnaris occasionally result in substantial mortality (e.g., the 2002 fish kill of primarily adult Chinook salmon, as discussed below).

Both *C. shasta* and *P. minibicornis* spend part of their life cycle in an invertebrate host and another part in a fish host (Figure 3.4-9). Transmission of these parasites is limited to areas where the invertebrate host is present. In the Klamath River, their invertebrate host is the annelid polychaete worm *Manayunkia speciosa* (Bartholomew et al. 1997, 2007). Once the polychaetes are infected, they release *C. shasta* and *P. minibicornis* actinospores into the water column. Actinospores are generally released when temperatures rise above 50°F and remain viable from three to seven days at temperatures from 51.8 to 64.4°F, with temperatures outside that range resulting in a shorter period of viability (Foott et al. 2007). The longer the period of viability, the wider the distribution of the actinospores within the river, and thus the higher the risk of exposure for salmon (Bjork and Bartholomew 2010). Actinospore abundance, a primary determinant of infectious dose, is controlled by the number of polychaetes and the prevalence and severity of infection within their population. The river channel downstream from Iron Gate Dam has been atypically stable since dam construction, and has provided favorable habitat for the polychaete worm host, likely increasing the parasite load to which the fish are exposed. High parasite loads are believed to lead to higher rates of mortality (Fujiwara et al. 2011). Ray et al. (2014) evaluated *in situ* juvenile salmonid exposure using sentinel cages. Studies found that increasing parasite concentrations and water temperatures were positively associated with the proportion of juvenile fish that experienced infection and mortality. Spore concentration and water temperature were more important determinants of exposure and mortality of juvenile Chinook and coho salmon, than was river flow. The location of peak actinospore concentrations varies among years, and Som et al. (2016a) report that the most frequent location of the peak in concentrations occurs near the confluence of Beaver Creek.

Figure 3.3-2. Lifecycle of *Ceratomyxa shasta*. Source: NMFS 2012.

Salmon become infected when the actinospores enter the gills, eventually reaching the intestines where the parasite replicates and matures to the myxospore stage. Myxospores are shed by the dying and dead salmon, and the cycle continues with infection of polychaete worms by the myxospores (Figure 3.4-9) (Bartholomew and Foott 2010). Som et al. (2016a) states that myxospores released from adult salmon carcasses contribute the bulk of myxospores to the system; mostly from carcasses upstream of the confluence with the Shasta River.

The polychaete host for the parasite is present in a variety of habitat types, including runs, pools, riffles, edge-water, and reservoir inflow zones, as well as sand, gravel, boulders, bedrock, aquatic vegetation, and it is frequently found among mats of filamentous periphytic algal species (e.g., Cladophora) that traps fine sediment and detritus (Bartholomew and Foott 2010).

The highest densities of polychaetes have been observed in slow-flowing and more stable, depositional habitats (e.g., pools with sand) (Bartholomew and Foott 2010), especially if instream flows remain constant. The mobilization of particles on the bed of the channel downstream from Iron Gate Dam depends directly upon the size of the substrate and magnitude of peak flows. The greater the flows, the larger the particles likely to be moved, and the smaller the particle, the lower the flow required for mobilization. Polychaetes are more persistent if the substrate remains immobile for long periods (on the order of years). Under historical conditions, frequent flood events and natural sediment supply, combined with considerable intra-annual flow variability, ensured that the substrate was frequently mobilized. Under existing conditions with dams in place, sediment supply is reduced, flow variability is decreased, and conditions supporting the persistence of polychaetes are more prevalent (Shea et al. 2016).

Susceptibility to *C. shasta* is also influenced by the genetic type of *C. shasta* encountered by the fish (Som et al. 2016a). Atkinson and Bartholomew (2010) conducted an analysis of the genotypes of *C. shasta* and the association of these genotypes with different salmonid species, including Chinook and coho salmon, steelhead, rainbow trout, and redband trout. In a genetic analysis, the *C. shasta* genotypes were characterized as Type 0, Type I, Type II, and Type III (Table 3.3-10). In the Williamson River, although parasite densities had been found to be high, sentinel Chinook salmon were resistant to infection because the genotype specific to Chinook salmon was absent (Hurst et al. 2012).

Table 3.3-10. *Ceratomyxa Shasta* Genotypes in the Klamath Basin.

***C. shasta* Genotype**	**Distribution**	**Affected Species**	**Notes**
Type 0	Upper and Lower Klamath Basin	native steelhead, rainbow, and redband trout	Usually occurs in low densities, is not very virulent, and causes little or no mortality
Type I	Lower Klamath Basin	Chinook salmon	If the Type I genotype were carried into the Upper Klamath Basin, only Chinook salmon would be affected
Type II	Klamath Lake, Upper and Lower Klamath Basin	coho salmon in Lower Klamath Basin and non-native rainbow trout	The "biotype" found in the Upper Klamath Basin does not appear to affect coho salmon in sentinel studies
Type III	Assumed widespread in Klamath Basin based on presence in fish	all salmonid species	Prevalence of this genotype is low and it infects fish but does not appear to cause mortality

Native populations of salmonids in waters where *C. shasta* is endemic generally develop a high degree of resistance to the disease. Stocking et al. (2006) conducted studies of the seasonal and spatial distribution of *C. shasta* in the Klamath River. The study included the exposure of fall-run Chinook salmon (Iron Gate Hatchery strain). The study found the polychaete host, *M. speciosa*, from Upper Klamath Lake to the mouth of the river. Although infection rates were high in non-native, non-resistant rainbow trout, used as sentinel fish in the upper Klamath River upstream of Iron Gate Dam and downstream from the Williamson River, mortality rates were very low (Stocking et al. 2006). Chinook salmon at this location did not become infected. Minimal mortality in both was likely due to low levels of parasites in this area and a predominance of Type 0 genotype of *C. shasta*. Because the parasites are endemic to the watershed, the native salmonid populations have some level of resistance to the disease.

Upper Klamath River and Connected Waterbodies

Many of the diseases and parasites described above can occur in the Upper Klamath River. *C. shasta* and *P. minibicornis* are both known to occur in the Upper Klamath Basin (NMFS 2006a), and *C. shasta* densities have been reported to be as high in the

Williamson River (Hurst et al. 2012) as in the area downstream from Iron Gate Dam (Hallett and Bartholomew 2006). However, in the section of the river upstream of J.C. Boyle Reservoir, *C. shasta* does not have the same serious effects as it does downstream from Iron Gate Dam, because of the genotype of the parasite (Type 0, II, and III) and the higher resistance of the redband trout to the disease. Historically *C. shasta* and *P. minibicornis* occurred in the Upper Klamath Basin and resident fish upstream of the dams evolved with these parasites (Hamilton et al. 2011). The current infectious zone and high parasite loads below Iron Gate Dam are the result of a synergistic effect of numerous factors (FERC 2007, Hamilton et al. 2011), including: (1) close proximity of myxospore-shedding carcasses (concentration of carcasses); (2) abundant polychaete populations that are found in atypically stable habitats; (3) suitable water temperatures (greater than 59°F) during periods when juvenile salmonids are present; and 4) low flow variability (Bartholomew and Foott 2010). This synergy would be unlikely in the Upper Klamath River (Hamilton et al. 2011), and the NMFS (2006a, USFWS/NMFS Issue 2(B)) concluded that the movement of anadromous fish upstream of Iron Gate Dam presents a relatively low risk of introducing pathogens to resident fish (e.g., redband trout, cutthroat trout).

Upper Klamath River – Hydroelectric Reach

As described above, Stocking et al. (2006) found the polychaete host for *C. shasta* and *P. minibicornis* throughout the mainstem Klamath River, including the reach from J.C. Boyle Reservoir to Iron Gate Dam (the Hydroelectric Reach), and within the Lower Klamath Project reservoirs. However, these polychaete populations are most abundant at reservoir inflow areas with densities decreasing with distance from reservoir/river interface, but not disappearing entirely (Stocking and Bartholomew 2007). In order for an area to develop as an infectious zone, several factors need to coincide, including microhabitats with low velocity, and stable flows, which are rare within this reach (Bartholomew and Foott 2010).

Middle and Lower Klamath River

In the Klamath River downstream of Iron Gate Dam, the polychaete host for *C. shasta* and *P. minibicornis* is aggregated into small, patchy populations. The reach of the Klamath River from the Shasta River to Seiad/Indian Creek is known to be a highly infectious zone with high actinospore exposure, particularly from May through August (Beeman et al. 2008, Bartholomew and Foott 2010). This portion of the river contains dense populations of polychaetes within low-velocity habitats with *Cladophora* (a filamentous green periphytic algae), sand-silt, and fine organic material in the substrate (Stocking and Bartholomew 2007). As described above, the reduced bedload mobility has increased the persistence of polychaetes under existing conditions (Som et al. 2016b). High parasite prevalence in the Lower Klamath River is considered to be a combined effect of high spore input from heavily infected, spawned adult salmon that congregate downstream from Iron Gate Dam and Iron Gate Hatchery, and the proximity to dense populations of polychaetes (Bartholomew et al. 2007). The highest rates of infection occur in the Lower Klamath River downstream from Iron Gate Dam, generally in the reach from Shasta River to Seiad (Stocking and Bartholomew 2007, Bartholomew and Foott 2010, Bartholomew et al. 2017).

Despite potential resistance to *C. shasta* and *P. minibicornis* in native populations, salmon exposed to high levels of the parasite may be more susceptible to disease—particularly juvenile salmon, and more so at higher (>59ºF [>15ºC]) water temperatures. In summarizing data collected from 2005 through 2008, Bartholomew and Foott (2010) reported that juvenile Chinook and coho salmon migrating downstream had infection rates as high as 90 percent and 50 percent, respectively. During April to August 2009 True et al. (2010) found 54 percent of juvenile Chinook salmon in the Klamath River upstream of the confluence with the Trinity River had parasitic infection from *C. shasta*, and 85 percent were infected with *P. minibicornis*. Water temperatures were not reported. During April to August 2012 True et al. (2013) found 30 percent of juvenile Chinook salmon in the Klamath River upstream of the confluence with the Trinity River had parasitic infection from *C. shasta*, and 69 percent were infected with *P. minibicornis.* True et al. (2013) reported that both *C. shasta* prevalence of infection increased in 2012 compared to 2011 (2011 results not reported). Environmentally, 2012 consisted of a relatively normal temperature profile for the Klamath River. No manipulated pulse flow from Iron Gate Dam (as in 2011) or extended period of precipitation (as in 2010) occurred. True et al. (2013) concluded that the typically warm river temperatures (59–75.2°F) observed in May–July, coupled with earlier high *C. shasta* actinospore densities (May versus June in 2011) in the infectious zone, resulted in an increase in annual infection prevalence compared to the previous monitoring year. Overall, the 2012 annual infection prevalence for juvenile Chinook salmon during outmigration was relatively moderate compared to historical levels observed for the monitoring program (2006–2011).

High disease infection rates are apparently resulting in high mortality of outmigrating smolts. Studies of outmigrating coho salmon smolts by Beeman et al. (2008) estimated that mortality rates were between 35 and 70 percent in the Klamath River near Iron Gate Dam. Their studies also suggested that higher spring discharge increased smolt survival (Beeman et al. 2008).

Between May and July 2004, the USFWS, the Yurok Tribe, and the Karuk Tribe reported high levels of mortality and disease infections among naturally-produced juvenile Chinook salmon captured in downstream migrant traps fished in the Klamath River (Nichols and Foott 2005). Visible symptoms observed included bloated abdominal cavities, pale gills, bloody vents, and pop-eye. Infected fish also exhibited lethargic behavior, poor swimming ability and increased vulnerability to handling stress. The primary cause of the disease was found to be *C. shasta*, with *P. minibicornis* observed as well. Weekly prevalence of *C. shasta* infection for all sites combined ranged from 15 to 56 percent, with the peak observed in fish captured in late May. Expanding from the trap efficiency data the authors estimated 45 percent of the population passing Big Bar was infected with *C. shasta.* Weekly prevalence of *P. minibicornis* infection for all sites combined ranged from 36 to 93 percent with the peak observed in fish captured on mid-June. Expanding from the trap efficiency data the authors estimated 94 percent of the population passing Big Bar was infected with *P. minibicornis.* The authors concluded that the high incidence of dual myxozoan infection (98 percent of *Ceratomyxa* infected fish), and associated pathology suggested that most of the *C. shasta* infected juvenile Chinook salmon would not survive. The 2004 mortality event was not quantified because of limited resources and other problems associated with sampling small fish in a large river system.

Other recent fish kills include the June 1998 and June 2000 fish kills. CDFG (2000) estimated 10,000 to 300,000 individuals, mostly young-of-year, killed in the June 2000 event. CDFG (2000) stated that, "we did not attempt to systematically or statistically quantify total [young of the year] chinook and steelhead mortality. CDFG's initial assessment of mortality in the "tens of thousands" range should be considered a very conservative minimum. I [CDFW staff] believe many more fish died than we originally observed during our surveys because of the time period involved (mid-to-late June; approximately three weeks) and the apparent high rate of scavenging (dead fish being quickly consumed and therefore unavailable for observation). It is probable that a number on an order of magnitude greater (i.e., >100,000 to 300,000) may be more realistic."

The cause of the 2000 fish kill was believed to be infection with *C. shasta* and columnaris. For comparison, in 2010 through 2012, years with lower river temperatures and conditions less conducive to disease infection, prevalence of *C. shasta* in emigrating juvenile Chinook salmon during the peak migration period was less than 30 percent (True et al. 2013).

For adult salmon, disease has been less frequent and of a different nature. Ich, a protozoan parasite that spreads horizontally from fish to fish, and columnaris have occasionally had a substantial impact, particularly when habitat conditions include exceptionally low flows, high water temperatures, and high densities of fish (such as adult Chinook salmon migrating upstream in the fall and holding at high densities in pools). For adult salmon the effects of Ich and columnaris are generally not as harmful as the observed effects of the myxozoan parasites on juveniles, although the 2002 fish kill in the Lower Klamath River provided dramatic evidence of the ability of Ich and columnaris to cause significant adult salmon mortality, with more than 33,000 adult salmon and steelhead lost during a disease outbreak (CDFG 2004). Most of the fish affected by the 2002 fish die-off were fall-run Chinook salmon in the lower 36 miles of the Klamath River (CDFG 2004). Based on a review of available literature and historical records, this was the largest known pre-spawning adult salmonid die-off recorded on the Klamath River and possibly the Pacific Coast (USFWS 2003). Subsequent reviews of the 2002 fish kill by CDFG (2004), NRC (2004), and USFWS (2003) determined several factors contributed to the epizootic outbreak of Ich and columnaris. An above-average number of Chinook salmon entered the Klamath River during this period. Flows in September 2002 were among the lowest recorded in the last 50 years (CDFG 2004), which may have caused crowding in holding areas that increased transmission of disease. Low flows can also be associated with high water temperature and lower than normal dissolved oxygen concentrations (NRC 2004). While high temperatures may have contributed to the fish kill, temperatures were not unusually high in 2002 when compared to the historical record (Belchick et al. 2004). There is little historical data on dissolved oxygen, but it has been monitoring since 2001—and dissolved oxygen concentrations were similar in 2001 and 2002. During the 2002 fish kill, dissolved oxygen concentrations did not fall below 6.0 mg/L and were eliminated as a potential cause (Belchick et al. 2004). Low river discharges were apparently unsuitable for migrating adult salmon, resulting in a large number congregating in the warm water of the Lower Klamath River (USFWS 2003). Fish passage may also have been impeded by low flows, contributing to crowding (CDFG 2004). The NRC did not rule out low flows as a contributing factor but hypothesized that high water temperatures may have also inhibited the fish from moving upstream (NRC 2004). Whether inhibited by low flows, high temperatures, or both, fish in the Lower Klamath River stopped migrating upstream, resulting in crowded, stressful conditions and possibly longer residence times in a confined reach of the river. Belchick et al. (2004) states that "consideration of all pertinent data led to the conclusion that in 2002 a relatively robust run of adult fall Chinook entered the Klamath River approximately one week earlier than usual. Environmental conditions in the River at the time of the 2002 fall-run Chinook salmon run were characterized by low flow rates and volume, and an apparent lack of migration cues to proceed upriver. The resultant migration delay, crowded conditions, and warm water temperatures provided an ideal environment for the proliferation of Ich and columnaris.

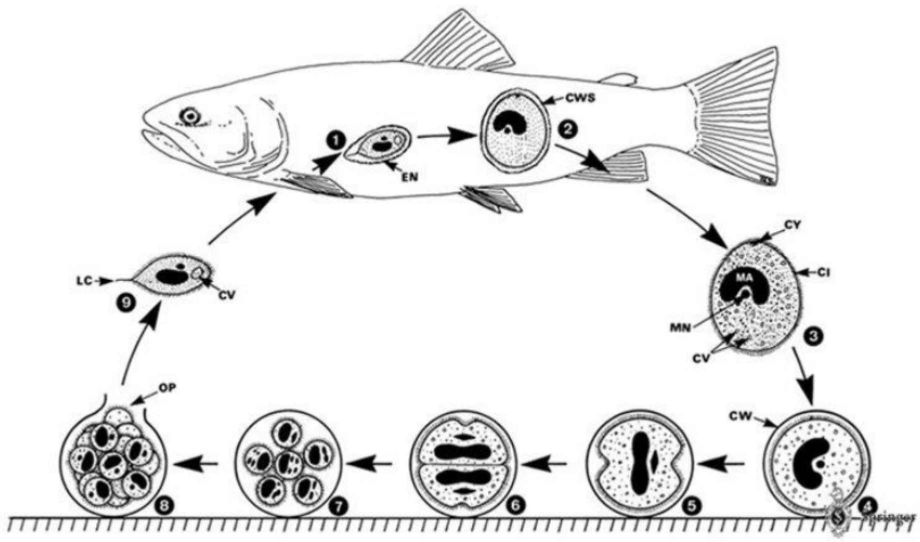

Figure 3.3-3. Lifecycle of *Ichthyophthirius multifis* (Ich). In stages 1 and 2 the adult parasite lives within the fish host; in stage 3 the adult parasite is motile outside of the host fish and attaches to a bottom substrate before dividing into an immature form; in stages 4 through 8 the immature form divides numerous times and is then released as stage 9, the infective stage of the parasite. Source: Strange 2010.

Although losses of adult salmonids can be substantial when events such as the 2002 fish die-off occur, the combination of factors that leads to adult infection by Ich and columnaris disease are not be as frequent as the annual exposure of juvenile salmon to *C. shasta* and *P. minibicornis*, as many juveniles must migrate each spring downstream past established populations of the invertebrate polychaete worm host.

FERC (2007) concluded that the Klamath Hydroelectric Project has likely contributed to conditions that foster disease and lead to salmon losses in the Middle and Lower Klamath River by (1) increasing the density of spawning adult fall-run Chinook salmon downstream from Iron Gate Dam; (2) promoting the development of attached algae beds that provide favorable habitat for the polychaete alternate host for *C. shasta* and *P. minibicornis*; and (3) contributing to water quality conditions that increase the stress level of juvenile and adult salmonids and increase their susceptibility to disease. The water quality conditions that may increase stress levels include: (1) increased water temperatures in the late summer and fall; (2) elevated ammonia concentrations and swings in dissolved oxygen and pH associated with algal blooms in project reservoirs; and (3) effects of exposure to elevated levels of microcystin produced from microcystis blooms in Klamath Hydroelectric Project reservoirs, which may also result in direct mortality. Dissolved oxygen and pH dynamics, including dissolved oxygen concentrations that do not meet the Basin Plan minimum dissolved oxygen criteria and pH concentrations that exceed the Basin Plan instantaneous maximum of 8.5 s.u., for the Hydroelectric Reach, the Middle and Lower Klamath River, and the Klamath River Estuary, are discussed in Section 3.2.2.5 *Dissolved Oxygen* and Section 3.2.2.6 *pH.* A discussion of fish exposure to microcystin toxin in the Hydroelectric Reach and the Klamath River downstream from Iron Gate Dam is presented below in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project – Algal Toxins*. Seasonal production of ammonia occurs in the hypoxic (dissolved oxygen less than 2 mg/L) or anoxic (no dissolved oxygen) bottom waters of Copco No. 1 and/or Iron Gate reservoirs on a seasonal basis. But, no actual ammonia toxicity events have been reported in the reservoirs or in the Middle Klamath River downstream from Iron Gate Dam, and no acute or chronic toxicity exceedances of Basin Plan criteria for ammonia have been observed in the river (Appendix C – *Sections C.3.11* and *C.3.2.1*).

In 2013, NMFS and USFWS issued a joint BiOp (NMFS and USFWS 2013) of the proposed operations of the Klamath Irrigation Project by the USBR in Klamath County in Oregon, and Siskiyou and Modoc counties in California. In this 2013 BiOp, NMFS concluded that flow variability would increase mainstem Klamath River flows when precipitation and snow melt is occurring in the Upper Klamath Basin, which would help to dilute actinospore concentrations and/or disturb polychaetes and their habitats. In addition, it found that flow variability would provide dynamic fluvial environments in the mainstem Klamath River that may impair polychaete fitness, reproductive success, or infection with *C. shasta* and *P. minibicornis*. Compared to observed conditions during the period of record, NMFS concluded that proposed operations of the Klamath Irrigation Project under the 2013 BiOp would increase the magnitude and frequency of peak flows, which would likely decrease the abundance of polychaetes in the spring and summer following a channel maintenance flow event (NMFS and USFWS 2013). The proposed operations of the Klamath Irrigation Project would increase the magnitude and frequency of channel maintenance flows between 5,000 and 10,000 cfs relative to the observed period of record (e.g., the Klamath Irrigation Project would have an estimated two-year flood frequency of 5,454 cfs whereas the observed period of record had 5,168 cfs). This conclusion is also supported by the analysis of Shea et al. (2016), who examined the flow history in the Klamath River relative to sediment mobilization. The increase in magnitude and frequency of channel maintenance flows between 5,000 and 10,000 cfs would likely decrease the abundance of polychaetes in the spring and summer following a channel maintenance flow event (NMFS and USFWS 2013, Alexander et al. 2016, Som et al. 2016b). In the 2013 BiOp, NMFS concluded that the increase in magnitude and frequency of channel maintenance flows between 5,000 and 10,000 cfs would likely decrease the actinospore concentrations relative to the observed period of record when the channel maintenance flow event occurs in the spring, particularly in May and June.

However, the first years of 2013 BiOp implementation included severe drought conditions, and although the USBR was operating the Klamath Irrigation Project in accordance with the 2013 BiOp, the infection rate for *C. shasta* in the Klamath River downstream of Iron Gate Dam greatly exceeded the incidental take maximum (U.S. District Court 2017a). As described in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*, this led to a court-order requiring USBR to provide, as necessary, three specific flows in the Klamath River, as measured immediately downstream of Iron Gate Dam: annual winter-spring surface flushing flows, biennial winter-spring deep flushing flows, and spring-summer emergency dilution flows, if needed (U.S. District Court 2017a–c). The court-ordered flushing flows and emergency dilution flows are not part of existing conditions for the Proposed Project, because they went into effect after the Notice of Preparation was filed by the State Water Board in December 2016, and because the data evaluating the effectiveness of flows and their potential impacts is not yet robust. The flushing and emergency dilution flows are detailed in Section 4.2.1.1 *Summary of Available Hydrology Information for the No Project Alternative* as part of the No Project Alternative because they would likely only continue to apply if Iron Gate Dam remains in place, or if a nidus remains despite dam removal (these flows are also discussed in Section 4.4 *Continued Operations with Fish Passage Alternative*).

Klamath River Estuary and Pacific Ocean Nearshore Environment

While disease and parasites occur in the Klamath River Estuary and Pacific Ocean nearshore environment, these areas are not known to be important source areas for these stressors. Juvenile salmonids that are weakened by disease or parasites upstream may succumb to those diseases once they enter the estuary or ocean as a result of the additional stress created by adapting to the saline environment, but there is no evidence or observations of disease effects in this environment to date.

Fish Hatcheries

Under existing conditions, there are two fish hatcheries located along the Klamath River: Fall Creek Hatchery and Iron Gate Hatchery. Fall Creek Hatchery was built in 1919 by the California Oregon Power Company in Fall Creek, near its confluence with the Klamath River (RM 200.3), as compensation for the loss of spawning grounds that occurred with the construction of Copco No. 1 Dam. Fall Creek Hatchery facilities were last used by CDFW periodically from 1979 to 2003 to raise Chinook salmon yearlings. Fall Creek Hatchery yearlings were released into the Klamath River at Iron Gate Hatchery. Although many of the Fall Creek Hatchery facilities remain operable, the hatchery has not produced fish since 2003 when all fish production was moved to Iron Gate Hatchery.

Iron Gate Hatchery is part of the Lower Klamath Project and was originally constructed in 1962 as mitigation for blockage of fish passage caused by the construction of Iron Gate Dam. Iron Gate Hatchery facilities are located approximately 0.5 miles downstream of Iron Gate Dam, adjacent to the Bogus Creek tributary. CDFW operates Iron Gate Hatchery with the following annual production goal (CDFW 2014):

- 75,000 yearling coho salmon (age-1 releases during spring)
- 900,000 yearling fall-run Chinook salmon (age-1 releases during fall)
- 5,100,000 fall-run Chinook salmon smolts (age-0 releases during spring)
- 200,000 yearling steelhead (age-1 releases during spring)

However, the ability to meet the above production goals varies annually based on adult returns and hatchery performance. Coho salmon production has averaged 75,000 yearlings (achieving production goals) and 866 adult returns on an annual basis (CDFW 2014). Coho returns to Iron Gate Hatchery have significantly and steadily declined from a high of 2,466 adults in the 2001/2002 return year to a low of 38 adults in the 2015/2016 return year (CDFW 2016b). From 2005 through 2018 actual fall-run Chinook salmon yearling production has averaged 955,931 (exceeding production goals), and actual smolt production has averaged 4,276,728 (around a million fewer smolts than the goal on average) (K. Pomeroy, CDFW, pers. comm., 2018). The fall-run Chinook salmon hatchery spawner return goal is 8,000 fish. Total Chinook salmon returns to Iron Gate Hatchery between 1978 and 2016 ranged from 2,558 to 72,474 and averaged

16,206 fish (CDFW 2017). From 2000 to 2016, adult winter steelhead returns to Iron Gate Hatchery averaged 242, and peaked at 631 in 2001 (CDFW 2016b). Returns have been declining, and in 2016 no adult steelhead returned to the hatchery (CDFW 2016b). The low adult returns of steelhead have resulted in no production of steelhead yearlings from Iron Gate Hatchery since 2012.

It appears that progeny from Iron Gate Hatchery releases have contributed significantly to the ocean and in-river fisheries since the late 1960s (PacifiCorp 2004a). PacifiCorp (2004a) estimates that based on smolt-to-adult survival studies conducted on Iron Gate fall Chinook salmon, the Iron Gate Hatchery production contributes about 50,000 fish annually to the Chinook salmon, coho salmon, and steelhead fisheries, in addition to escapement back to the hatchery.

The net effect of hatchery releases on naturally occurring stocks is difficult to assess, with both positive and negative consequences potentially occurring due to a multitude of factors including, brood stock source, system carrying capacity, timing of release, degree of competition, and environmental selection pressures (NMFS 2017), as discussed below. Potential benefits of hatchery releases include increases in adult abundance supporting fisheries and increased marine-derived nutrient transfer to freshwater systems from returning hatchery-origin adults (NMFS 2017). Potential negative effects include genetic risks, competition and predation, hatchery facility effects on water quality, effects of weirs and other hatchery infrastructure, masking of current wild population status due to the presence of large numbers of hatchery-origin fish, incidental fishing pressure, and disease transfer from hatchery to wild fish. CDFW (2014) noted that in the Klamath River, adverse hatchery-related effects pose a very high stress to all life stages of natural salmon populations because hatchery origin adults make up greater than 30 percent of the total number of adults. Data from Ackerman et al. (2006) indicate that substantial straying of Iron Gate Hatchery fish may be occurring into important tributaries of the Middle Klamath River. Straying has the potential to reduce the reproductive success of natural salmonid populations (Mclean et al. 2003, Chilcote 2003, Araki et al. 2007) and negatively affect the diversity of the populations via outbreeding depression[85] (Reisenbichler and Rubin 1999). Returns of adult salmon to Iron Gate Hatchery, and fall-run Chinook salmon in particular, influence aquatic resources in the Middle and Lower Klamath River. Iron Gate Hatchery (RM 192.4) has a profound influence on Klamath River fall Chinook salmon in the vicinity of the hatchery. Kinziger et al. (2013) found the proportion of naturally spawning fall Chinook salmon of origin decreased with distance from the hatchery. Natural origin Chinook sampled in Bogus Creek (RM 192.6), Shasta River (RM 179.5), and the Scott River (RM 145.1) had decreasing proportions of hatchery genetics with increasing distance from the hatchery. The influence of Iron Gate Hatchery genetics on fall Chinook salmon is greatly diminished by the confluence with the Scott River.

A Hatchery Genetic Management Plan (HGMP) for the Iron Gate Hatchery (CDFW 2014) recently redefined the operation of this hatchery from a mitigation hatchery to one now operated to protect and conserve the genetic resources of the Upper Klamath population unit of the SONCC coho salmon ESU. Included in the HGMP are defined monitoring and evaluation activities to evaluate effects of the hatchery activities on the abundance, productivity, spatial structure, and diversity of the SONCC coho salmon and

[85] Outbreeding depression is the displacement of locally adapted genes in a wild population.

the magnitude or relative impact of the hatchery program on other actions that influence SONCC coho salmon.

Fall-run Chinook salmon returns to Iron Gate Hatchery and the blockage created by Iron Gate Dam, concentrate spawners and post-spawn carcass densities between Iron Gate Dam and the Shasta River confluence. As described in the *Disease and Parasites* section above, high parasite prevalence in the Lower Klamath River is considered to be a combined effect of high spore input from heavily infected, spawned adult salmon that congregate downstream from Iron Gate Dam and Iron Gate Hatchery and the proximity to dense populations of polychaetes (Bartholomew et al. 2007).

The release of Chinook salmon smolts and yearlings from Iron Gate Hatchery also affects disease interactions. The release from Iron Gate Hatchery overlaps temporally and spatially with the period of high infection potential, and studies suggest that therefore a high proportion of the Iron Gate Hatchery Chinook salmon stock can become infected with *C. shasta* and *P. minibicornis* (Som et al. 2016a). The hatchery-released juvenile fish that become infected and experience mortality lower in the Klamath River may become another source of myxospores to the Lower Klamath River.

The Chinook salmon released to the Klamath River annually also likely result in deleterious effects on natural spawning populations, including competitive pressure between hatchery-derived and natural origin fish in the limited habitat areas (e.g., thermal refugia) used by rearing juveniles in the Klamath River (NMFS 2010a). Iron Gate Hatchery releases Chinook salmon from the middle of May to the end of June, a period when discharge from Iron Gate Dam is in steep decline and water temperatures are rapidly rising, which may create competition between hatchery and natural fish (Chinook salmon, coho salmon, and steelhead) for food and limited resources, especially limited space and resources in thermal refugia (NMFS 2010a). Negative hatchery effects due to competition, leading to displacement and lower growth, are well documented (Flagg et al. 2000, McMichael et al. 1997). In the Clackamas River, Oregon, hatchery steelhead released in the upper basin resulted in an exceedance of system carrying capacity, resulting in negative outcomes for natural-origin fish (Kostow et al. 2003 and Kostow and Zhou 2006) and up to a 50 percent decline in the number of recruits per spawner and a 22 percent decline in the maximum number of natural-origin recruits. These trends appear to have reversed after releases of hatchery fish were discontinued in 2000. Such density-dependent negative effects of hatchery-released fish can extend even into the marine environment, especially during periods of poor ocean conditions (Beamish et al. 1997, Sweeting et al. 2003).

Algal Toxins

Algae produced in Upper Klamath Lake and the reservoirs in the Klamath Hydropower Reach (Copco No. 1 and Iron Gate reservoirs) may be deleterious to the health of aquatic organisms in Upper Klamath Lake and the Klamath River. Some cyanobacteria species, such as *Microcystis aeruginosa*, produce toxins that can cause irritation, sickness, or in extreme cases, death to exposed organisms (see Section 3.2.2.7 *Chlorophyll-a and Algal Toxins* and Appendix C.6). While direct links to fish health are still somewhat unclear, data collected from the Klamath Basin indicates that algal toxins bioaccumulate in tissue from fish and mussels at concentrations that may be detrimental to the affected species (Fetcho 2011), as discussed below.

While the Proposed Project would not affect the occurrence of algal toxins in Upper Klamath Lake, the following summary is provided to characterize ongoing research regarding the potential effects of microcystin toxin on native fish species in the Klamath Basin. A reconnaissance study was conducted in Upper Klamath Lake to evaluate the presence, concentration, and dynamics of microcystin exposure by Lost River sucker and shortnose sucker. The U.S. Geological Survey (USGS) collected water samples at multiple lake sites from July to October 2007 and June through September 2008 and found evidence of gastrointestinal lesions in juvenile suckers sampled from around the lake, although organ damage was absent from many fish and most of the affected fish were collected in the northern portion of the lake. The pathology of the lesions was consistent with exposure to microcystin, and evidence of a route of exposure was suggested by gut analysis showing that juvenile suckers had ingested chironomid larvae, which had in turn ingested *Aphanizomenon flos-aquae* and colonies of *Microcystis aeruginosa*. The lesions were observed when liver necrosis was either present or absent suggesting that the gastro-intestinal tract was the first point of toxin contact. The authors hypothesized that the lesions were caused by algal toxins, and that the route of exposure to toxins was an oral route through the food chain, rather than exposure to dissolved toxins at the gills (VanderKooi et al. 2010). However, there were other possible explanations for the lesions, including the potential for an undetected viral infection. Conclusive pathology experiments demonstrating that exposure of juvenile suckers to algal toxins via the described oral routes can cause the types of lesions observed have not yet been done. The pathologies and evidence therefore are consistent with the hypothesis of exposure to algal toxins but do not constitute proof of a causal mechanism. Additional work to describe the observed pathologies is ongoing.

In the Hydroelectric Reach and the Klamath River downstream from Iron Gate Dam, the occurrence of microcystin toxin in fish and mussel tissue has been reported in multiple studies with variable results depending on season, location, and fish species (Fetcho 2006; Kann 2008; CH2M Hill 2009a,b; Prendergast and Foster 2010; Kann et al. 2010 a,b; Kann et al. 2013; Fetcho 2011). During July through September 2007, 85 percent of fish and mussel tissue samples collected from the Klamath River, including samples from Iron Gate and Copco No. 1 reservoirs, exhibited microcystin bioaccumulation, with the total microcystin congeners ranging from less than detection levels to 2,803 ng/g (Kann 2008). While it is not known whether the levels of microcystin bioaccumulation measured in 2007 were harmful to fish and/or mussel populations, levels exceeded the public health guidelines defined by Ibelings and Chorus (2007), indicating that ingestion of the fish or mussels would potentially pose a health hazard to humans (Kann 2008). Within Copco No. 1 and Iron Gate reservoirs, samples of muscle and liver tissues from resident fish (e.g., yellow perch [*Perca flavescens*] and crappie [*Pomoxis nigromaculatus*]) exhibited detectable levels of two of eight microcystin congeners (i.e., chemically different forms of microcystin) in muscle and liver tissues of 36 yellow perch samples during September 2007 (Kann 2008). Unbound or "free" microcystin (the form of microcystin that could be further bioaccumulated if the fish were to be ingested by humans or other predators) was not detected in muscle tissues of yellow perch and crappie during May, June, July, September, and November 2008 (total samples = 196) (CH2M Hill 2009a). In 2010, algal toxins were found in salmonid tissues collected from the Middle Klamath River near Happy Camp (Kann et al. 2013). In contrast, data from 2008 and 2009 did not show microcystin bioaccumulation in the tissue and liver samples from fish collected from Copco No. 1 and Iron Gate reservoirs (CH2M Hill 2009, PacifiCorp 2010).

Further downstream in the Lower Klamath River, Fetcho (2006) reported that liver and muscle tissue samples from five Chinook salmon taken from the Klamath River at or near Weitchpec (near RM 43.3) in 2005 did not contain detectable levels of microcystin. However, two steelhead liver samples, collected on October 3, 2005 did contain measurable levels of microcystin at trace and 0.54 ug/g concentrations. PacifiCorp collected liver and muscle tissue samples from five Chinook salmon and three steelhead in the middle Klamath River and the Lower Klamath River downstream from the Trinity River in October 2007 and reported that no detectable levels of un-bound or “free” microcystin (the form of microcystin that could be further bioaccumulated if the fish were to be ingested by humans or other predators) were found (CH2M Hill 2009b). Because fish livers are not typically consumed, those fish exhibiting elevated microcystin levels in liver tissue may not have posed a public health concern with respect to consumption.

As noted above, while it is not known whether the levels of microcystin measured in the Lower Klamath River fish tissue samples were harmful to fish populations, the range of concentrations (up to approximately 2,800 ng/g) indicate that direct effects to fish health due to microcystin exposure such as stress and/or disease are a possibility (Kann et al. 2013). During the October period that Chinook salmon samples were collected, the 2010 longitudinal microcystin sampling in river water showed very high microcystin levels being exported from Iron Gate Reservoir and transported downstream to areas where Chinook salmon were migrating upstream. The variation in fish tissue results in Copco No. 1 and Iron Gate reservoirs and the Klamath River downstream from Iron Gate Dam across multiple studies suggests that a combination factors is likely to influence the concentration of microcystin in fish tissue, including patchy distributions of algal blooms within the Lower Klamath Project reservoirs and the downstream Klamath River, the ability of fish to move in and out of algal bloom areas where microcystin is likely most prevalent, and food web interactions that may result in differing degrees of bioaccumulation depending on the fish species.

Microcystin can also bioaccumulate in the tissue of mussels in the Lower Klamath River. Kann (2008) reported on the concentrations of eight individual microcystin congeners in freshwater mussel tissue samples obtained from the Klamath River in July and November 2007. Microcystin congeners were detected in July in composite and individual tissue samples from the Klamath River near the Klamath Highway Rest Area (at RM 178), near Seiad Valley (at RM 132.7) and at Big Bar (near RM 51). Individual mussel samples taken later in the year in November from the Klamath River near Orleans (at RM 59), near Happy Camp (at RM 108), near Seiad Valley (at RM 132.7), at the Brown Bear River Access (at RM 157.5), and near the Klamath Highway Rest Area (at RM 178) did not contain detectable levels of microcystin congeners. As noted above, 85 percent of fish and mussel tissue samples collected during July through September 2007 in the Klamath River, including Iron Gate and Copco No. 1 reservoirs, exhibited microcystin bioaccumulation (Kann 2008). While it is not known whether the levels of microcystin measured in the Lower Klamath River mussel tissue samples were harmful to mussel populations, results indicated that all of the World Health Organization (WHO) total daily intake guideline values were exceeded, including several observations of values exceeding acute total daily intake thresholds (Kann 2008). In a retrospective letter to PacifiCorp (August 6, 2008), the California OEHHA stated that they “would have recommended against consuming mussels from the affected section of the Klamath River, and yellow perch from Iron Gate and Copco No. 1 Reservoirs, because their average concentrations exceeded 26 nanograms per gram (ng/g),” which is the OEHHA upper bound of advisory tissue levels fish or shellfish consumption (for a single serving per week based on 8 ounces uncooked fish). Additional public health advisories were issued in 2009 and 2010 in Copco No. 1 and Iron Gate reservoirs, as well as downstream locations in the Klamath River (including locations on the Yurok Reservation), for microcystin levels in ambient and/or freshwater mussel tissue (Kann et al. 2010a,b, Fetcho 2011).

Aquatic Habitat and Instream Flows

Instream flows influence habitat availability for aquatic species. USBR manages Upper Klamath Lake to meet the requirements of the 2013 BiOp (NMFS and USFWS 2013)[86] and its contract requirements for USBR's Klamath Irrigation Project (USBR 2010). The Klamath Irrigation Project affects instream flows in the Klamath River downstream of Upper Klamath Lake, including the California portion of the Area of Analysis for aquatic resources. Studies to determine how fish habitat changes with flow have been conducted in portions of the Klamath River, including two reaches between J.C. Boyle Reservoir and Iron Gate Dam, for selected life stages of rainbow trout (BLM 2002) and seven locations between Iron Gate Dam and the Klamath River Estuary for selected life stages of Chinook salmon, coho salmon, and steelhead (Hardy et al. 2006).

The following sections describe the amount of flow-related aquatic species habitat in various portions of the Klamath. Where specific information is not available for a species or area, the analysis contained herein uses hydrologic changes, species habitat requirements, and comparisons with those species for which there is specific information to qualitatively assess changes in flow-related habitat. This information was used to evaluate how the Proposed Project might result in changes to the amount of flow-related habitat. It was not possible to rely on the hydrologic record of the past decade for describing the amount of habitat available under existing conditions because of management actions made over the past eight years to protect listed fish species (e.g., minimum Upper Klamath Lake elevations, minimum flows downstream from Iron Gate Dam). These changes are described in the 2013 BiOp for the Klamath Irrigation Project (NMFS and USFWS 2013), and the instream flows under existing conditions are described in Table 3.6-8 in Section 3.6.2.2 *Basin Hydrology*.

The natural hydrograph (flow regime) of a river is the characteristic pattern of flow quantity, timing, rate of change of hydrologic conditions, and variability across time scales (hours to multiple years), all without the influence of human activities (Poff et al. 1997). There are no measured river discharge data downstream from Keno Dam prior to implementation of USBR's Klamath Irrigation Project. However, modeled flows downstream of Iron Gate Dam that explicitly remove the Klamath Irrigation Project flow component offer a reasonable approximation of natural discharge downstream of Keno Dam (USBR 2005). Model results indicate that the historical, natural hydrograph for the Klamath River and its tributaries was characterized by high spring flows triggered by melting snow, typically near the end of April, followed by receding flows during summer months, and the base flow condition by September (NRC 2004). This recurring

[86] As described in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*, following implementation of the 2013 BiOp, a court-order required USBR to implement three specific flows in the Klamath River: winter-spring surface flushing flows, winter-spring deep flushing flows, and spring-summer emergency dilution flows (U.S. District Court 2017a–c). The court-ordered flushing flows and emergency dilution flows are not part of existing conditions for the Proposed Project, because they went into effect after the Notice of Preparation was filed by the State Water Board in December 2016.

seasonal flow pattern influenced the adaptations of native aquatic organisms, as reflected in the timing of their key life history stages (NRC 2004). Given the diversity of flows inherent to the natural hydrograph, the Klamath River historically supported a range of riverine habitats and allowed the various anadromous fish species and life history strategies to evolve over time.

Upper Klamath River and Connected Waterbodies

USBR manages Upper Klamath Lake to meet the requirements of the 2013 BiOp (NMFS and USFWS 2013)[87] and its contract requirements for USBR's Klamath Irrigation Project (USBR 2010). Aquatic habitat and instream flows in the Upper Klamath River upstream of the influence of J.C. Boyle Reservoir are not thoroughly analyzed for this EIR, since aquatic species within California are not heavily influenced by these flows other than through the operation of the USBR's Klamath Irrigation Project, where the latter is controlled through the requirements of the 2013 BiOp (see below discussions).

Upper Klamath River – Hydroelectric Reach

Under its existing license, PacifiCorp operates the J.C. Boyle Powerhouse as a peaking facility, meaning that water is run through the powerhouse to generate electricity cyclically depending on water availability and power demand. Rapid changes in flow associated with hydropower peaking operations, can result in inhospitable conditions for aquatic species downstream. Peaking operations at J.C. Boyle Powerhouse result in fluctuating flows in the Hydroelectric Reach of the Upper Klamath River that vary based on power generation needs. For example, substantial changes in flow (from 350 to 3,000 cfs) can occur within the course of a single day in the 17-mile long J.C. Boyle Peaking Reach (the reach of the Klamath River between J.C. Boyle Powerhouse and Copco No. 1 Reservoir). These flow fluctuations in this reach can also result in rapid temperature changes between 5 and 59°F during the summer months (ODEQ 2010). These flow fluctuations may also result in stranding of fish and invertebrates (Dunsmoor 2006), reductions in aquatic invertebrate production (City of Klamath Falls 1986, as cited in Hamilton et al. 2011), displacement of fish, and higher energetic costs to fish to maintain their position (FERC 2007). In the trial-type hearing for the relicensing of the Klamath Hydroelectric Project (NMFS 2006a), it was found that this reach had lower macroinvertebrate drift rates than would occur without the hydroelectric project operations, suggesting a reduced food base for fish.

Fish studies in the Lower Klamath River have shown considerable biological impacts due to power peaking flows (City of Klamath Falls 1986, FERC 2007, BLM 2002, Wales and Coots 1950). From June 1948 to May 1949, Wales and Coots (1950) estimated that hydropower peaking operations resulted in the loss of over 1.8 million salmonid fingerlings downstream from Copco No. 1 and Copco No. 2 dams. Daily mean flows fell below 100 cfs in the Klamath River downstream from Copco No. 2 Dam and near Fall Creek (USGS Gage No. 11512500) on fifty occasions between water years 1931 and 1937.

[87] As described in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*, following implementation of the 2013 BiOp a court-order required USBR to implement three specific flows in the Klamath River: winter-spring surface flushing flows, winter-spring deep flushing flows, and spring-summer emergency dilution flows (U.S. District Court 2017a–c). The court-ordered flushing flows and emergency dilution flows are not part of existing conditions for the Proposed Project, because they went into effect after the Notice of Preparation was filed by the State Water Board in December 2016.

Middle and Lower Klamath River

As described in Section 3.1.6.1 *Klamath River Flows under the Klamath Irrigation Project's 2013 BiOp*, the 2013 BiOp provides minimum flows downstream of Iron Gate Dam for the protection of coho salmon. The 2013 BiOp also includes an Environmental Water Account (EWA) with provisions for flow alterations to protect ESA-listed species, including the release of dilution/flushing water from Upper Klamath Lake to reduce juvenile coho salmon disease below Iron Gate Dam. Consultation with NMFS and USFWS has been reinitiated on the Klamath Irrigation Project in the Upper Klamath Basin (see Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*). Additional detail on flows and habitat in the Middle and Lower Klamath River are provided in Section 3.6.2.2 *Basin Hydrology*.

Klamath River Estuary and Pacific Ocean

Aquatic habitat within the Klamath River Estuary is highly influenced by freshwater inflows from upstream, and physical processes in the estuary such as sand-berm dynamics at the river mouth. The Klamath River Estuary spans approximately four to five miles upstream of the mouth. Wallace (1998) notes the formation of a sill at the river mouth in late summer or early fall causing a standing water backup up to six miles upstream. During high tides, saltwater was observed in the summer and early fall from the mouth upstream, ranging approximately 2.5 to four miles depending on the time period in which samples were taken (Wallace 1998).

Water temperatures in the Klamath River Estuary are related to temperatures and flows entering the estuary, the presence and location of a salt water wedge, and the timing and duration of the formation of a sand berm across the estuary mouth. The salt water wedge is formed when the estuary mouth is open and denser salt water from the ocean sinks below the lighter fresh river water; the resulting wedge moves up and down the estuary with the daily tides. The salt water wedge results in thermal stratification of the estuary with cooler, high salinity ocean waters remaining near the estuary bottom, and warmer, low salinity river water near the surface. Input of cool ocean water and fog along the coast minimizes extreme water temperatures much of the time (see also Section 3.2.2.2 *Water Temperature*).

Critical Habitat

The ESA requires that USFWS and NMFS designate critical habitat[88] for the listed species they manage. Critical habitat has been designated for four species within the California portion of the Area of Analysis for aquatic resources: coho salmon, shortnose suckers, Lost River suckers, and eulachon. The endangered population of Southern Resident Killer Whales that includes Klamath River salmon in its diet is also discussed here, and critical habitat for green sturgeon is discussed as well, despite the exclusion of Klamath River from the critical habitat designation.

[88] The ESA defines critical habitat as "the specific areas within the geographical area occupied by the species, at the time it is listed, on which are found those physical or biological features (I) essential to the conservation of the species and (II) which may require special management considerations or protection; and specific areas outside the geographical area occupied by the species at the time it is listed that are determined by the Secretary to be essential for the conservation of the species."

Coho Salmon

Critical habitat for the SONCC coho salmon ESU was designated on May 5, 1999 and includes the water, substrate, off-channel habitat, and adjacent riparian zones of estuarine and riverine reaches accessible to listed coho salmon between Cape Blanco, Oregon and Punta Gorda, California. Marine areas were excluded from the final critical habitat designation. "Accessible reaches" are defined as those within the historical range of the ESU that can still be occupied by any life stage of coho salmon. Specifically, in the Klamath Basin, all river reaches downstream from Iron Gate Dam on the Klamath River and Lewiston Dam on the Trinity River are designated as critical habitat (NMFS 1999b).

Features of critical habitat considered essential for the conservation of the SONCC ESU (NMFS 1997b) include (1) substrate, (2) water quality, (3) water quantity, (4) water temperature, (5) water velocity, (6) cover/shelter, (7) food, (8) riparian vegetation, (9) space, and (10) safe passage conditions. Primary Constituent Elements (PCEs) for SONCC coho salmon are described in NMFS (1999b) as follows: "In addition to these factors, NMFS also focuses on the known physical and biological features (PCEs) within the designated area that are essential to the conservation of the species and that may require special management considerations or protection. These essential features may include, but are not limited to, spawning sites, food resources, water quality and quantity, and riparian vegetation."

Shortnose Sucker and Lost River Sucker

The final designation of critical habitat for shortnose and Lost River suckers was published by the USFWS on December 11, 2012 (USFWS 2012). The proposed critical habitat area is within Klamath and Lake Counties, Oregon, and Modoc County, California. Critical habitat units include: (1) approximately 146 stream miles and 117,848 acres of lakes and reservoirs for Lost River sucker; and (2) approximately 128 stream miles and 123,590 acres of lakes and reservoirs for shortnose sucker (USFWS 2012).

The 2013 Revised Recovery Plan (USFWS 2013a) identifies a recovery unit for both shortnose and Lost River within the California portion of the Area of Analysis: the reservoirs along the Klamath River downstream of Keno Dam (including Copco No. 1, Copco No. 1, and Iron Gate reservoirs), known as the Klamath River Management Unit.

When proposing critical habitat, USFWS considers the physical and biological features essential to the conservation of the species which may require special management considerations or protection. These include, but are not limited to: (1) space for individual and population growth and for normal behavior; (2) food, water, air, light, minerals, or other nutritional or physiological requirements; (3) cover or shelter; (4) sites for breeding, reproduction, or rearing (or development) of offspring; and (5) habitats that are protected from disturbance or are representative of the historical, geographical, and ecological distributions of a species. PCEs are the specific elements of physical and biological features that are essential to the conservation of the species. The PCEs identified in the critical habitat designation are as follows: (1) water in sufficient depths and quantity; (2) spawning and rearing habitat; and (3) areas that contain abundant food (USFWS 2013a). The 2013 Revised Recovery Plan (USFWS 2013a) cites predominant threats to these suckers as lack of spawning habitat, continued loss of habitat, lake elevation fluctuations that reduce access to vegetated habitat, water diversions, competition and predation by introduced species, hybridization with other sucker species, isolation of remaining habitats, and drought. Degradation of water quality resulting from timber harvest, dredging activities, removal of riparian vegetation, and livestock grazing may also cause problems for these species (USFWS 2013a).

Green Sturgeon

In 2009, NMFS designated critical habitat for the Southern DPS of green sturgeon which encompasses all coastal marine waters of the United States less than 60 fathoms deep (approximately 360 ft) from Monterey Bay, California north to Cape Flattery, Washington. The estuary portion of the Eel and Klamath/Trinity rivers was specifically excluded from the critical habitat designation (NMFS 2009b). The Northern DPS of green sturgeon, the only DPS documented to occur in the Klamath Basin, is not federally listed and therefore critical habitat has not been designated for this DPS.

Eulachon

Critical habitat for the Southern DPS eulachon in the Klamath River was designated by NMFS on October 20, 2011 (NMFS 2011). NMFS designated approximately 539 miles of riverine and estuarine habitat in California, Oregon, and Washington within the geographical area occupied by the Southern DPS of eulachon. The designation includes 16 rivers and creeks extending from and including the Mad River, California to the Elwha River, Washington. NMFS did not include any nearshore marine or offshore areas in the Eulachon critical habitat designation. NMFS did not identify any unoccupied areas as being essential to conservation and thus, did not designate any unoccupied areas as critical habitat. Tribal lands were excluded from designation after evaluating the impacts of designation and benefits of exclusion associated with Tribal land ownership and management by the Tribes. NMFS excluded from designation all lands of the Lower Elwha Tribe, Quinault Tribe, Yurok Tribe, and Resighini Rancheria. These lands were excluded because designating these Tribes' Indian lands as critical habitat would have an impact on federal policies promoting Tribal sovereignty and self-governance. In the Lower Klamath River, designated critical habitat extends from the mouth of the Klamath River upstream to Omogar Creek, a distance of 10.7 miles, excluding tribal lands. The physical or biological features essential for conservation of this species include: (1) freshwater spawning and incubation sites with water flow, quality, and temperature conditions and substrate supporting spawning and incubation; (2) freshwater and estuarine migration corridors free of obstructions with water flow, quality and temperature conditions supporting larval and adult mobility, and with abundant prey items supporting larval feeding after the yolk sac is depleted; and (3) nearshore and offshore marine foraging habitat with water quality and available prey, supporting juveniles and adult survival.

Southern Resident Killer Whale

In November 2006, NMFS designated critical habitat for Southern Resident Killer Whales (NMFS 2006c). Critical habitat includes all waters seaward from a contiguous line delimited by the 20-foot depth relative to extreme high water within three designated areas: (1) the Haro Strait and waters around the San Juan Islands; (2) Puget Sound; and (3) the Strait of Juan de Fuca. Coastal and offshore areas have not been designated as critical habitat, though they are recognized as important for the Southern Resident Killer Whales. No critical habitat for Southern Resident Killer Whales occurs within the Area of Analysis for aquatic resources. However, the PCEs for Southern Resident Killer Whales includes: (1) water quality to support growth and development; (2) prey species of sufficient quantity, quality and availability to support individual growth, reproduction and development, as well as overall population growth; and (3) passage conditions to allow for migration, resting, and foraging.

Within the Area of Analysis, the PDE for "prey species" is relevant. During winter, two of the three pods of Southern Resident Killer Whales (named the K and L Pods) frequent the outer west coast of the United States as far south as California, eating Columbia/Snake River, Central Valley, Puget Sound, Fraser River, and other coastal stocks of Chinook salmon. While Southern Resident Killer Whales have been shown to consume Klamath River Chinook Salmon, the Klamath River is considered by NMFS and WDFW tenth out of the top ten priority Chinook Salmon populations for Southern Resident Killer Whales (NMFS 2018b, NMFS and WDFW 2018).

Essential Fish Habitat (EFH)

EFH is designated for commercially fished species under the Magnuson-Stevens Fishery Conservation and Management Reauthorization Act (Magnuson-Stevens Act). The Magnuson-Stevens Act (section 3) defines EFH as "those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity." Adverse effects occur when EFH quality or quantity is reduced by a direct or indirect physical, chemical, or biological alteration of the waters or substrate, or by the loss of (or injury to) benthic organisms, prey species and their habitat, or other ecosystem components. The Magnuson-Stevens Act requires federal fishery management plans, developed by NMFS and the Regional Fishery Management Councils, to describe the habitat essential to the fish being managed and to describe threats to that habitat from both fishing and non-fishing activities. To protect EFH, federal agencies are required to consult with NMFS on activities that may adversely affect EFH.

EFH has been designated for three species of salmon, 83 groundfish species, and five pelagic species in the Area of Analysis for aquatic resources. EFH includes freshwater, estuarine and marine waters for salmon, and marine waters for coastal pelagic and groundfish species. More specific descriptions of EFH are provided below.

Chinook and Coho Salmon

Coho and Chinook salmon are managed under the Magnuson-Stevens Act and EFH is described in Amendment 14 to the Pacific Coast Salmon Fishery Management Plan (PFMC 2012). EFH for Chinook salmon is also described in the same management plan and is identical to that for coho salmon in the Klamath Basin. EFH has been designated for the mainstem Klamath River and its tributaries from its mouth to Iron Gate Dam, and upstream the Trinity River to Lewiston Dam. EFH includes the water quality and quantity necessary for successful adult migration and holding, spawning, egg-to-fry survival, fry rearing, smolt migration, and estuarine rearing of juvenile coho and Chinook salmon.

Groundfish

EFH for Pacific Coast groundfish includes all waters and substrate within areas with a depth less than or equal to 1,914 fathoms (approximately 3,500 meters) shoreward to the mean higher high-water level or the upstream extent of saltwater intrusion (defined as upstream and landward to where ocean-derived salts measure less than 0.5 ppt during the period of average annual low flow). The Klamath River Estuary, which extends from the river's mouth upstream to near the confluence with Ah Pah Creek, is included in the Pacific groundfish EFH (50 CFR § 660.395).

Pelagic Fish

EFH for coastal pelagic species, including finfish (northern anchovy, Pacific sardine, Pacific [chub] mackerel, and jack mackerel) and market squid, occurs from the shorelines of California, Oregon, and Washington westward to the exclusive economic zone[89] (370 km off coast) and above the thermocline where sea surface temperatures range from 50 to 78.8ºF. During colder winters, the northern extent of EFH for coastal pelagic species may be as far south as Cape Mendocino, and during warm summers it may extend into Alaska's Aleutian Islands. In each of these seasonal examples, the Klamath River Estuary and coastline would be included as EFH for these species.

3.3.3 Significance Criteria

The Proposed Project could affect aquatic resources directly or indirectly, and through a variety of mechanisms. These effects could be additive or offsetting. In determining the significance criteria, the Lower Klamath Project EIR analysis considers the total effect of the factors described above on native fish populations and their habitat in relation to the Proposed Project. These impacts could vary substantially in intensity, severity, geographic extent, population-level impact, and duration. The intensity of an impact refers to how severely it affects an organism. This severity can range from sublethal behavioral adaptations such as avoidance of a specific condition, to mortality. The geographic extent refers to how much of the species' potential habitat is affected. Population-level impact refers to the proportion of the total population that is expected to be affected. As described above in Section 3.3.2.1 Aquatic Species [coho salmon], Williams et al. (2006) described nine population units of coho salmon in the Klamath Basin to support recovery planning for the listed coho salmon SONCC ESU. Analysis of coho salmon in this EIR considers impacts and benefits for each of the nine population units in the Klamath Basin separately but makes a significance determination for all population units combined within the Klamath Basin to be consistent with the approach to assessing other aquatic species populations. Duration refers to how long the effect is anticipated to persist (hours, days, months, or years), and considers resiliency of the population to the impact (e.g., resilient populations recovery more quickly to impacts). Criteria for determining significant impacts on aquatic resources are also informed by Appendix G of the CEQA Guidelines (California Code of Regulations title 14, section 15000 et seq.).

The Lower Klamath Project EIR considers short- and long-term effects to aquatic resources. For the Proposed Project aquatic resources impact analysis, short term is defined as less than five years following dam removal (unless otherwise indicated), which includes the periods of reservoir drawdown, dam deconstruction, and early restoration activities. A period of five years was selected as short-term, because for most aquatic resources this represents one to two generations. Long term is defined as more than five years following dam removal (unless otherwise indicated), which in most cases is more than two generations.

In the short term, effects of the Proposed Project would be significant if they:

- Substantially reduce the abundance (greater than 50 percent reduction) of a year class for aquatic species.
- Substantially decrease the quality or availability (greater than 50 percent reduction) of habitat for a native aquatic species.

[89] Exclusive economic zone is a sea zone prescribed by the United Nations Convention on the Law of the Sea over which a state has special rights regarding the exploration and use of marine resources.

- Substantially decrease the quality of designated PCEs, or availability (greater than 50 percent reduction) of designated critical habitat under the ESA, or EFH under the Magnuson-Stevens Act.

In the long term; five years after removal of all dams, effects of the Proposed Project would be significant if they:

- Substantially reduce the abundance (greater than 50 percent reduction) of an adult population or year class for aquatic species.
- Substantially decrease the quality or availability (greater than 50 percent reduction) of habitat for a native aquatic species.
- Substantially decrease the quality of designated PCEs, or availability (greater than 50 percent reduction) of designated critical habitat under the ESA, or EFH under the Magnuson-Stevens Act.

3.3.4 Impact Analysis Approach

This section provides an overview of the methods used in the evaluation of aquatic resources. This section is organized to describe methods used to evaluate effects on physical habitat (e.g., from suspended sediment, bed elevation, water quality, etc.), as well as the methods used to address effects on biological process such as fish disease and parasites. Methods are also described to specifically address aquatic habitat, critical habitat, Essential Fish Habitat (EFH), and communities that respond to environmental impacts unique from fish species such as freshwater mussels and benthic macroinvertebrates.

The following sources were assessed to determine the scope of existing local policies relevant to the Proposed Project:

- Del Norte County General Plan (Mintier & Associates et al. 2003):
  - Section 1 (Natural Resources/Conservation), Policies 1.A.1, 1.A.6, 1.A.14, 1.B.1, 1.C.1, 1.C.2, 1.C.3, 1.C.4, 1.E.2, 1.E.3, 1.E.8, 1.E.9, 1.E.11, 1.E.12, 1.E.28, and 1.E.29
- Humboldt County General Plan for Areas Outside of the Coastal Zone (Humboldt County 2017):
  - Conservation and Open Space Element, Water Resources Element, Policies BR-P4, BR-P11, BR-P12, BR-S2, BR-S4, BR-S6, WR-P5, WR-P23, WR-P39, and WR-P46
- Klamath County Comprehensive Plan (Klamath County 2010):
  - Goal 5 (Open Space, Scenic, and Historic Area and Natural Resources), Policy 16
- Siskiyou County General Plan (Siskiyou County 1980):
  - The Conservation Element (Siskiyou County 1973), Wildlife Habitat, Objectives 1, 5–8
  - The Land Use Element (Siskiyou County 1997), Policy 41.13

Most of the aforementioned policies (and objectives) are stated in generalized terms, consistent with their overall intent to protect aquatic resources, including special-status aquatic species. By focusing on the potential for impacts to specific aquatic resources within the Area of Analysis, consideration of the more general local policies listed above is addressed through the specific, individual analyses presented in Section 3.3.5 *[Aquatic Resources] Potential Impacts and Mitigation*.

The following sources were assessed to determine the scope of existing HCPs relevant to the Proposed Project and potential for overlap with the Primary Area of Analysis for Aquatic Resources: (a) PacifiCorp's Interim Operations Habitat Conservation Plan for the Klamath Hydroelectric Project (PacifiCorp 2012) and (b) Green Diamond Forest Habitat Conservation Plan (Green Diamond Resource Company 2018). These HCPs also provide generalized terms for protection of aquatic resources, including special-status aquatic species. Consideration of the HCPs is inherently addressed by the individual analyses presented in Section 3.3.5 *[Aquatic Resources] Potential Impacts and Mitigation*, which focus on the potential for impacts to specific special-status aquatic species and other aquatic resources defined in Area of Analysis.

3.3.4.1 Suspended Sediment

Suspended sediment can have a multitude of effects on aquatic species, including direct lethal impacts, or sublethal effects on behavior and physiology. The most commonly observed effects of suspended sediment on fish reported in the scientific literature include: (1) avoidance of turbid waters in homing adult anadromous salmonids, (2) avoidance or alarm reactions by juvenile salmonids, (3) displacement of juvenile salmonids, (4) reduced feeding and growth, (5) physiological stress and respiratory impairment, (6) damage to gills, (7) reduced tolerance to disease and toxicants, (8) reduced survival, and (9) direct mortality (Newcombe and Jensen 1996). Information on both concentration and duration of suspended sediment is necessary for understanding the potential severity of its effects on salmonids (Newcombe and MacDonald 1991). Herbert and Merkens (1961) stated that "there is no doubt that many species of fresh-water fish can withstand extremely high concentrations of suspended solids for short periods, but this does not mean that much lower concentrations are harmless to fish which remain in contact with them for a very long time." Effects of suspended sediment on fish may be exacerbated if pollutants or other stressors (e.g., water temperature, disease) are present as well.

As described in Appendix E of this EIR, the potential effects of suspended sediment on anadromous fish species for the Proposed Project were assessed using the SRH-1D model (Huang and Greimann 2010, as summarized in USBR 2012). The SRH-1D model provides an estimate of SSCs at different points on the Klamath River on a daily average estimate. This information is used to assess the impacts of SSCs on fish in dam removal years 1 and 2, based on the concentration and duration of exposure using an approach described by Newcombe and Jensen's (1996). Newcombe and Jensen (1996) reviewed and synthesized 80 published reports of fish responses to suspended sediment in laboratories, streams, and estuaries and established a set of equations to calculate "severity of ill effect" (SEV) indices. A suite of six equations were developed that evaluate the effects of suspended sediment (at various concentrations, durations of exposure, and particle sizes) on various taxonomic groups of fishes and life stages of species within those groups. These effects are compared to those that fish would be expected to encounter under existing conditions, as described in Section 3.6.1 *Summary of Available Hydrology Information for the Proposed Project*.

For each simulation year in the 48-year record, the duration of SSCs at a range of concentrations was calculated for each species and life-history stage (e.g., duration of SSC over 1,000 mg/L during spring-run Chinook salmon adult upstream migration). The results of modeling all potential years were summarized for each life-stage of each species assessed. Because the suspended sediment varies with hydrology, and in order to account for (and compare) the range of results and impacts that might occur under each alternative, three scenarios were selected for analysis, with the goal of defining a most likely impacts on fish scenario for the potential impacts to fish, as well as a reasonable range of potential impacts, encompassed by extremes—a "least impacts on fish scenario" and a "worst impacts on fish scenario." These represent the sediment concentrations for the median, the lowest 10 percent, and highest 10 percent of years in the available hydrological record.

- **Most-likely impacts on fish:** This scenario represents the conditions that are most likely to occur for each species and life stage—that is to say SSCs and durations with a 50 percent (median) exceedance probability for the mainstem Klamath River downstream from Iron Gate Dam. This means that there is an equal chance that the SSCs would be higher or lower than described. Exceedance probabilities were based on modeling SSCs for all water years from 1961 to 2009 under the Proposed Project.
- **Least impacts on fish:** This scenario represents the least impacts on fish from potential sediment-related impacts to a species and life stage. It uses suspended sediment concentrations and durations with a 90 percent exceedance probability. This means that under this rare, least-impacts-on-fish scenario the probability of these concentrations and durations being equal to or less than this level for each assessed species and life-stage in any one year is 10 percent, and the probability of them being exceeded is 90 percent.
- **Worst impacts on fish:** This scenario represents the worst impacts on fish of potential sediment-related impacts to the species and life stage. It uses SSCs and durations with a 10 percent exceedance probability. This means that under this rare, worst-impacts-on-fish scenario the probability of these concentrations and durations being equal to or greater than this level for each assessed species and life-stage in any one year is 10 percent, and the probability of them being less than this level is 90 percent.

The likelihood, however, that conditions under the Proposed Project would track the aforementioned scenarios precisely for each species is slim. It is more likely that different species and different life stages would be exposed to different SSCs and durations within the ranges described. For example, there are relatively few instances in modeled hydrologic record in which the median "most-likely impacts on fish" condition would occur in the same water year for all life-stages of a given species, and even fewer instances in which the median condition would occur in the same water year for all species and all life-stages. For the "least impacts on fish" and "worst impacts on fish" scenarios, the predicted SSCs and durations would be unlikely to occur (10 percent probability) during nearly all water years in the modeled hydrologic record. There are even fewer, and potentially no, instances in which the "least impacts on fish" and "worst impacts on fish" scenarios for SSCs and durations would occur in the same water year for all life-stages of a given species, and no instances in which they would occur in the same water year for all species and all life-stages.

An alternative analytic approach was considered using predicted SSCs and exposure durations associated with a particular water year type. However, it was determined that this approach had too much potential to exaggerate or understate the range of possible impacts, as it did not provide sufficient granularity in terms of the range of possible conditions experienced by particular species and/or life stages.

In assessing impacts, the above scenarios were applied for each species, and for each life stage of that species, taking into account when the species and what percent of the population is likely to be present in the Klamath River mainstem (including avoidance behavior). This EIR analysis describes the range of potential impacts to various life stages of aquatic species including relative mortality rates and sublethal impacts and were evaluated against the relevant significance criteria.

3.3.4.2 Bed Elevation and Grain Size Distribution

As described in Section 3.11 *Geology, Soils, and Mineral Resources* and Appendix F of this EIR, the analysis of potential changes in channel bed elevations and grain size distribution in response to increased bedload supply and transport also relied upon output from the SRH-1D model (Huang and Greimann 2010, USBR 2012). The changes were evaluated for a range of hydrologic conditions for short-term changes (using a 2-year timeframe) and long-term changes (including analysis of 5, 10, 25, 50 years in the future) changes using a range of flows taken from historical hydrology. For bedload dynamics two years following the changes associated with dam removal is considered sufficient for assessing short-term impacts. Long-term simulations were not conducted for the Klamath River upstream of Iron Gate Dam based on observations that the bedload sediment conditions in that reach are relatively stable and persistent, and therefore at the end of 2 years following dam removal would be representative and would persist through time, allowing for mild fluctuations as a function of hydrology rather than project effects (USBR 2012).

The effects determination used analysis of the model results and knowledge of habitat requirements of affected fish species to determine how changes in bed elevation and substrate composition would affect aquatic resources (e.g., pool habitat, spawning gravel, benthic habitat). Changes in substrate composition occurring as a result of dam removal that decreased habitat suitability were assumed to be harmful to aquatic resources and were evaluated against the relevant significance criteria.

Bedload transport in the area upstream of the influence of J.C. Boyle Reservoir are not anticipated to be affected by dam removal and are not expected to be substantially affected by the Proposed Project, are not within California, and are not evaluated further in this EIR. Link River Dam and Keno Dam would remain in place and would continue to affect hydrology and sediment transport as they do currently.

3.3.4.3 Water Quality

The analysis of potential short-term (0−5 years) and long-term (5 or more years) water quality-related effects on fish under the Proposed Project is based on the water quality impacts analysis (see Section 3.2.5 *[Water Quality] Potential Impacts and Mitigation*) for parameters to which fish are sensitive (e.g., suspended sediment concentrations [SSCs], dissolved oxygen, pH), as well as effects determinations for state and approved tribal designated beneficial uses that are directly related to fish.

This EIR evaluates the potential effects of sediment-associated toxins on fish under the Proposed Project by using the results of multiple screening-level comparisons of sediment contaminant levels identified in reservoir sediments that are currently trapped behind the dams. These water quality methods are described in greater detail in Section 3.2.4.7 *Inorganic and Organic Contaminants*. Alterations in water quality occurring as a result of dam removal under the Proposed Project that are projected to decrease (or increase) habitat suitability or to result in direct effects on aquatic species are evaluated against the relevant significance criteria.

3.3.4.4 Water Temperature

The EIR uses water temperature output from three quantitative models (see Section 3.2.4.1 *[Impact Analysis Approach] Water Temperature* and Appendix D for details regarding the water temperature models) to evaluate the potential impacts related to changes in water temperature on species within each study reach of the Area of Analysis. Water temperature modeling results were compared to the thermal tolerances of focal species and associated life stages to determine relative suitability for these species under the Proposed Project. Changes in water temperature occurring as a result of dam removal that were predicted to decrease (or increase) habitat suitability or result in direct effects on aquatic species were evaluated against the relevant significance criteria.

3.3.4.5 Fish Disease and Parasites

Fish diseases, specifically *C. shasta* and *P. minibicornis*, have periodically contributed to substantial mortality for Klamath River salmonids (discussed in detail in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*). Environmental variables such as temperature, flow, sediment (bedload composition and stability), plankton (high quality food abundance), and nutrients are thought to affect the abundance of *P. minibicornis* and *C. shasta* via habitat for the intermediate invertebrate host (annelid polychaete worm *Manayunkia speciose*); therefore, differences in river habitat conditions that are predicted under the Proposed Project are anticipated to affect the abundance of these parasites and their infection rates in Klamath Basin salmonids. Bartholomew and Foott (2010) prepared a compilation of available information regarding Myxozoan disease relative to the Klamath River and, in their analysis they considered several factors that could, if co-occurring, lead to high disease infection rates of fish, including:

- Physical habitat components that support the invertebrate host species (pools, eddies, sediment, mats of filamentous green algae [periphyton])
- Microhabitats with low velocity and unnaturally stable flows
- Close proximity to salmon spawning areas
- Water temperatures higher than 59°F

Ich and columnaris may also occasionally have a substantial impact on aquatic resource (e.g., 2002 fish kill, CDFW 2004). Factors that could, if co-occurring, lead to high Ich and columnaris infection rates of fish, including:

- Exceptionally low flows
- Water temperatures higher than 59°F

- High densities of fish (such as adult Chinook salmon migrating upstream in the fall and holding at high densities in pools).

The potential effects of the Proposed Project on fish disease were evaluated based on the predicted effect of dam removal on the environmental factors that drive disease infection rates. The predicted outcome for increased or decreased fish disease and mortality were evaluated against the relevant significance criteria.

3.3.4.6 Aquatic Habitat

To assess the effect of the Proposed Project on available aquatic habitat, changes to habitat area were assessed for each life stage qualitatively, using available data on suitable habitat area upstream of existing barriers predicted to be affected by the alternatives, habitat requirements, and expected changes in instream flows under the alternatives. Qualitative analyses in this EIR rely on data evaluated for other affected factors (water temperature and fish passage) and expected changes in geomorphic processes, such as short- and long-term changes in sediment transport and deposition, to determine increases or decreases in habitat relative to existing conditions for the different species and life stages in the various reaches. Changes in aquatic habitat quality and quantity occurring as a result of dam removal were evaluated against the relevant significance criteria.

3.3.4.7 Critical Habitat

NMFS has designated critical habitat for coho salmon, Southern Resident Killer Whales, and eulachon, and USFWS has designated critical habitat for shortnose and Lost River suckers. Within critical habitat, NMFS and USFWS has determined that the PCEs essential for the conservation of these species are those sites and habitat components that support one or more life stage. Critical habitat for Southern Resident Killer Whales does not extend into coastal or offshore habitats (NMFS 2006c). The effects of each alternative on critical habitat were based on evaluation of the physical, chemical and biological changes that were expected to occur to designated critical habitat within the Area of Analysis for aquatic resources and how those changes would affect the PCEs (for those species for which PCEs have been designated) for that critical habitat in the short- and long-term; and were evaluated against the relevant significance criteria for critical habitat.

3.3.4.8 Essential Fish Habitat

The effects of the Proposed Project and each alternative on EFH were based on evaluation of the physical, chemical and biological changes that were expected to occur to EFH within the Area of Analysis for aquatic resources and whether those changes would have short- and long-term negative or beneficial effects on this habitat in terms of its quantity and quality; and were evaluated against the relevant significance criteria for EFH.

3.3.4.9 Freshwater Mollusks

Increased levels of fine sediment, both suspended in the water column and along the channel bed, can inhibit the growth, production, and abundance of freshwater mollusks (especially mussels and clams). Therefore, the analysis of impacts associated with the

Proposed Project focuses on short- and long-term changes in SSCs (Aldridge et al. 1987, as cited in Henley et al. 2000) and stream substrate texture (Howard and Cuffey 2003, Vannote and Minshall 1982). The evaluation focuses on freshwater mussels because of their similar distribution to other freshwater mollusks, similar habitat requirements, their longer life-span, and lack of information regarding the effects of sediment on clams and other mollusks. Suspended sediment impacts on freshwater mussel species were evaluated using output from the SRH-1D (Huang and Greimann 2010) sediment transport model as discussed above for suspended and bedload sediment.

Aldridge et al. (1987, as cited in Henley et al. 2000) showed that exposure to SSCs of 600-750 mg/L led to reduced survival of freshwater mussels found in the eastern United States. No duration of exposure was cited in the study. No comparable data are available for the species in the Klamath River. Using 600 mg/L as the minimum SSCs that would be detrimental to freshwater mussels, alternatives were compared to each other by determining the number of days during which this criterion threshold would be exceeded.

Analysis of impacts due to changes in bedload transport on the four species of freshwater mussels considered modeled changes in median sediment size, under the Proposed Project. Changes in habitat quality and quantity predicted for mussels and clams, as well as predictions of potential direct impacts (mortality), were evaluated against the relevant significance criteria.

3.3.4.10 Benthic Macroinvertebrates

Suspended sediment and turbidity can cause stress to benthic macroinvertebrate (BMI) populations through impaired respiration; reduced feeding, growth, and reproductive abilities; and reduced primary production (Lemly 1982, Vuori and Joensuu 1996). Therefore, potential short-term and long-term effects of the Proposed Project on BMIs were evaluated for both short- and long-term changes in SSCs and bedload sediment. Suspended sediment impacts on BMIs were evaluated using output from the SRH-1D (Huang and Greimann 2010) sediment transport model as discussed above for suspended and bedload sediment.

Changes in substrate size or embeddedness may influence the distribution, abundance, and community structure of BMIs (Bjornn et al. 1977, McClelland and Brusven 1980, Ryan 1991). Bed texture changes that would occur under the Proposed Project were qualitatively evaluated to determine whether changes in substrate composition would likely decrease macroinvertebrate abundance or alter the community composition to the extent that these communities could no longer support sufficient fish populations in the Area of Analysis for aquatic resources.

The effects on BMIs were based on water quality determinations (e.g., dissolved oxygen, toxicity) (see Section 3.2 *Water Quality*) and evaluated in the same manner as described for fish and mollusks. Changes in habitat quality and quantity predicted for BMIs, as well as predictions of potential direct impacts (mortality), were evaluated against the relevant significance criteria.

3.3.5 Potential Impacts and Mitigation

The Proposed Project would affect the physical, chemical, and biological components of habitat within portions of the Klamath Basin. These effects would result from changes in suspended sediment, bedload sediment, water quality, water temperature, disease and parasites, habitat availability, and flow-related habitat. As described in the following sections, these changes would act in both beneficial and harmful ways on species, critical habitat, and EFH. Some of the changes would be short-term, and others permanent. This section first describes the Proposed Project's anticipated effects on these key ecological attributes that could affect aquatic resources. As was the case under the descriptions of key attributes under the Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*, this section includes, as relevant, specific analysis relevant to specific segments of the Area of Analysis. More detailed technical descriptions of the Proposed Project's projected effects on suspended sediment, bedload sediment, and potential impacts on aquatic species, can be found in Appendices E and F of this EIR. Based on the analysis of effects to key ecological attributes, this section then goes on to discuss specific impacts and evaluate them under the significance criteria, discuss mitigation measures, and determine impact significance.

3.3.5.1 Suspended Sediment

Suspended sediment effects under the Proposed Project are summarized here, and are described in more detail in Potential Impact 3.2-3 *Short-term increases in suspended sediments due to release of sediments currently trapped behind the Lower Klamath Project dams*, and Appendix E. As discussed below, suspended sediment analysis interprets model output from USBR (2012) with modifications in light of proposed changes to the drawdown rate that would increase the peak sediment concentrations and decrease the duration of such elevated concentrations.

<u>Hydroelectric Reach</u>

Sediment transport modeling of the impacts of dam removal indicate high short-term SSCs in the Hydroelectric Reach under the Proposed Project (USBR 2012, 2016). Modeled SSCs downstream of J.C. Boyle Reservoir would be high (>1,000 mg/L) in the short term, but concentrations would be considerably less than those anticipated to occur downstream from Copco No. 1 and Iron Gate reservoirs due to the relatively small volume of the sediment deposits behind J.C. Boyle Dam (eight percent of total volume for the Lower Klamath Project). The suspended sediments released from J.C. Boyle would quickly move into the California portion of the Hydroelectric Reach. Elevated suspended sediments in the Hydroelectric Reach during reservoir drawdown would be a significant and unavoidable impact (see Potential Impact 3.2-3). Predicted SSCs decrease to less than 100 mg/L within five to seven months following drawdown, and concentrations further decrease to less than 10 mg/L within six to 10 months following drawdown of J.C. Boyle Reservoir.

Modeling of sediment concentrations downstream of Copco No. 1 Reservoir during drawdown also indicates short-term sediment concentrations would be high (>5,000 mg/L) in the California portion of the Hydroelectric Reach due to dam removal. Predicted spikes in SSC after one to two months of reservoir drawdown correspond to increases in Klamath River flow through the Hydroelectric Reach due to spring storm events, and within six to 10 months following drawdown would decrease to levels that exist under existing conditions (e.g., <100 mg/L).

Middle and Lower Klamath River

Under the Proposed Project, full removal of the Lower Klamath Project reservoirs would result in the release of 5.3 to 8.6 million cubic yards (1.2 to 2.3 million tons) of sediment stored in the reservoirs into the Klamath River downstream from Iron Gate Dam (USBR 2012), resulting in higher SSCs than would normally occur under existing conditions. Reservoir drawdown (lowering of reservoir water surface elevation) is expected to commence in dam removal year 1, and to be completed in dam removal year 2 (Section 2.7.2 *Reservoir Drawdown*). Based on the suspended sediment modeling (USBR 2012), SSCs are expected to exceed 1,000 mg/L directly downstream of Iron Gate Dam for around two to three continuous months, with the potential for peak concentrations exceeding 5,000 mg/L for hours or days, depending on hydrologic conditions during dam removal. Model results indicate SSC would be highest during the period of greatest reservoir drawdown (January through mid-March of dam removal year 2), as erodible material behind the dams is mobilized downstream (see Potential Impact 3.2-3). During normal to dry water years, modeled SSCs would begin to decline in late March of dam removal year 2 and would continue declining through early summer of dam removal year 2 (USBR 2012). If it is a wet year, it may take longer to drain the reservoirs and high (>250 mg/L) concentrations may extend until June. Differences between the modeled conditions and the Proposed Project would be expected to increase the magnitude of peak SSCs but decrease the duration of elevated SSCs compared to modeled SSCs (see Potential Impact 3.2-3). The Proposed Project incorporates a higher maximum drawdown rate (i.e., 5 feet per day compared to 3 feet per day) and sediment jetting during drawdown that would transport more erodible material, so less erodible material would be available to be transported after drawdown concludes and SSCs potentially would decline more rapidly after drawdown. However, modeled SSCs are used as a conservative estimate of the duration of elevated SSCs. The SSCs would be near background conditions for all water year types within the first year following removal. Tributaries between the Hydroelectric Reach and the estuary contribute a significant amount of both water and suspended sediments to the Klamath River mainstem. This causes the influence of Lower Klamath Project reservoir sediment releases to decline in the downstream direction. At Iron Gate Dam (Figure 3.2-11 through 3.2-13), where SSCs are artificially low under existing conditions (because of sediment trapping by the dam) SSCs would remain elevated above existing conditions throughout the first 2 years, and in the long term would decrease (as reservoir deposited sediments evacuated) to return to levels slightly higher than the current levels as sediment naturally transports downstream. At Orleans, where SSCs under existing conditions are higher because of inputs of tributaries, under a most-likely impact on fish scenario, the effects of the Proposed Project would be similar to existing conditions by late April when SSCs from the Proposed Project are predicted to decrease. Under a worst impacts on fish scenario SSCs are projected to remain somewhat elevated above existing conditions until October during the year of dam removal. By Klamath Station (downstream of confluence with Trinity River) SSCs under existing conditions are higher than at the upstream sites as a result of sediment input from tributaries. As a result, SSCs from the Proposed Project and those under existing conditions would be similar under all scenarios by late spring of the year of dam removal.

Klamath River Estuary

As a result of the influence of Lower Klamath Project reservoir sediment releases declining in a downstream direction, the difference between SSCs from the Proposed Project and those under existing conditions would be relatively minor in the Klamath

River Estuary (USBR 2012). The SSCs and durations under the most-likely impacts on fish scenario would be similar to those that occur under existing extreme conditions (10 percent exceedance) and resemble those that would be expected to occur about one in 10 years on average under existing conditions. Under the worst impacts on fish simulation, SSCs and durations would be slightly higher (around 10 percent) than those for the existing extreme conditions during the winter of dam removal.

Pacific Ocean Nearshore Environment

In contrast to the Lower Klamath River, modeled short-term SSCs following dam removal are not available for the nearshore marine environment adjacent to the Klamath River. Substantial dilution of the mainstem river SSCs is expected to occur in the nearshore under the Proposed Project. Based on data from 110 coastal watersheds in California, where nearshore SSCs were measured at greater than 100 mg/L during the El Niño winter of 1998 (Mertes and Warrick 2001), peak SSCs leaving the Klamath River Estuary from upstream sources including the Proposed Project may be diluted by 1 to 2 orders of magnitude; for example from greater than 1,000 mg/L to greater than 10–100 mg/L. Therefore, the SSCs in the nearshore ocean would be expected to be similar to what would occur during existing extreme conditions.

As described in detail in Potential Impact 3.2-3, during several large flood events on the geographically proximal Eel River in the winter of 1997 and 1998, Geyer et al. (2000) found that: 1) flood conditions were usually accompanied by strong winds from the southern quadrant; 2) the structure of the river plume was strongly influenced by the wind-forcing conditions; and 3) during periods of strong southerly (i.e., downwelling favorable) winds, the plume was confined inside the 164-ft isobath (i.e., sea floor contour at around 164-ft below the water surface), within about 4 miles of shore. Based upon Eel River plume studies and current knowledge of northern California oceanographic patterns, the fine sediment discharged to the Pacific Ocean nearshore environment under the Proposed Project would likely be delivered to the ocean in a buoyant river plume that hugs the shoreline as it is transported northward. However, since the flushing of sediments from behind the dams would occur over a number of weeks to months (and perhaps to some degree over 1–2 years), the plume carrying reservoir sediments would likely be influenced by a range of meteorological and ocean conditions (e.g., storm and non-storm periods, differing storm directions). Therefore, some of the time the plume would likely be constrained to shallower nearshore waters, while at other times it would likely extend farther offshore and spread more widely, including within some or all of the Klamath River Management Zone. While elevated SSCs (i.e., 10–100 mg/L) created in the nearshore plume would affect physical water quality characteristics specified in the Ocean Plan (i.e., visible floating particulates, natural light attenuation, the deposition rate of inert solids), the effects are likely to be within the range of concentrations and duration caused by historical storm events.

River plumes and the associated habitat conditions they create are considered to be areas of high productivity for marine organisms (Grimes and Funucane 1991, Morgan et al. 2005), and create abrupt changes in marine water quality conditions (e.g., water temperature, salinity, sediment) that support salmonids (Schabetsberger et al. 2003, De Robertis et al. 2005). Due to the relatively small magnitude of SSCs released to the nearshore environment, the anticipated rapid dilution of the sediment plume as it expands in the ocean, and the relatively low rate of deposition of sediments to the Pacific Ocean nearshore environment bottom substrates, any SSCs elevations associated with the Proposed Project are not anticipated to have effects on species distinguishable from existing conditions.

3.3.5.2 Bed Elevation and Grain Size Distribution

The potential effects of increased bedload supply and transport on channel bed elevations and grain size under the Proposed Project are described in Appendix F and summarized in Section 3.11.5.4 *Channel Morphology and Substrate*. As a result of the Proposed Project, the bedload transport processes that salmon evolved with and depend upon to provide substrate suitable for spawning and early rearing in streams and rivers (that are currently interrupted by the Lower Klamath Project dams) would be restored to a more natural condition.

3.3.5.3 Water Quality

Upper Klamath River and Connected Waterbodies

Dam removal activities under the Proposed Project would not affect water quality in the following areas of the Upper Klamath Basin: Wood, Williamson, and Sprague Rivers, Upper Klamath Lake, and Link River to the upstream end of J.C. Boyle Reservoir.

However, existing water quality problems have the potential to negatively impact anadromous salmonids' ability to access waters upstream of the Hydroelectric Reach under the Proposed Project. Water quality problems (e.g., excessive water temperatures and low dissolved oxygen) in the Keno Impoundment/Lake Ewauna during late spring, summer, and early autumn, led NMFS and USFWS to prescribe interim trap-and-haul measures in their Section 18 Prescriptions for the Klamath Hydroelectric Project (DOI 2006) to transport primarily adult fall-run Chinook salmon past Keno Impoundment/Lake Ewauna during periods when conditions would be harmful to salmonids. This would entail seasonal, upstream trap and haul for primarily fall-run adult Chinook salmon around the Keno Impoundment/Lake Ewauna when dissolved oxygen and water temperatures do not meet the applicable criteria (i.e., typically during July through October), since migrating salmonids would have access to this reach of the Klamath River. In the downstream Keno Impoundment/Lake Ewauna, dissolved oxygen reaches very low levels (less than 1 to 2 mg/L) during July through October of most years as algae transported from Upper Klamath Lake settle out of the water and decay (see Figure 3.4-9 in Appendix C.4.1.1). During most years, the Keno Impoundment/Lake Ewauna reach of the Klamath River (Link River Dam to Keno Dam) maintains dissolved oxygen concentrations greater than 6 mg/L from mid-November through mid-June (Appendix C.4.1.1). These dissolved oxygen concentrations are generally acceptable for migrating adult anadromous salmonids (USEPA 1986) for these months and are typically above the ODEQ water quality objective for cool water aquatic life (6.5 mg/L minimum, see Section 3.2.2.5 *Dissolved Oxygen*). Under KHSA Section 7.5.1, the Secretary of the Interior shall initiate a study to evaluate disposition of Keno Dam, including fish passage. Eventual attainment of the Oregon (ODEQ 2002, 2010) and California (USEPA 2008) TMDLs for dissolved oxygen (and other water quality parameters that would improve dissolved oxygen [i.e., pH, chlorophyll-*a*]) would improve water quality in the Keno Impoundment/Lake Ewauna and potentially eliminate water quality as a potential limitation to fall Chinook migration, and therefore the need for trap and haul activities around these waterbodies. However, full TMDL compliance does not reflect the existing condition and it would be speculative at this point to identify either the mechanisms necessary to implement the TMDLs or the timing required to achieve full compliance.

Upper Klamath River - Hydroelectric Reach

As described in Potential Impact 3.2-9, dam removal would result in short-term increases in oxygen demand and corresponding reductions in dissolved oxygen within the Hydroelectric Reach, with anoxia (0 mg/L) possible during reservoir drawdown periods when suspended sediment concentrations are at their peak (January to March of dam removal year 2). This would be a significant and unavoidable impact. In the long term, the Proposed Project would result in somewhat reduced daily fluctuations in dissolved oxygen in the Peaking Reach from the Oregon-California state line to Copco No. 1 Reservoir, which may be due to elimination of hydropower peaking operations (Potential Impact 3.2-10). Dissolved oxygen in the free-flowing river reaches replacing the reservoirs would no longer experience the extreme conditions of super-saturation (i.e., greater than 100 percent saturation) in surface waters and hypolimnetic oxygen depletion in bottom waters of Copco No. 1 and Iron Gate reservoirs during the April/May through October/November period, which would be generally beneficial.

Under the Proposed Project, pH in the Hydroelectric Reach would no longer experience high levels (pH greater than 9) during seasonal algal blooms in the surface waters of Copco No. 1 and Iron Gate reservoirs (Potential Impact 3.2-11). pH in the free-flowing reaches of the river replacing the reservoirs would not exhibit such high levels, instead possessing a more typical riverine signal. While daily fluctuations in pH could occur due to periphyton growth in the river reaches previously occupied by Lower Klamath Project reservoirs, the increases are expected to consistently meet water quality objectives to support beneficial uses and would therefore be beneficial.

Middle and Lower Klamath River

Sediment release associated with dam removal under the Proposed Project would cause short-term increases in oxygen demand and corresponding reductions in dissolved oxygen (Potential Impact 3.2-9) in the Middle Klamath River. During reservoir drawdown periods when suspended sediment concentrations are at their peak (January to March of dam removal year 2), dissolved oxygen concentrations would drop to very low levels (potentially 0 mg/L) immediately downstream from Iron Gate Dam and, depending on background conditions at the time of reservoir drawdown, would remain below 5 mg/L until approximately the confluence with the Shasta River (RM 179.5), or as far downstream as RM 121.7 (approximately 10 miles downstream of Seiad Valley [RM 132]). Recovery to the North Coast Basin Plan water quality objective of 90 percent saturation (i.e., 10–11 mg/L) is anticipated to occur in the reach from Seiad Valley to the mainstem confluence with Salmon River (RM 66), and would therefore not affect dissolved oxygen in the Lower Klamath River, the Klamath River Estuary or the Pacific Ocean nearshore environment.

Removal of the Lower Klamath Project dams under the Proposed Project and conversion of the reservoir reaches to a free-flowing river would result in long-term seasonal (July through November) increases in dissolved oxygen for the reach immediately downstream from Iron Gate Dam (Potential Impact 3.2-10), which would be beneficial relative to existing conditions. Increased diel (i.e., 24-hour period) variability in dissolved oxygen would also occur in the reach immediately downstream of Iron Gate Dam to approximately Seiad Valley (RM 132.7), with modeled concentrations consistently in compliance with the Basin Plan water quality objective of 85 percent saturation. Long-term effects of dam removal on dissolved oxygen would diminish with distance downstream from Iron Gate Dam, with similar or the same predicted dissolved oxygen concentrations and similar magnitude and duration of diel fluctuations by Seiad Valley (RM 132.7) and no differences by the confluence with the Trinity River (RM 43.3).

Under the Proposed Project, pH in the Middle Klamath River downstream from Iron Gate Dam (particularly upstream of the Shasta River confluence [RM 179.5]) during late-summer and early-fall months (August–September) would experience generally high pH (8 to slightly greater than 9 s.u.) and large daily variations in pH during periods of high photosynthesis (Potential Impact 3.2-11). The magnitude of photosynthesis and community respiration from periphyton growth in the Middle Klamath River under the Proposed Project is not entirely certain, but differences in pH between the Klamath TMDL model "TMDL dams-in" (T4BSRN) and "TMDL dams-out" (TOD2RN) scenarios decrease in magnitude with distance downstream from Iron Gate Dam, and are considerably dampened by the Scott River confluence (RM 145.1).

3.3.5.4 Water Temperature

Upper Klamath River – Hydroelectric Reach

Under the Proposed Project, the Hydroelectric Reach would no longer be dominated by hydropower peaking events and flows would more closely mimic the natural hydrograph. Elimination of peaking operations at J.C. Boyle Powerhouse would result in water temperatures in the J.C. Boyle Peaking Reach at the Oregon-California state line (RM 214.1) that exhibit slightly lower daily maximum values (0.0–3.6°F) and lower diel (i.e., 24-hour period) water temperature variation during June through September as compared to a "dams-in" condition, with temperatures moving toward the natural thermal regime (see also Potential Impact 3.2-1).

In the absence of the Lower Klamath Project reservoirs, hydraulic residence time in this reach would likely decrease from several weeks to less than a day, and water temperature suitability for native aquatic species would be improved (Hamilton et al. 2011). Removal of the Lower Klamath Project reservoirs would result in a slight increase in flow as the evaporative losses would be reduced. Evaporation from the surface of the reservoirs is currently about 11,000 acre-feet/year and after dam removal the evapotranspiration in the same reaches is expected to be approximately 4,800 acre-feet/year, potentially resulting in a gain in flow to the Klamath River of up to approximately 6,200 acre-feet/year (USBR 2011). Whether this increase would contribute to increased instream flows or be used upstream to supplement irrigation deliveries is uncertain, so this EIR discloses the potential increase but does not rely on it for conclusions (see also Section 3.8.4 *[Water Supply/Water Rights] Impacts Analysis Approach*). The reservoir drawdowns would allow tributaries and springs such as Fall, Shovel, and Spencer creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). To assess whether hot springs near the Shovel Creek confluence with the Klamath River heat the water to an extent that it would be necessary to assess impacts to fisheries, water temperatures were recorded in Shovel Creek on November 1, 2017, and were 3.3°F cooler than in the mainstem Klamath River (46°F in Shovel Creek), and 0.6°F cooler on December 5, 2017 (39.9°F in Shovel Creek) (KRRC 2018). On the same dates, water temperature data was collected both upstream and downstream of the Klamath Hot Springs, located in the

Klamath River downstream of the confluence with Shovel Creek. Water temperatures on November 1, 2017 were 1.4°F warmer downstream of the hot springs, and 0.2°F cooler on December 5, 2017; no evidence of appreciable warming as a result of the hot springs was observed on these dates (KRRC 2018).

Temperature conditions would also improve farther downstream in the Hydroelectric Reach. From Copco No. 1 Reservoir to Iron Gate Reservoir, removal of the Lower Klamath Project reservoirs would result in a decrease in water temperatures during the fall and spring (discussed in detail in Potential Impact 3.2-1). The effects of changes in temperature regimes within this reach would be similar to those discussed in detail below for the Middle and Lower Klamath River.

Removing the Lower Klamath Project dams would allow access to tributaries upstream of Iron Gate Dam that could provide additional habitat for anadromous fish (DOI 2007), including groundwater-fed areas resistant to water temperature increases caused by changes in climate (Hamilton et al. 2011). In addition, the mainstem downstream from Iron Gate Dam would reflect natural temperature regimes (Hamilton et al. 2011). The conversion of an additional 22 miles of reservoir habitat to riverine and riparian habitat (Cunanan 2009) would improve water quality by restoring the nutrient cycling and aeration processes provided by a natural channel. These improvements resulting from implementing the Proposed Project would likely moderate the anticipated stream temperature increases resulting from climate change (see Potential Impact 3.2-1).

Middle and Lower Klamath River

The thermal lag caused by water storage in Lower Klamath Project reservoirs and the associated increased thermal mass would be eliminated in the Lower Klamath River under the Proposed Project (see Potential Impact 3.2-1). This elimination would cause water temperatures to become more in sync with historical migration and spawning periods for the Klamath River, warming earlier in the spring, and cooling earlier in the fall compared to existing conditions (Hamilton et al. 2011).

Under the Proposed Project, warmer springtime temperatures would result in fry emerging earlier (Sykes et al. 2009), encountering favorable temperatures for growth sooner than under existing conditions (Figure 3.3-2), which could support higher growth rates and encourage earlier outmigration downstream similar to what likely occurred under historical conditions, and reducing stress and disease (Bartholow et al. 2005, FERC 2007). A predicted earlier outmigration in response to elevated water temperatures in the spring is also supported by a vast body of literature relating to increased growth rates and thermal response of outmigrating salmonids (as reviewed by Hoar 1988). In addition, fall-run Chinook salmon spawning in the mainstem during fall would no longer be delayed (reducing pre-spawn mortality) (Figure 3.3-3), and adult migration would occur in more favorable water temperatures than under existing conditions (Figure 3.3-3). Overall, these changes would result in water temperatures more favorable for salmonids in the mainstem Klamath River downstream from Iron Gate Dam.

The elimination of the thermal lag would also cause water temperatures to have natural diel variations (Figure 3.3-3) similar to what would have occurred historically in the Klamath River. This effect would be most pronounced downstream from Iron Gate Dam, would decline with distance downstream, and by the confluence of the Salmon River (RM 66) would exhibit no difference between the Proposed Project and existing conditions. The highest temperatures experienced by aquatic species would increase during summer (June through August), which could increase physiological stress, reduce growth rates, and increase susceptibility to disease during summer (Figure 3.3-3).

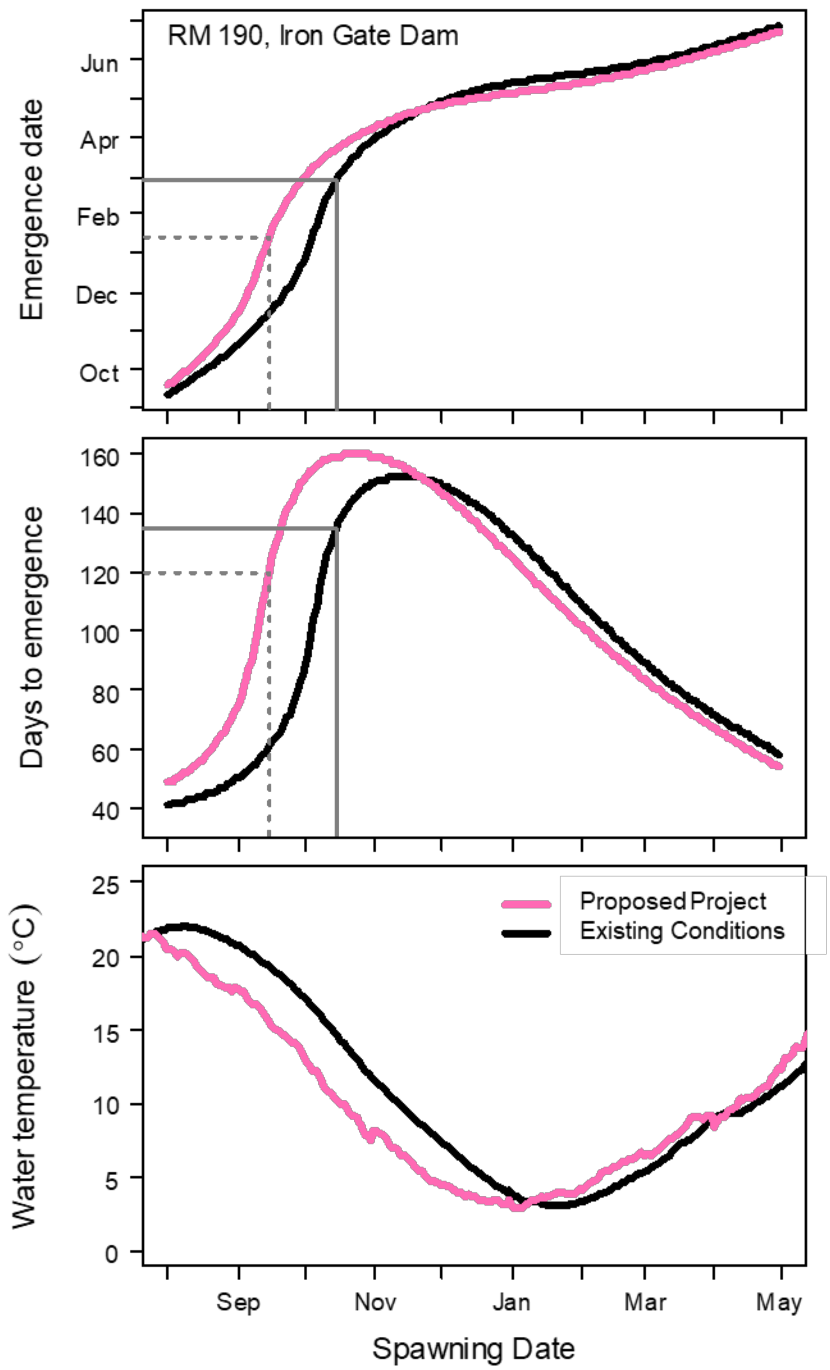

Figure 3.3-4. Perry et al. (2011) Modeled Time Series of Average Daily Mean Water Temperature (lower panel) Predicted at Iron Gate Dam (RM 193.1) Under the Proposed Project and Existing Conditions. Days to emergence (middle panel) and date of emergence (upper panel) for fall-run Chinook salmon was estimated as a function of spawning date assuming that emergence would occur at 889 degree days (accumulated heat related to development) after spawning (Perry et al. 2011).

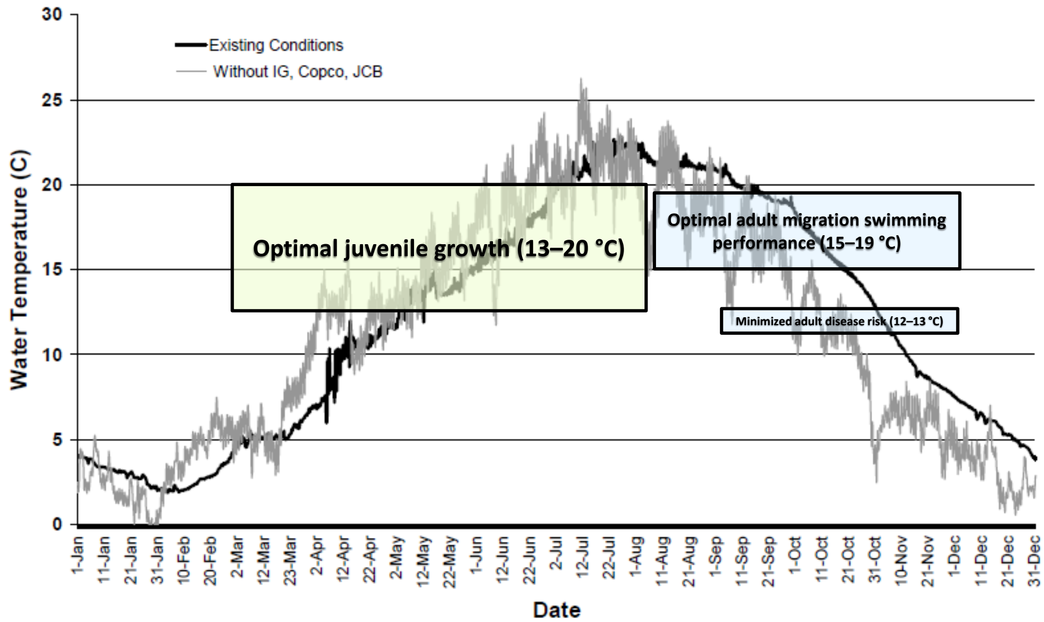

Figure 3.3-5. PacifiCorp (2005) Simulated hourly water temperatures below Iron Gate Dam based on a dry water year (WY 2002) for existing conditions compared to the Proposed Project (without Lower Klamath Project dams), and USEPA (2003) water temperature criteria for salmonid growth and migration.

However, the FERC EIS (2007) states that the increase in average and maximum daily temperatures may be compensated for by lower temperatures at night, which NRC (2004) concludes may allow rearing fish to move out of temperature refugia to forage at night, allowing growth to occur even when ambient day time temperatures are above optimal. Foott et al. (2012) observed positive growth and no apparent effect of elevated temperature on immune function or fitness in Klamath River juvenile Chinook salmon held over a 23-day period under conditions in the laboratory that simulated fluctuating water temperature profiles similar to what would be observed in the Klamath River under the Proposed Project. Salmonids in the Klamath River have been observed to use cooler hours to migrate between thermal refugia (Belchik 2003), and the decrease in minimum temperatures during the spring, summer, and fall under the Proposed Project would be beneficial for fish (Figure 3.3-3). Increased nighttime cooling of water temperatures is important to salmonids in warm systems, providing regular thermal relief, time for repair of proteins damaged by thermal stress, and significant bioenergetic benefits that help fish persist under marginal conditions (Schrank et al. 2003, NRC 2004). In addition, Dunsmoor and Huntington (2006) suggest that lower nighttime temperatures with dam removal would allow fish to leave thermal refugia in the Klamath River to forage and thereby allow more effective use of the available refugia habitat. Overall, the Proposed Project reductions in minimum daily temperatures below those under existing conditions would benefit salmonids in the Klamath River mainstem, helping them to tolerate the warmer periods of the year when dwelling in the mainstem, but also allowing feeding excursions when confined to refugia during the warmer times of the day.

Simulations of water temperatures without the Lower Klamath Project reservoirs (as discussed in Hamilton et al. 2011) show that the temperature difference with and without dams would be greatest directly downstream from Iron Gate Dam, but could extend an additional 120 to 130 river miles downstream. Estimated decreases in stream temperature with dam removal relative to existing conditions are likely to be smaller with continued climate change; however, temperature conditions for aquatic resources would be much improved under the Proposed Project as compared to existing conditions (see Potential Impact 3.2-1).

Klamath River Estuary and Pacific Ocean Nearshore Environment

The influence of the Proposed Project on water temperature would likely decrease with distance downstream from Iron Gate Dam, and it is unlikely that dam removal under the Proposed Project would have detectable effects on water temperatures in the Klamath River Estuary and Pacific Ocean nearshore environment (see Potential Impact 3.2-1).

3.3.5.5 Fish Disease and Parasites

The Proposed Project would be expected to reduce impacts on salmon from fish disease. As discussed in detail in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*, currently the greatest disease-related mortality is for juvenile salmonids due to *C. shasta* and *P. minibicornis* in the Middle Klamath River downstream from Iron Gate Dam. Among all of the salmon life stages, juvenile salmon tend to be most susceptible to *P. minibicornis* and *C. shasta*, particularly during their outmigration in the spring months (Beeman et al. 2008). The main factors contributing to risk of juvenile salmonid infection by *C. shasta* and *P. minibicornis* include availability of habitat (pools, eddies, and sediment) for the polychaete worm intermediate host *(Manayunkia speciose)*; microhabitat characteristics (static flows and low velocities); congregations of spawned adult salmon with high spore; polychaete proximity to spawning areas; planktonic food sources for polychaete from Lower Klamath Project reservoirs; and water temperatures greater than 59°F (Bartholomew and Foott 2010). For adult salmon, Ich and columnaris have occasionally resulted in substantial mortality, particularly when habitat conditions include exceptionally low flows, high water temperatures, and high densities of fish (such as adult Chinook salmon migrating upstream in the fall and holding at high densities in pools). This section addresses changes to these disease factors anticipated under the Proposed Project, and predicted affects for juvenile and adult salmonid life stages.

Removal of Iron Gate Dam and the three upstream facilities would reduce the concentration of adult salmon and carcasses that presently occurs downstream of Iron Gate Dam. Greater dispersal of spawning adult salmon would reduce their proximity to existing dense populations of polychaetes. FERC's analysis (FERC 2007) concluded that restoring access to reaches upstream of Iron Gate Dam for anadromous fish would allow adult fall-run Chinook salmon to distribute over a greater length of the river, reducing crowding and the concentration of disease pathogens that currently occur in the reach between Iron Gate Dam and the Shasta River.

Under the Proposed Project, sediment bedload transport rates would increase downstream from the current location of Iron Gate Dam which currently includes habitats with large populations of polychaetes. Under existing conditions, actinospores released from this portion of the Klamath River pass downstream and infect juvenile salmon in the current infectious zone downstream from the Shasta River to Seiad (RM 132.7)

(Bartholomew and Foott 2010). In addition, while the area of significant sediment deposition under the Proposed Project is located upstream of Cottonwood Creek, sediment transport rates would also increase downstream from Cottonwood Creek (Appendix F). This increased movement and transport of sediment (sand, silt, and clay) is anticipated to disrupt polychaete habitat from the current location of Iron Gate Dam to downstream from Shasta River, resulting in reduced actinospore releases.

Warm water temperatures increase risk of disease transmission. Dam removal would mean cooler temperatures in the late summer and fall, but slightly warmer temperatures during spring and early summer. FERC (2007) concluded that dam removal would enhance water quality and reduce the cumulative effects on water quality and habitat that contribute to disease-induced salmon die-offs in the Klamath River downstream from Iron Gate Dam. In turn, this would benefit salmon outmigrants from tributaries downstream from Iron Gate Dam, such as the Shasta and Scott rivers. Based on existing data it appears that a reduction in temperature during late summer and fall would have the effect of reducing disease rates (Bartholomew and Foott 2010). Reduced disease in the mainstem is anticipated to benefit outmigrating smolts that are currently exposed at high rates in disease hotspots.

FERC (2007) concluded that more rapid cooling of river temperatures in the fall with the Lower Klamath Project dams removed may also allow for fall Chinook salmon spawning to occur earlier in the fall. Bartholow et al. (2005) and FERC (2007) also suggest that earlier warming of the river system could trigger juvenile salmonids to out migrate earlier. This is consistent with findings that the cumulative exposure of temperature is more important predictors of migration of juvenile Chinook salmon than flow or length-of-day (Sykes et al. 2009). As previously described, increased water temperatures in the spring would likely result in earlier emergence and growth, and encourage earlier migration downstream. In addition, a slight increase in the rate at which water temperatures increase in the spring would be likely to improve the growth rates of newly emerged fall Chinook salmon fry (FERC 2007). Earlier migration downstream and improved growth would likely mean most outmigrants would avoid periods of high disease infection of juvenile salmon (Bartholow et al. 2005).

Flows also play an important role in the regulation of disease in the Klamath River. Elimination of Lower Klamath Project reservoirs under the Proposed Project would not result in major flow alterations as flows in the Klamath River are regulated through mandatory federal conditions imposed on the Klamath Irrigation Project located upstream of J.C. Boyle, but elimination of the Lower Klamath Project would create more flow variability due to peak flows from storm events no longer being retained in Lower Klamath Project reservoirs as well as a loss of flow variability in the portion of the Lower Klamath River below J.C. Boyle due to cessation of peaking operations. As described in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*, 2017 court-ordered flushing flows have been required in 2017 and 2018, with the intent of reducing disease in the Lower Klamath River by mobilizing bedload sediments to disrupt the periphyton intermediate host (discussed below). In addition, court ordered dilution flows were required in 2018. Flushing and dilution flows are not modeled as part of existing conditions hydrology under the Proposed Project. As described in Section 3.1.6, the 2017 court-ordered flows include a requirement to ensure that certain high flows are reached each winter, and also include an emergency dilution requirement if juvenile fish disease reaches high levels in the infection nidus. The emergency dilution flows were used in 2018. While there has not been sufficient time to collect sufficient data on the efficacy of the flushing flows, the necessity to use the emergency dilution flows in 2018 suggest that the addition of the flushing flows is insufficient on its own to resolve the issue of fish disease downstream of Iron Gate Dam. Because polychaete populations are located outside of the main flow along the margins of the river (Bartholomew and Foott 2010), variable flows disrupt this habitat. Therefore, removal of the Lower Klamath Project dams would disrupt microhabitat conditions and is expected to reduce polychaete populations (Stocking and Bartholomew 2007, Bartholomew and Foott 2010) and presumably, reduce infection rates within polychaete populations both in the short and long term (Hetrick et al. 2009).

Periphyton (attached algae) provides habitat for the intermediate host of *C. shasta* and *P. minibicornis*, and would also affect disease in the Klamath River. Some of the Project's anticipated effects would tend to support increased periphytic algal growth, while others would tend to reduce it from existing conditions. Under the Proposed Project additional periphytic growth including *Cladophora* is anticipated within the Hydroelectric Reach In the long term, which could provide habitat for the intermediate host of *C. shasta* and *P. minibicornis*. The existing reservoirs foster growth of phytoplankton algae. Under a riverine system, phytoplankton's ecological advantage is reduced, and attached aquatic vegetation would tend to increase. In the absence of other factors, this could possibly increase the prevalence of the intermediate host for *C. shasta* and *P. minibicornis*. However, dam removal would also create other conditions that tend to offset the growth of aquatic vegetation. These conditions include a restoration of bedload sediment transport, increased flow variability, and a more normal (and variable), riverine temperature regime with substantially cooler fall water temperatures. FERC (2007) concluded that restoring natural sediment transport processes would likely contribute to the scour of (attached algae) downstream from the current site of Iron Gate Dam, and deposited gravel and sand would provide a less favorable substrate for periphyton because of its greater mobility during high flow events than the existing armored substrate (see also Section 3.4.5.2 *Periphyton*).

The current infectious nidus (reach with high infectivity) for *C. shasta* and *P. minibicornis* is located in the Klamath River downstream of Iron Gate Dam, where returning adult spawners congregate. Removal of the Lower Klamath Project dams would allow anadromous salmonids to move upstream in the mainstem Klamath River and tributaries upstream of Iron Gate Dam. Currently, with Iron Gate Dam blocking upstream fish passage and trapping sediment, 2017 court-ordered flushing flows are released from Iron Gate Dam for the purpose of disrupting the nidus downstream of Iron Gate Dam and reducing disease risk, although, as described above, the change in flow regime has not, in isolation, been successful in avoiding high disease concentrations. Under the Proposed Project, it is anticipated that the nidus would no longer form downstream of Iron Gate Dam, and the risk of a new nidus forming upstream is low, in the absence of the 2017 flow requirements for the reasons described above. Because the 2017 flow requirements ensure a minimum level of bedload-sediment movement in winter to disrupt the disease cycle, the likelihood of reduction in disease risk would be enhanced by including the 2017 flow requirements.

Although the conditions leading to the nidus forming downstream of Iron Gate Dam would be ameliorated, some disease factors would continue under the Proposed Project, including eight years of additional Iron Gate Hatchery operations that would potentially result in continued (through post-dam removal year 10) congregations of mostly adult fall-run Chinook salmon in the reach from Iron Gate Dam downstream to Seiad Valley

(Section 3.3.5.6 *Fish Hatcheries*). Under the Proposed Project, if a nidus were to remain in the vicinity of Iron Gate Hatchery, or theoretically were to form within newly accessible upstream habitat (however unlikely), flushing and emergency dilution flow releases as required by the 2017 court order may be required from a new upstream location to achieve the same ecological benefits (i.e., disruption of nidus).

It is unlikely that a new infectious nidus would be re-created upstream. The current infectious zone and high parasite loads below Iron Gate Dam are the result of a synergistic effect of numerous factors that occur within the current disease zone in the Klamath River from the reach from Shasta River downstream to Seiad Valley (FERC 2007, Hamilton et al. 2011, Bartholomew and Foott 2010). These factors include: (1) close proximity of myxospore-shedding carcasses (concentration of carcasses); (2) abundant polychaete populations that are found in atypically stable habitats; (3) suitable water temperatures (greater than 59°F) during periods when juvenile salmonids are present; and 4) low flow variability (Bartholomew and Foott 2010). This synergy would be unlikely in the Upper Klamath River (Hamilton et al. 2011). The likelihood of those synergistic factors developing upstream of Iron Gate Dam would be reduced as carcasses would likely be more dispersed in the watershed than occurs in the restricted habitat downstream of Iron Gate Dam (Foott et al. 2012). Iron Gate Dam is both the limit of anadromy, and the site of the current fish hatchery that accounts for a substantial proportion of all adult returning fish annually. As discussed under Section 3.3.5.3 *Water Quality*, the Keno Impoundment/Lake Ewuana has the potential to be a habitat barrier during most years for fall-run Chinook due to poor water quality during the late summer, and therefore NMFS and USFWS have prescribed fish passage measures for the Keno Impoundment/Lake Ewuana to be used during periods of poor water quality (DOI 2007). If fish passage were not provided at Keno Impoundment/Lake Ewuana, few fall-run Chinook salmon would migrate past this location, few smolts would be produced, and therefore congregations of adult fall-run Chinook salmon would be unlikely to occur since few returning adults would have a natal cue to migrate past this location. In contrast, downstream of Iron Gate Dam thousands of adults have a natal que to return to the hatchery, and congregations regular occur during the fall. Under the Proposed Project, those conditions that are believed to result in development of an infectious nidus below Iron Gate Dam or could result in development of a potential infectious nidus upstream of Iron Gate Dam, are unlikely to occur.

Historically, it appears spawning concentrations of Upper Klamath Basin Chinook salmon were located primarily in the Sprague River (Lane and Lane Associates 1981). However, there is no information indicating that high densities of polychaetes occur in the Sprague River (Foott et al. 2012). Thus, the synergistic factors that contribute to an infectious nidus for emigrants below Iron Gate Dam and near the Iron Gate Hatchery are unlikely to occur at this location under the Proposed Project either.

There is some concern regarding a disease zone in the lower Williamson River downstream from the confluence with the Sprague River, where there are currently high parasite densities observed (Hurst et al. 2012). However, there is no reason to anticipate congregations of adult migrants at this location. In addition, maximum temperatures in the Williamson River do not exceed the disease threshold of 59°F in all years (Bartholomew and Foott 2010, Hamilton et al. 2011). Overall, the risk of a juvenile salmon disease response in the Williamson River would be lower than existing conditions in the Middle Klamath River, but not negligible in all water years (S. Foott, USFWS, pers. comm., 2012).

Removal of the Lower Klamath Project dams would allow anadromous salmonids to move upstream in the mainstem Klamath River and tributaries upstream of Iron Gate Dam, altering disease dynamics between anadromous salmonids and resident species upstream of Iron Gate Dam. However, available information indicates that fish passage would not increase the risk of disease for resident species that occur upstream of Iron Gate Dam (NMFS 2006a). Pathogens (e.g., *C. shasta* and *P. minibicornis)* exist throughout the Klamath River System in both the Upper and Lower Basins, so migration of wild anadromous fish upstream and downstream from Iron Gate Dam would not increase the risk of introducing new pathogens to resident trout residing upstream of Iron Gate Dam (NMFS 2006a). In addition, native Klamath River trout are generally resistant to *C. shasta*. Recently several new *C. shasta* genotypes have been discovered in the Klamath River (described in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*). Disease risk is related to host genotype specificity (Atkinson and Bartholomew 2010). It is not expected that introduction of *C. shasta* genotypes upstream would be deleterious because fish in the upstream Basin have shown resistance to the downstream genotypes. Redband trout would presumably have been exposed to genotypes of *C. shasta* during the pre-dam period, and their populations were abundant. Because the salmonid species in the Klamath Basin already co-occur with the genotype of *C. shasta* to which they are susceptible, and the salmonid species are less susceptible to other genotypes of *C. shasta*, expanding the distribution of the different genotypes of *C. shasta* would be unlikely to be deleterious to salmonids. In addition, The Chinook Salmon Expert Panel convened to attempt to answer specific questions related to the Proposed Project compared with existing conditions (Goodman et al. 2011), concluded that the Proposed Project offers greater potential than the existing conditions in reducing disease-related mortality in Klamath River Chinook salmon. Overall, movement of anadromous salmonids into the Upper Klamath Basin presents a relatively low risk of introducing pathogens to resident fish (NMFS 2006a, USFWS/NOAA Fisheries Service Issue 2(B)).

3.3.5.6 Fish Hatcheries

As described under Section 2.7.6 *Hatchery Operations*, under the Proposed Project, the Fall Creek Hatchery would be reopened, and both the Iron Gate Hatchery and Fall Creek Hatchery would continue to operate for a period of eight years following dam removal (through post-dam removal year 7, Table 3.3-11), with the following production goals (Appendix B: *Definite Plan – Section 7.8.3*):

- 3,400,000 fall-run Chinook salmon age 0 smolts at Iron Gate Hatchery (released in spring)
- 1,000,000 fall-run Chinook salmon age 1 yearling smolts at Fall Creek Hatchery (released in fall)
- 75,000 age 1 yearling coho salmon smolts at Fall Creek Hatchery (released in spring)

Although the ability to meet the production goals varies annually based on adult returns and hatchery performance, since 2005 the current fall-run Chinook salmon yearling smolt goals, and current coho salmon yearling smolt goals have been achieved on average, whereas fall-run Chinook salmon age 0 smolts are typically about a million smolts shy of current production goals (K. Pomeroy, CDFW, pers. comm., 2018). Considering actual production achieved, hatchery operations under the Proposed

Project would constitute a reduction in production goals from existing conditions of around 87 percent for yearling fall-run Chinook salmon smolts, 20 percent for fall-run Chinook salmon age 0 smolts, 100 percent for steelhead (although no steelhead have been released since 2012), and no change in production goals for coho salmon smolts. Moving production and releases from Iron Gate Hatchery to Fall Creek Hatchery is not anticipated to have a discernable effect on aquatic resources.

A Hatchery Genetic Management Plan (HGMP) for the Iron Gate Hatchery (CDFW 2014) recently redefined the operation of this hatchery from a mitigation hatchery to one now operated to protect and conserve the genetic resources of the Upper Klamath population unit of the SONCC coho salmon ESU. Included in the HGMP are defined monitoring and evaluation activities to evaluate effects of the hatchery activities on the abundance, productivity, spatial structure, and diversity of the SONCC coho salmon and the magnitude or relative impact of the hatchery program on other actions that influence SONCC coho salmon. Operation of the Fall Creek Hatchery would therefore be managed with a particular focus on supporting recolonization of coho salmon in newly accessible habitat.

For the first eight years following dam removal, the effect of hatchery production on aquatic resources would be similar to existing conditions, as described in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*. The continuation of production (albeit reduced) would affect adult returns for fall-run Chinook and coho salmon, as described for species specific aquatic resource impacts in Section 3.3.5.9 *Aquatic Resource Impacts*.

The elimination of hatchery production eight years after Lower Klamath Project dam removals under the Proposed Project would affect aquatic resources in the Area of Analysis. When production is ceased (post-dam removal year 7), adult coho salmon progeny of hatchery releases would potentially continue to return through post-dam removal year 9 (three-year old returns released as age 1), and hatchery adult fall-run Chinook salmon through post-dam removal year 10 (four-year old returns released in post-dam removal year 7) (Table 3.3-11). After post-dam removal year 3, fewer coho and Chinook salmon adults would possess a natal cue to return to the location of Iron Gate Hatchery (and none after post-dam removal year 10), because there would be fewer smolts released there starting in dam removal year 2, and no artificial supplementation of the population from that location after post-dam removal year 7. In addition, during post-dam removal years 7 through 10 for fall-run Chinook salmon and dam removal years 7 through 9 for coho salmon hatchery adults would continue to return to Iron Gate or Fall Creek hatcheries (natal cue) but would not be collected. For this three to four-year period, straying of hatchery adults into areas of natural spawning may increase. Straying has the potential to reduce the reproductive success of natural salmonid populations (Mclean et al. 2003, Chilcote 2003, Araki et al*.* 2007) and negatively affect the genetic diversity of the populations (Reisenbichler and Rubin 1999). Based on the current low numbers of adult returns of coho salmon, increased straying into Fall Creek for a few years is unlikely to have a substantial effect. Fall-run Chinook salmon adults straying into Bogus Creek and Fall Creek may be high during this period, but there would also be greater access to newly available habitat, likely dispersing adults over a greater area and reducing potential impacts.

The current infectious nidus for salmonid smolts (i.e., reach with highest infectivity) for *C. shasta* and *P. minibicornis* appears to be the result of the synergistic effect high spore input from heavily infected, spawned adult salmon that congregate downstream from Iron Gate Dam and Iron Gate Hatchery and the proximity to dense populations of polychaetes (Bartholomew et al. 2007). Juveniles released from Iron Gate Hatchery may also contribute to the infectious nidus (Som et al. 2016a), as hatchery-released juvenile fish that become infected and experience mortality further downstream in the Klamath River and potentially become another source of myxospores threatening aquatic resources in the Lower Klamath River. The greater dispersal of release locations of smolts (Iron Gate Hatchery and Fall Creek Hatchery) starting in post-dam removal year 1 would reduce density of juveniles in that year, and reduce congregations of adults by post-dam removal year 3, and therefore reduce the risk of the infectious nidus forming in the Middle Klamath River in the short-and long-term.

Table 3.3-11. Hatchery releases and adult returns under the Proposed Project.

Species		Dam Removal Year		Post-dam Removal Year							
		1	2[a]	1	2	3	4	5–7[b]	8	9	10
Chinook salmon	Produced	N smolts from existing habitat and existing H smolts (age 0 in spring and age 1 in fall)	N smolts from existing habitat and reduced H smolts	N smolts from new habitat and reduced H smolts	N and reduced H smolts	N and reduced H smolts	N and reduced H smolts	N and reduced H smolts	N smolts	N smolts	N smolts
	Returning	N and H adults (age 3–4) downstream of Iron Gate Dam	N and H adults access new habitat	N and H adults	N and H adults	N adults from new habitat (progeny of post-dam removal year 1 outmigration) and reduced H adults	N and reduced H adults	N and reduced H adults	N and reduced H adults	N and reduced H adults	N adults and last H adults (age 4, progeny of post-dam removal year 7 outmigration)
Coho salmon	Produced	N smolts from existing habitat and H smolts (age 1)	N smolts from existing habitat and H smolts	N smolts from new habitat and H smolts from Fall Creek	N and H smolts	N and H smolts	N and H smolts	N and H smolts	N smolts	N Smolts	N smolts
	Returning	N and H (age 3) downstream of Iron Gate Dam	N and H adults access new habitat	N and H adults	N and H adults	N adults from new habitat (progeny of post-dam removal year 1 outmigration) and H adults	N and H adults	N and H adults	N and H adults	N and last H adults (progeny of post-dam removal year 7 outmigration)	N adults

[a] Early drawdown of Copco No. 1 begins in dam removal year 1. Drawdown of all reservoirs occurs and dams are removed in dam removal year 2 (see Table 2.7-1). Reduced hatchery releases begin in dam removal year 2 and continue for eight years until post-dam removal year 7.
[b] Final year of hatchery releases occurs in post-dam removal year 7.
H smolt from hatchery releases or adult progeny of hatchery release
N smolt from natural spawning or adult progeny of natural spawning

Overall, dispersing hatchery operations in the short term and discontinuing hatchery operations after eight years following Lower Klamath Project dams removal would reduce the risk of nidus forming in the mainstem Klamath River in the short- and long-term. In addition, hatchery juveniles would no longer be released after post-dam removal year 7 during natural smolt outmigration. Therefore, it is anticipated that the Proposed Project would result in reduced impacts to aquatic resources due to fish disease and parasites in the short- and long-term. Population and other impacts of altered hatchery operations vary for aquatic species and are discussed for specific impacts below.

3.3.5.7 Algal Toxins

The removal of the Lower Klamath Project reservoirs, particularly the larger Copco No. 1 and Iron Gate reservoirs, would decrease or eliminate excessive growth of phytoplankton, and in particular large seasonal blooms of blue-green algae and associated toxins (e.g., microcystin), by eliminating large areas of quiescent habitat where these phytoplankton species currently thrive. In the nutrient-rich Klamath River system, the elevated water temperatures and increased light levels that occur during the summer and early fall under existing conditions result in seasonal blue-green algae blooms in the phytoplankton and periphyton Area of Analysis, and especially the Hydroelectric Reach (Section 3.4.2.3 *Hydroelectric Reach*). As analyzed in Potential Impact 3.4-2, the Proposed Project would dramatically decrease the amount of optimal (calm, slow-moving reservoir) habitat available to support nuisance and/or noxious phytoplankton species, resulting in a corresponding decrease in phytoplankton blooms, alleviating high seasonal concentrations of algal toxins and associated bioaccumulation of microcystin in fish and freshwater mollusk tissue for species downstream of the Lower Klamath Project reservoirs.

While some microcystin may be transported to downstream reaches of the Klamath River from large blooms occurring in Upper Klamath Lake, the levels would not be nearly as high as those experienced under existing conditions, because seasonal blooms in Copco No. 1 and Iron Gate reservoirs are the primary source of *Microcystis aeruginosa* to the Middle and Lower Klamath River (see Section 3.4.2 *Phytoplankton*). Overall, bioaccumulation of algal toxins in freshwater mollusk and fish tissue would be expected to decrease in the mainstem Klamath River from the Hydroelectric Reach to the Klamath River Estuary.

3.3.5.8 Aquatic Habitat

As described in Section 2.1 *Project Objectives*, a primary purpose of the Proposed Project is to increase habitat availability for anadromous salmonids in the Klamath River, for the benefit of the salmonid populations and the recreational, commercial, and cultural uses related to the health of the salmon fishery. The Proposed Project is intended to increase the amount of aquatic habitat by removing migration barriers, and also to improve the quality of the habitat, as related to the operation of the existing hydroelectric facilities. There is some disagreement among experts as to the amount of habitat that Chinook salmon and steelhead would be able to reach, based primarily[90] on the impact of water quality problems in the Lake Ewauna/Keno Reservoir reach and in Upper

[90] Both dams that would remain under the Proposed Project (Keno Dam and Link River Dam), have fish passage facilities.

Klamath Lake, discussed in greater detail in Upper Klamath River and Connected Waterbodies, immediately below. Because coho salmon are not expected to migrate to these reaches, the same concern does not affect estimates of additional coho habitat.

It is worth noting that based on comments received during the public scoping process (Appendix A), it appears that there is concern from some about the historic distribution of salmonids in the Klamath River Basin, with individuals asserting that historical geomorphic features or water quality may have limited upstream migration prior to dam construction (see below paragraph). However, as this document is an analysis of habitat availability upon implementation of the Proposed Project, including consideration of existing and projected future river conditions, this EIR does not further address questions of the historic distribution of salmonids in the Klamath River Basin.

A few commenters (Appendix A) have suggested that a reef existed at the location of Copco No. 1 Dam that would have limited anadromous salmon passage. Boyle (1976) describes an andesite "reef" at the location of Copco No. 1 Dam prior to dam construction and reservoir inundation. He observed evidence of a historical lake formed by this reef that extended approximately five river miles upstream. While the reef may have been a barrier to migration of Chinook salmon when it was originally formed, Boyle is clear that the reef was one of the oldest exposed formations found in the Siskiyou Mountains, and that this barrier and lake existed in the geologic history. At the time of Copco No. 1 Dam construction, no impediments to upstream Chinook salmon migration were described by Boyle. Boyle (1976) describes large runs of salmon at the site of Copco No. 1 in the early 1900's, and details that a fish ladder was considered for construction at Copco No. 1 Dam, but in coordination with California Fish and Game Commission a fish hatchery was proposed for Fall Creek in lieu of passage. Further, historical records reviewed by Hamilton et al. (2005) and Hamilton et al. (2016), and genetic information obtained from archaeological sites analyzed by Butler et al. (2010), indicate that prior to the construction of Copco No. 1 Dam, Chinook salmon (fall- and spring-run based on observed and documented timing) were abundant in, and spawned in, tributaries of the Upper Klamath Basin (i.e., upstream of the described reef and eventual location of Copco No. 1 Dam), Shovel and Spencer creeks, as well as the Sprague, Williamson, and Wood rivers. This conclusion was further recognized in a trial-type hearing concerning federal fisheries requirements in *Klamath Hydroelectric Project* (FERC Project No. 2082, Docket # 2006-NMFS-0001) (Sept. 29, 2006) (hereinafter "NMFS 2006a"). Thus, it appears that there was no "reef" forming a barrier to fish migration at the time Copco No. 1 was built.

The habitat quantity and quality that would be accessible under the Proposed Project within the Area of Analysis are described below for each of the key reaches.

Upper Klamath River and Connected Waterbodies

Removal of the four hydroelectric dams eliminates all of the impassable dams that prevent salmon from accessing an estimated 360 miles of potential anadromous fish habitat upstream of Upper Klamath Lake and Keno Impoundment/Lake Ewauna, with key habitat tributaries being the Woods, Williamson and Sprague rivers (Huntington 2006, DOI 2007, NMFS 2007b). However, FERC's (2007) analysis of habitat access for anadromous fish with fish passage excluded these 360 miles of anadromous fish habitat based upon poor water quality conditions in Upper Klamath Lake and Keno Impoundment/Lake Ewauna during summer months. The Chinook Salmon Expert Panel (Goodman et al. 2011) also concluded that substantial gains in Chinook salmon abundance for areas upstream of Keno Impoundment/Lake Ewauna would be contingent upon successfully resolving limitations associated with poor water quality problems in Upper Klamath Lake and Keno Impoundment/Lake Ewauna. The Coho Salmon and Steelhead Expert Panel (Dunne et al. 2011) stated that poor water quality in Keno Impoundment/Lake Ewauna and in Upper Klamath Lake, and the possibility of difficult passage at Keno Dam, could impede steelhead from reaching improved habitat in the Upper Klamath River. Note that as discussed above (Section 3.3.2.2 *Physical Habitat Descriptions*), fish passage at Keno Dam is in the process of being improved by the USBR.

These concerns for anadromous salmonid migration and spawning overstate the seasonal habitat limitations of Keno Impoundment/Lake Ewauna and Upper Klamath Lake because of the manner in which the seasonal water quality impairments intersect with steelhead, spring-run Chinook, and certain fall-run Chinook life histories.

Regarding Upper Klamath Lake's availability as habitat/migration corridor, a study by Maule et al. (2009) strongly suggests that Upper Klamath Lake habitat can support salmonids, except during the summer (June through September). Maule et al. (2009) examined the response of salmon to Upper Klamath Lake under existing conditions. Iron Gate Hatchery Chinook salmon were tested in the lake and the lower Williamson River to assess whether existing conditions would physiologically impair salmon reintroduced into the Upper Klamath Basin. Juvenile Chinook salmon were tested in cages in 2005 and 2006. These juveniles showed normal development as smolts in Upper Klamath Lake and survived well in both locations (Maule et al. 2009). Maule et al. (2009) concluded that there was little evidence of physiological impairment or significant vulnerability to *C. shasta* that would preclude this stock from being reintroduced into the Upper Klamath Basin. In addition, the dominant life history of fall-run Chinook salmon (Type I) outmigrate to the ocean in spring and would not rear during the stressful summer period in the Upper Klamath Basin. Type II and Type III life history would rear during summer and outmigrate during either fall (Type II) or spring (Type III). Thus, conditions for juvenile fall-run Chinook emigration through Upper Klamath Lake appear favorable. Due to the spring migration period for adult and juvenile spring-run Chinook salmon and steelhead, the migratory life stages would generally avoid the period of poor water quality in Upper Klamath Lake as well. Cool groundwater spring inputs in the Williamson River and on the west side of Upper Klamath Lake would likely provide thermal refugia for the non-migratory juvenile salmonid rearing life stages.

Similar to the severe water quality impairments in Upper Klamath Lake, the serious water quality issues in Keno Impoundment/Lake Ewauna are not year round. Both DOI and NMFS have long recognized the issue of seasonally poor water quality typically between June 15 and November 15 in Keno Impoundment/Lake Ewauna. This is a time period when nearly all adult fall- and some (later portion) spring-run Chinook salmon would be migrating upstream. When water quality is poor both DOI and NMFS prescribed the transfer of primarily adult fall-run Chinook salmon upstream of the Keno Impoundment/Lake Ewauna for the purposes of restoration and safe, effective, and timely passage (DOI 2007, NMFS 2007b). If fish passage were not provided, upstream migrating adults would presumably locate spawning habitat downstream.

Upper Klamath River - Hydroelectric Reach

This reach would be fundamentally altered under the Proposed Project, with the removal of the dams and associated reservoirs, and the restoration of riverine systems and habitat connectivity. Under the Proposed Project anadromous fish (Chinook salmon, steelhead, coho salmon, and Pacific lamprey) access would be restored to an estimated 80 miles of habitat within the mainstem Klamath River and tributaries upstream of Iron Gate Dam and downstream of Keno Dam (DOI 2007, Cunanan 2009). Primary tributary habitat that would be available for salmonids includes Fall, Jenny, Shovel, and Spencer creeks. In addition to the tributaries and the current reaches of the mainstem, the 80 miles of habitat includes restoration of 21.2 miles of currently inundated mainstem and tributary riverine habitat (Cunanan 2009) for resident and anadromous fish. The current reservoirs inundate sections of the river that had high sinuosity and complex channels that historically provided high quality salmonid spawning and rearing habitats (Hetrick et al. 2009). Modeling indicates that the river would return to a similar channel morphology following dam removal, ad discussed in Appendix F. In addition, proposed habitat restoration within the reservoir areas (described in Section 2.7.4 *Restoration Within the Reservoir Footprint*) is designed to slow water velocities along the bank and thus has the potential to create backwater and rearing habitat for coho salmon. Proposed habitat restoration components include manually creating connectivity to tributaries, incorporating floodplain habitat features (e.g., side channels), creating bank-line complexity to slow water velocities, and placing large wood habitat features (Appendix B: *Definite Plan*).

Under the Proposed Project, short-term alterations to the hydrograph would result from the release of water stored in the Lower Klamath Project reservoirs. Based on modeling results, this release is expected to last about three months, from January 1 into mid-March of dam removal year 2, but could vary depending on hydrologic conditions (USBR 2012), increasing the magnitude of flows downstream from the dams during the drawdown period. River flows would be expected to remain below the 10-year flood event.

In the long term flows would increase not only in the bypass reaches, but also in all other mainstem reaches due to changes in operations and the absence of reservoir evaporation. Hydrology in the J.C. Boyle Peaking Reach would follow the natural hydrograph more closely, including increased duration and magnitude of high flows, and cessation of daily extreme flow fluctuations (characteristic of hydroelectric peaking operations).

Increases in flows resulting from changes in peaking operations at J.C. Boyle Dam would provide more habitat than under existing conditions for redband/rainbow trout and other resident riverine species, as well as anadromous fish or lamprey that reestablish in this area. These flows are expected to meet channel maintenance needs to route coarse sediments, build bars, erode banks, flush fine sediments, scour vegetation and undercut and topple large woody riparian vegetation (NRC 2008). The removal of Lower Klamath Project dams would reestablish geomorphic and vegetative processes that form channels that provide fish habitat and spawning gravels in this reach, especially in the former bypassed reaches (FERC 2007). In addition, the impacts associated with daily extreme flow fluctuations resulting from hydroelectric peaking operations (e.g., stranding, displacement, reduced food production, and increased stress) would no longer occur.

Middle and Lower Klamath River

As described above, reservoir drawdown under the Proposed Project would result in increased flows for about four months once drawdown begins. Over the long term, the Proposed Project would alter the hydrograph so that the duration, timing, and magnitude of flows would be more similar to the unregulated conditions under which the native fish community evolved (Hetrick et al. 2009). While mean annual flows would not substantially change from existing flows due to the lack of active reservoir storage (Stillwater Sciences 2009b, USBR 2012), daily, seasonal, and annual flow variability would increase. It is anticipated that restoration of the hydrologic function of the river system under the Proposed Project would support the creation of habitat diversity and maintain biophysical attributes of the Klamath River (Stanford et al. 1996, Poff et al. 1997).

The Proposed Project would substantially decrease the transit time of water in the Hydroelectric Reach, because it would no longer be impounded by the reservoirs, resulting in a shift in the timing of the occurrence of low flow periods to earlier in summer than currently occurs (Balance Hydrologics Inc. 1996, NRC 2004). These hydrologic effects would likely be more important in upstream areas (directly downstream from Iron Gate Dam) than downstream areas (downstream from the confluence of the Scott River) due to the substantial flow contribution of tributaries to the Klamath River (USBR 2012). In addition, these hydraulic changes would result in changes to water quality, water temperatures, sediment transport, and riparian habitat, as described in subsequent sections.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Hydrologic and hydraulic modeling results (described in Section 3.6.2.3 *Flood Hydrology*) indicate that because of the influence of the tributaries entering the Klamath River downstream from Iron Gate Dam, the flow changes for the Proposed Project would not substantially affect the flows entering the estuary. Specifically, Potential Impact 3.6-1 and Potential Impact 3.6-3 provide further discussion and information on this effect. Therefore, the Proposed Project would not affect flow-related fisheries habitat in the estuary or the Pacific Ocean.

3.3.5.9 Aquatic Resource Impacts

Potential Impact 3.3-1 Effects on coho salmon critical habitat quality and quantity due to short-term sediment releases and long-term changes in habitat quality and quantity due to dam removal.

In the short term, under the Proposed Project, designated critical habitat supporting SONCC coho salmon would be degraded from elevated SSCs and sediment deposition downstream of Iron Gate Dam (see Section 3.3.5.1 *Suspended Sediment* and Appendix E of this EIR, and Section 3.3.5.2 *Bed Elevation and Grain Size Distribution* and Appendix F of this EIR). The specific features of critical habitat and designated PCEs considered essential for the conservation of the SONCC ESU that would be adversely impacted in the short term include spawning substrate, water quality, and safe passage conditions. Quality of spawning substrate for coho salmon downstream of Iron Gate Dam would be substantially degraded during the spawning season following dam removal, while most of the spawning habitat occurring in tributaries would remain unaltered by the Proposed Project (Appendix E). Water quality in the mainstem Klamath River downstream of Iron Gate Dam would be substantially degraded in the short term from increased suspended sediment and decreased dissolved oxygen, resulting in a substantial reduction in rearing and migration habitat suitability for juvenile and smolt coho salmon during the winter and spring following dam removal (Appendix E). Passage conditions would be impaired for adult upstream migrants during the fall and winter of dam removal from both increased suspended sediment, and the risk of sediment deposits at tributary confluences (Appendices E and F). Passage conditions would be impaired for coho salmon smolts during spring following dam removal from increased suspended sediment (Appendix E). Based on the substantial short-term decrease in quality of the features of critical habitat and PCEs supporting SONCC coho salmon, there would be a significant impact to coho salmon critical habitat under the Proposed Project in the short term.

However, the Proposed Project includes aquatic resource measures AR-1 (Mainstem Spawning) and AR-2 (Juvenile Outmigration) to reduce the short-term effects of SSCs on coho salmon PCEs of critical habitat. In addition, mitigation measures AQR-1 and AQR-2 (described below), would be required to increase certainty of the effectiveness of the aquatic resource measures AR-1 and AR-2 and to reduce the short-term significant adverse impacts of the Proposed Project on coho salmon critical habitat. Aquatic resource measures submitted as part of the Proposed Project are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan − Appendix I*. AR-1 includes the development and implementation of a monitoring and adaptive management plan to offset the impacts of Lower Klamath Project dam removal on mainstem spawning habitat. AR-1 actions include a 2-year tributary confluence monitoring effort and addressing sediment and debris obstructions that block volitional upstream passage from the Klamath River into tributaries. Monitoring would occur periodically for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-1 Mainstem Spawning (detailed below) further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. Aquatic Resource Measure AR-1 also includes a spawning habitat evaluation on the Klamath River and tributaries in the Hydroelectric Reach. Most coho salmon spawning occurs in tributaries, and very few coho salmon have been observed spawning in the mainstem Klamath River. Therefore, the spawning habitat actions of AR-1 are focused on offsetting impacts of the Proposed Project on Chinook salmon and steelhead. However, due to the similar spawning habitat requirements of coho salmon to both species, these actions would benefit coho salmon as well. If spawning habitat conditions following dam removal do not meet target metrics[91] developed to offset the anticipated loss of Chinook salmon and steelhead redds due to the Proposed Project, AR-1 specifies that spawning gravel augmentation would be completed within the mainstem, with additional spawning habitat actions within tributaries. These tributary spawning habitat restoration actions would be completed in Jenny Creek, Shovel Creek, Fall Creek, and/or Spencer Creek and could include removal of artificial fish passage barriers, or placement of large woody debris to trap and retain spawning gravels. Mitigation Measure AQR-1 Mainstem Spawning (detailed below) further specifies the range of actions that shall be conducted in tributaries to offset impacts to critical habitat. Implementation of the Proposed Aquatic Resource Measure AR-1 along with Mitigation Measure AQR-1 would reduce the short-term

[91] Spawning gravel in the amount of 44,100 yd^2 for fall Chinook salmon and 4,700 yd^2 for steelhead

potential impacts of SSCs on coho salmon spawning habitat in dam removal year 2 by improving access to tributary habitat where impacts from SSC on habitat in the mainstem can be avoided, and by augmenting spawning gravel, ensuring that suitable spawning habitat in mainstem and tributaries is available following dam removal. Given implementation of AR-1 and AQR-1, suitable coho salmon spawning habitat quality and quantity would not be substantially reduced as a result of the Proposed Project.

Proposed Aquatic Resource Measure AR-2 includes three primary actions: 1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; 2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River; and 3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cold water tributaries or nearby off-channel ponds. Implementation of proposed Aquatic Resource Measure AR-2 would reduce the short-term effects of SSCs on rearing habitat for coho salmon juveniles in the mainstem during dam removal by actively transporting up to 500 juvenile coho salmon from vulnerable mainstem areas to off-channel ponds protected from the effects of the Proposed Project, thus offsetting water quality impacts to critical habitat. Other native fish captured during the seining and trapping effort, such as juvenile steelhead and juvenile Chinook salmon would be relocated into tributary streams adjacent to the salvage locations. Proposed Aquatic Resource Measure AR-2 would also reduce the potential short-term effects of SSCs to migratory habitat for coho salmon smolts by maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No.11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-2 Juvenile Outmigration (detailed below) further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. In addition, proposed Aquatic Resource Measure AR-2 would reduce the potential short-term effects of SSCs to migratory habitat for coho salmon smolts by rescuing and transporting smolts if mainstem SSC are high, and water temperatures within tributaries are too poor to provide safe refuge (a decision to be made in regular consultation with the Aquatic Technical Work Group [ATWG[92]]). These measures would effectively provide juvenile coho salmon short-term refuge in suitable habitat as an alternative to exposure to temporarily degraded critical habitat from periods of high SSC in the mainstem habitat following dam removal.

Based on the wide distribution of coho salmon critical habitat within tributaries, implementation of the KRRC's proposed aquatic resource measures (AR-1 and AR-2), and implementation of the mitigation measures (AQR-1 and AQR-2) developed for this EIR (where both sets of measures were designed to offset short-term impacts to PCEs of critical habitat), there would not be a substantial decrease in the quality of a substantial proportion of habitat for coho salmon critical habitat in the short term. Therefore, the Proposed Project would have no significant impact on coho salmon critical habitat in the short term.

[92] The ATWG would be comprised of agency and tribal fisheries scientists to review the aquatic resource (AR) mitigation measures included in the Proposed Project.

In the long term, the Proposed Project would increase the amount of habitat available to coho salmon upstream of currently designated critical habitat and improve water quality and bedload characteristics in the mainstem Klamath River within current critical habitat.

The Proposed Project would restore access for Upper Klamath River coho salmon populations to the Hydroelectric Reach. The 2006 administrative trial-type hearings evaluating fish passage mandatory conditions found that the record of evidence is inconclusive as to whether coho salmon's historical distribution extended upstream as far as Spencer Creek, but that the evidence definitively shows that based on historical records and tribal accounts coho salmon used habitat as far upstream as Fall Creek (NMFS 2006a). Based on Hamilton et al. (2005), the Proposed Project would expand coho salmon distribution to include historical high-quality spawning and rearing habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek, including in Jenny, Shovel, and Fall creeks. Together, this compromises around 80 miles of suitable potential habitat within the Hydroelectric Reach (DOI 2007, Cunanan 2009). Access to suitable habitat upstream of Iron Gate Dam would increase the availability of spawning sites, result in additional food resources, and provide access to areas of better water quality.

NMFS may consider whether to designate the newly available habitat as critical habitat as part of its five-year status review or as a separate reconsideration of the critical habitat designation for the species (J. Simondet, NMFS, pers. comm., 2011). But, it is speculative at this point to prejudge the outcome of any such consideration, so the EIR does not find that the anticipated coho habitat expansion would necessarily result in an increased in the amount of designated critical habitat.

As discussed in detail in Potential Impact 3.2-1, the thermal lag formerly caused by water storage in reservoirs and the associated increased thermal mass would be eliminated in the Lower Klamath River. This would result in Klamath River water temperatures that exhibit more natural diel (i.e., 24-hour period) variation and are more in sync with historical migration and spawning periods. These changes would result in water temperatures that are more favorable for salmonids in the mainstem Klamath River in the long term, thus improving the water quality PCE of critical habitat. Removal of the Lower Klamath Project dams and associated facilities would also increase dissolved oxygen concentrations and eliminate reservoir habitat that creates the conditions necessary for the growth of blue-green algae and other phytoplankton. Under the Proposed Project, increased bedload supply and transport following dam removal would increase the supply of gravel downstream from the removed dams as far downstream as Cottonwood Creek (see Appendix F). In the long term this would likely improve critical habitat for coho salmon by reducing median substrate to a size more favorable for spawning (USBR 2012).

Overall, these changes would be a substantial increase in the quality and quantity of coho salmon critical habitat in the long term. Therefore, the Proposed Project would be beneficial for coho salmon critical habitat in the long term.

Mitigation Measure AQR-1 – Mainstem Spawning.
Implementation of Action 1 of proposed Aquatic Resource Measure AR-1 (tributary-mainstem connectivity) shall be implemented in the tributaries identified in Action 1 of AR-1, as well as all newly created stream channels that were previously inundated by Project reservoirs prior to drawdown. As described in Appendix B: *Definite Plan –*

Appendix I, implementation of Action 1 of proposed Aquatic Resource Measure AR-1 would be conducted for at least two years following dam removal, including following a 5-year flow event if the event were to occur within that two years. This mitigation measure (AQR-1) ensures that in addition to the monitoring that shall be conducted as described for AR-1, monitoring shall also be conducted within one month following a 5-year flow event regardless of how many years since dam removal have passed, and if fish passage obstructions are identified, they shall be removed as described in AR-1 (Appendix B: *Definite Plan − Appendix I*). In addition, implementation of Action 1 of proposed Aquatic Resource Measure AR-1 shall include an evaluation and proposal of other actions to improve spawning and rearing habitat in tributaries to the Klamath River that meet the spawning targets identified in AR-1, which may include: installation of large woody material, riparian planting for shade coverage, wetland construction or enhancement, and cattle exclusion fencing.

Mitigation Measure AQR-2 – Juvenile Outmigration.
Implementation of Action 2 of proposed Aquatic Resource Measure AR-2 (tributary-mainstem connectivity monitoring) shall be implemented in the tributaries identified in Action 2 of AR-2 as well as all newly created stream channels that were previously inundated by Lower Klamath Project reservoirs prior to drawdown. As described in Appendix B: *Definite Plan − Appendix I*, implementation of Action 2 of AR-2 would be conducted for at least two years following dam removal, including following a 5-year flow event, if the event were to occur within that two years. This mitigation measure (AQR-2) ensures that in addition to monitoring described under AR-2, monitoring shall also be conducted within one month following a 5-year flow event regardless of how many years since dam removal have passed, and requires that if fish passage obstructions are identified in relation to the Proposed Project, they shall be removed as described in AR-2 (Appendix B: *Definite Plan − Appendix I*).

Significance
No significant impact with mitigation to coho salmon critical habitat in the short term

Beneficial for coho salmon critical habitat in the long term

Potential Impact 3.3-2 Effects on Southern Resident Killer Whale critical habitat quality due to short-term and long-term alterations to salmon populations due to dam removal.
The Klamath River contributes to critical habitat for Southern Resident Killer Whales through its contribution of salmon to their food supply (included as a PCE). The Proposed Project would not affect the geographic extent of critical habitat for this species, as it is located in the state of Washington. In the short term, salmon population abundance is anticipated to reduce under the Proposed Project, as described in Potential Impacts 3.3-7, 3.3-8, and 3.3-9. In the long term, the Proposed Project is expected to increase salmon populations (as described in Potential Impacts 3.3-7, 3.3-8, and 3.3-9), which could increase food supply for Southern Resident Killer Whales. However, data on the Southern Resident Killer Whale diet indicate that based on the migratory range and behavior of the population, the Klamath River salmon are anticipated to provide less than one percent of the diet of Southern Resident Killer Whales in most months under current and future conditions. While Southern Resident Killer Whales have been shown to consume Klamath River Chinook Salmon, the Klamath River is considered by NMFS and WDFW tenth out of the top ten priority Chinook Salmon populations for Southern Resident Killer Whales (NMFS 2018b, NMFS

and WDFW 2018). Because of the low proportion of the Sothern Resident Killer Whale diet being composed of salmon from the Klamath River, the Proposed Project would not be likely to substantially impact the habitat quality (i.e., food supply) of Southern Resident Killer Whales in the short term or long term. Therefore, the Proposed Project would have no significant impact to Southern Resident Killer Whale critical habitat in the short term and long term.

Significance

No significant impact to Southern Resident Killer Whale critical habitat in the short term

No significant impact to Southern Resident Killer Whale critical habitat in the long term

Potential Impact 3.3-3 Effects on eulachon critical habitat quality due to short-term sediment releases due to dam removal.

In the short term, under the Proposed Project, PCEs of critical habitat supporting eulachon would be degraded, including short-term adverse effects of suspended sediment (see Section 3.3.5.1 *Suspended Sediment* and Appendix E) primarily on spawning and egg incubation habitat, and adult and larval migration habitat (NMFS 2011) during eulachon spawning, and adult and larval migration period (primarily January through April). Eulachon are highly adapted to migrating and spawning during periods of increases suspended sediment, and suspended sediment released under the Proposed Project is predicted to be at levels similar to what occurs under existing conditions within the Klamath River Estuary, at least during infrequent storm events.

Critical habitat for the Southern DPS eulachon includes approximately 539 miles of riverine and estuarine habitat in California, Oregon, and Washington, of which the Klamath River Estuary is a small proportion (less than two percent). Although the Proposed Project could result in short-term reductions in habitat quality detrimental to PCEs (potentially spawning substrate composition during the year of dam removal) under a worst impacts on fish scenario, a negligible amount (less than two percent) of eulachon critical habitat would be effected for a short duration. Therefore, impacts to eulachon critical habitat would not be significant in the short term.

In the long term, SSCs would be similar to those under existing conditions. Natural bedload transport processes would resume, as the dams would no longer trap sediment supplied from areas upstream of Iron Gate Dam (see Appendix F). Channel bed elevations and grains size in the estuary and ocean would not be appreciably affected, because of the small contribution of the area upstream of Iron Gate Dam to the total bedload in the system. Water quality benefits resulting from the Proposed Project would largely have dissipated upstream of the estuary, and therefore, water quality in the estuary would be expected to remain un-altered in the long term (WQST 2011). Therefore, there would be no impact to eulachon critical habitat in the long term.

Significance

No significant impact to eulachon critical habitat in the short term

No significant impact to eulachon critical habitat in the long term

Potential Impact 3.3-4 Effects on Chinook and coho salmon Essential Fish Habitat (EFH) quality and quantity due to short-term sediment releases and long-term changes in habitat quality and quantity due to dam removal.

In the short term, under the Proposed Project, Chinook and coho salmon Essential Fish Habitat (EFH) is identical for both species and would be degraded from elevated SSCs and sediment deposition downstream of Iron Gate Dam (see Section 3.3.5.1 *Suspended Sediment* and Appendix E of this EIR, and Section 3.3.5.2 *Bed Elevation and Grain Size Distribution* and Appendix F of this EIR). The specific features of EFH that would be adversely impacted in the short term include water quality necessary for successful adult migration and holding, spawning, egg-to-fry survival, fry rearing, smolt migration, and estuarine rearing of juvenile Chinook and coho salmon. Water quality in the mainstem Klamath River downstream of Iron Gate Dam would be substantially degraded in the short term from increased suspended sediment and decreased dissolved oxygen, resulting in a substantial reduction in rearing and migration habitat suitability for juvenile and smolt Chinook and coho salmon during the winter and spring following dam removal (Appendix E). Passage conditions would be impaired for adult upstream Chinook and coho salmon migrants during the fall and winter of dam removal from both increased suspended sediment, and the risk of sediment deposits at tributary confluences (Appendices E and F). Quality of spawning substrate for Chinook and coho salmon downstream of Iron Gate Dam would be substantially degraded during the spawning season following dam removal, while most of the spawning habitat occurring in tributaries would remain unaltered by the Proposed Project (Appendix E). Passage conditions would be impaired for Chinook and coho salmon smolts during spring following dam removal from increased suspended sediment (Appendix E). Based on the substantial short-term decrease in quality of EFH for Chinook and coho salmon, there would be a significant impact to Chinook and coho salmon EFH under the Proposed Project in the short term.

However, the Proposed Project includes aquatic resource measures AR-1 (Mainstem Spawning) and AR-2 (Juvenile Outmigration) to reduce the short-term effects of SSCs on Chinook and coho salmon EFH. In addition, mitigation measures AQR-1 and AQR-2 (described above for Potential Impact 3.3-1), would be required to increase certainty of the effectiveness of the aquatic resource measures AR-1 and AR-2 and reduce the potential for short-term significant adverse impacts of the Proposed Project on Chinook and coho salmon EFH. Aquatic resource measures are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan − Appendix I*. Proposed Aquatic Resource Measure AR-1 includes the development and implementation of a monitoring and adaptive management plan to offset the impacts of Lower Klamath Project dam removal on mainstem spawning habitat. Proposed Aquatic Resource Measure AR-1 actions include a 2-year tributary confluence monitoring effort and addressing sediment and debris obstructions that block volitional upstream passage from the Klamath River into tributaries. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-1 Mainstem Spawning (described in detail in Potential Impact 3.3-1), developed for this EIR, further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. Proposed Aquatic Resource Measure AR-1 also includes a spawning habitat evaluation on the Klamath River and tributaries in the Hydroelectric Reach. If spawning habitat conditions following dam removal do not meet target metrics[93] developed to offset the anticipated loss of Chinook salmon and steelhead redds due to the Proposed Project, spawning gravel augmentation would be completed within the mainstem, with additional spawning habitat actions within tributaries. Tributary spawning habitat restoration actions to be completed in Jenny Creek, Shovel Creek, Fall Creek, and/or Spencer Creek could include removal of artificial fish passage barriers, or placement of large woody debris to trap and retain spawning gravels. Mitigation Measure AQR-1 Mainstem Spawning further specifies the range of actions that shall be conducted in tributaries to offset impacts to EFH. Implementation of proposed Aquatic Resource Measure AR-1 and Mitigation Measure AQR-1 would reduce the short-term impacts of SSCs on Chinook and coho salmon EFH in dam removal year 2 by improving access to tributary habitat where impacts from SSC on habitat in the mainstem can be avoided, and by augmenting spawning gravel to ensure that an equivalent amount of spawning habitat is available following dam removal. Therefore, it is anticipated that, in the short term, fewer Chinook and coho salmon would spawn in the mainstem prior to and following the dam removal, and suitable spawning gravel access would be maintained.

Proposed Aquatic Resource Measure AR-2 includes three primary actions: (1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; (2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River; and (3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cold water tributaries or nearby off-channel ponds. Implementation of proposed Aquatic Resource Measure AR-2 would reduce the short-term effects of SSCs on Chinook and coho salmon EFH in the mainstem during dam removal by actively transporting up to 500 juvenile coho salmon from vulnerable mainstem areas to off-channel ponds protected from the effects of the Proposed Project. Other native fish captured during the seining and trapping effort, such as juvenile Chinook salmon would also be relocated into tributary streams adjacent to the salvage locations, thus off-setting water quality impacts to Chinook and coho salmon EFH. In addition, proposed Aquatic Resource Measure AR-2 would reduce the short-term effects of SSCs to migratory Chinook and coho salmon EFH by rescuing and transporting smolts if mainstem SSC are high, and water quality conditions within tributaries are too poor to provide safe refuge (a decision to be made in regular consultation with the ATWG). Proposed Aquatic Resource Measure AR-2 would also reduce the potential short-term effects of SSCs to migratory habitat for Chinook and coho salmon smolts by maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No.11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-2 Mainstem Spawning (described in detail in Potential Impact 3.3-1) further specifies that monitoring shall also be conducted following a 5-year flow event, even if that flow event occurs more than two years following dam removal. These actions would effectively reduce the number of salmon juveniles and smolts potentially exposed to periods of high SSC in the mainstem habitat following dam removal, and therefore reduce the proportion of the population experiencing sub-lethal effects or mortality in temporarily degraded habitat.

---

93 Spawning gravel in the amount of 44,100 yd^2 for fall Chinook salmon and 4,700 yd^2 for steelhead

Based on the wide distribution and use of tributaries by both juvenile and adult Chinook and coho salmon, implementation of the KRRC's proposed aquatic resource measures (AR-1 and AR-2), and implementation of mitigation measures (AQR-1 and AQR-2) developed for this EIR (where both sets of measures were designed to offset short-term impacts to Chinook and coho salmon EFH), there would not be a substantial decrease in the quality of a large proportion of Chinook and coho salmon EFH in the short term. Therefore, the Proposed Project would have no significant impact on Chinook and coho salmon EFH in the short term.

In the long term, bedload supply and transport following dam removal would increase supply of gravel downstream from the dam as far downstream as Cottonwood Creek (see Appendix F). This would potentially improve EFH for Chinook and coho salmon by reducing median substrate to a size more favorable for spawning (USBR 2012). In the long term, the Proposed Project would also increase habitat for Chinook and coho salmon (upstream of currently designated EFH) by providing access to habitats upstream of Iron Gate Dam. EFH quality would be affected by improved water quality, and decreased prevalence of disease, as described above for coho salmon critical habitat. Improved access to habitats (upstream of currently designated EFH), improved water quality, increased sediment transport, and decreased prevalence of disease, would be beneficial to EFH for Chinook and coho salmon in the long term.

Significance

No significant impact with mitigation to Chinook and coho salmon EFH in the short term

Beneficial for Chinook and coho salmon EFH in the long term

Potential Impact 3.3-5 Effects on groundfish Essential Fish Habitat (EFH) quality due to short-term sediment releases and long-term changes in habitat quality due to dam removal.

EFH for Pacific Coast groundfish includes all waters and substrate within areas with a depth less than or equal to 3,500 meters (1,914 fathoms [ftm]) shoreward to the mean high-water level or the upriver extent of saltwater intrusion. Within the Area of Analysis for aquatic resources, this includes the Klamath River Estuary and Pacific Ocean nearshore environment.

In the short term, under the Proposed Project, impacts to the nearshore environment are not anticipated to be distinguishable from existing conditions, based on a relatively small magnitude of SSCs released to the nearshore environment, an anticipated rapid dilution of the sediment plume as it expands in the ocean, and a relatively low rate of deposition of sediments to the Pacific Ocean nearshore environment bottom substrates (Section 3.3.5.1 *Suspended Sediment*). EFH in the Klamath River Estuary could be affected by elevated SSCs for about four months during the winter following dam removal, during which time many groundfish species could be spawning. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks (potentially > 1,000 mg/L) downstream from Iron Gate Dam would still be substantial and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.3.5.1 *Suspended Sediment*). However, increased suspended sediment is not anticipated to substantially decrease the quality of groundfish EFH, which is adapted to periodic pulses of high sediment. In addition, the area of EFH for groundfish affected by the Proposed Project within the Klamath River Estuary is a very small proportion (<1 percent) of the total EFH designated for groundfish along the Pacific Coast. Therefore, impacts to groundfish EFH from the Proposed Project would have no significant impact in the short term.

In the long term, SSCs would be similar to those under existing conditions. Water quality benefits resulting from the Proposed Project would largely have dissipated upstream of the estuary, and therefore, water quality in the estuary would be expected to remain similar to existing conditions. Therefore, there would no impact to groundfish EFH from the Proposed Project in the long term.

Significance

No significant impact to groundfish EFH in the short term

No significant impact to groundfish EFH in the long term

Potential Impact 3.3-6 Effects on pelagic fish Essential Fish Habitat (EFH) quality due to short-term sediment releases and long-term changes in habitat quality due to dam removal.

EFH for coastal pelagic species occurs from the shorelines of California, Oregon, and Washington westward to the exclusive economic zone and above the thermocline where sea surface temperatures range from 50 to 78.8°F. Within the Area of Analysis for aquatic resources, this includes the Pacific Ocean nearshore environment. Substantial dilution of the mainstem river SSCs is expected to occur in the nearshore under the Proposed Project, and therefore the SSCs in the nearshore ocean would be expected to be similar to what would occur during existing extreme conditions. Pelagic fish are highly adapted to periods of increased suspended sediment and have the ability to swim away from areas of temporary poor habitat quality. In addition, the area for EFH for pelagic fish affected by the Proposed Project within the near-shore environment is a very small proportion (less than one percent) of the total EFH designated for pelagic species along the Pacific Coast. Overall, there would be no substantial reduction in the quality of pelagic fish EFH, and thus there would be no significant impact to pelagic fish EFH from the Proposed Project in the short term or long term.

Significance

No significant impact to pelagic fish EFH in the short term

No significant impact to pelagic fish EFH in the long term

Potential Impact 3.3-7 Effects on the fall-run Chinook salmon population due to short-term sediment releases and long-term changes in habitat quality, habitat quantity, and hatchery operations due to dam removal.

The potential for the Proposed Project to significantly increase the salmonid population in the Klamath River, including the fall-run Chinook salmon population, is an underlying purpose for the Proposed Project (KHSA 2016, Appendix B: *Definite Plan*). Therefore, as described in Section 2.7 *Proposed Project*, the drawdown timing for J.C. Boyle, Copco No. 1, and Iron Gate reservoirs under the Proposed Project was selected to minimize impacts from sediment release following dam removal under the Proposed Project to aquatic species, including fall-run Chinook salmon. Based on the distribution and life-history timing of fall-run Chinook salmon in the Klamath Basin, only a portion of

Chinook salmon adults, juveniles, and smolts are likely to be present in the mainstem Klamath River during the periods of greatest sediment transport between January and March. Most individuals are in tributaries, or further downstream during this time where concentrations would be diluted by tributary inflows. Additionally, the timing of drawdown coincides with periods of naturally high suspended sediment in the Klamath River, to which fall-run Chinook salmon have adapted by avoiding and tolerating.

This potential impact section begins with a summary of the available analysis predicting the response of the fall-run Chinook salmon population to the Proposed Action in the short- and long-term. The section then discusses in detail the potential short-term and long-term changes from the Proposed Project in each of the five study reaches within the Area of Analysis.

Quantitative modeling of fall-run Chinook salmon populations predict that the Proposed Project would increase Chinook salmon abundance. Modeling of dam removal and existing conditions by Oosterhout (2005) suggests that dam removal would substantially increase Chinook full-run spawners over a 50-year period relative to other management scenarios. Additional population capacity and modeling efforts support this conclusion (Huntington 2006, Dunsmoor and Huntington 2006, Hendrix 2011, Lindley and Davis 2011). Of these, the Hendrix (2011) life-cycle model (Evaluation of Dam Removal and Restoration of Anadromy, EDRRA) approach is considered the most intensive and robust conducted to date, because it explicitly addressed the Proposed Project, used stock-recruitment data from the Klamath River, explicitly incorporated variability in watershed and ocean conditions, and presented variance estimates of uncertainty.

Hendrix (2011) applied EDRRA to forecast the abundance of Chinook salmon (Type I and Type II life history strategies) for both the Proposed Project and continuation of existing conditions for the years 2012 to 2061. The EDDRA model did not incorporate potential climate change effects. The EDRRA Chinook salmon life cycle model assumes that current management rules (fishery control rule) established by the Pacific Fishery Management Council (PFMC) for management of Klamath River Chinook salmon would remain in place throughout the 50-year period of analysis. The PFMC has regulatory jurisdiction over salmon fishing within the 317,690-square mile exclusive economic zone from three miles to 200 miles off the coast of Washington, Oregon, and California. Since the management of salmon considers many factors that can fluctuate greatly from year to year (population abundance and environmental conditions) it is impossible to predict how future management decisions regarding the specific harvest of Klamath Basin salmon might change as a result of the Proposed Project. As stated in Hendrix (2011) “this rule is based on an optimal (i.e., escapement that produces maximum sustainable yield) escapement target after harvest of 40,700 (PFMC 2005).” The analysis uses the same escapement target (40,700 fish) for both alternatives despite the fact that Klamath Basin spawning distribution would be extended by hundreds of miles under the Proposed Project (as described below) and would therefore presumably have a higher escapement target. Therefore, in the EDRRA model, harvest and escapement targets to sustain the population are being managed optimally under existing conditions, whereas under the Proposed Project the escapement target is likely lower than would be required to fill newly accessible habitat. If the PFMC changes management under the Proposed Project based on additional access to spawning and rearing habitat, the harvest and escapement targets could be higher than predicted by the EDRRA model.

The EDRRA model assumes a flow regime under the Proposed Project based on the 2010 BiOp flows (NMFS 2010a), and implicitly incorporates water quality and disease by modeling a smolt survival rate that varies based on flows. The model assumes habitat restoration actions in the Upper- and Mid-Klamath basins, and it further assumes that these actions would take time to become effective. This EIR's analysis selectively uses the EDRRA modeling results that characterize conditions prior to habitat restoration because habitat restoration in the Upper- and Mid-Klamath basins is not included as part of the Proposed Project (aside from habitat restoration in Lower Klamath Project reservoirs). The EDDRA model also assumes active reintroduction efforts described in Hooton and Smith (2008), which would fully seed available fry habitats upstream of Iron Gate Dam, including the Upper Klamath Basin upstream of Upper Klamath Lake, prior to dam removal. Active reintroduction of fall-run Chinook salmon is not currently planned following dam removal under the Proposed Project. Instead, natural volitional reintroduction is anticipated under the Proposed Project and would require a longer time to meet the production levels predicted by the EDRRA model and reported by Hendrix (2011).

The EDRRA model assumes that Iron Gate Hatchery production does not occur under the Proposed Project. Therefore, the eight years of hatchery releases of Chinook salmon, after Lower Klamath Project dams removal, albeit at reduced production goals compared with existing conditions (43 percent decrease in Chinook age 0 and age 1 smolt release goals compared with current releases), would somewhat offset the lack of active reintroduction included in the EDRRA model.

From 1978 through 2016, returns of fall-run Chinook salmon adults to the Iron Gate Hatchery have ranged from 2,558 (in 1980) to 72,474 (in 2001), and averaged 16,559 (CDFW 2016b). During the same period, natural returns in the Klamath River (excluding Trinity River returns) ranged from 6,957 to 91,757 fall-run Chinook salmon, with an average of 31,379 fish (CDFW 2016a). While natural returns typically outnumber hatchery returns, the proportion of the Chinook salmon escapement composed of Iron Gate Hatchery returns has historically been substantial (approximately 35 percent of age 3 adults, KRTT 2011, 2013, 2015). Assuming a 43 percent decrease in smolt production relative to current (2005 through 2018) releases would result in a similar reduction in adult returns; it is possible that between post-dam removal years 3 and 10 (Table 3.3-11) an average of 7,120 fewer fish could return on an annual basis due to reduced hatchery releases. The elimination of the goal of releasing around six million Chinook salmon smolts and yearlings annually after eight years (post-dam removal year 7) would be anticipated to result in a reduction in adult hatchery returns to the Klamath River. Most adult returns are age 3 (around 75 percent), with some age 4 (around 23 percent), and a few age 5 (less than 2 percent) (KRTT 2011, 2013, 2015). As a result, progeny of hatchery releases are anticipated to return as adults continuing mostly through post-dam removal year 10 (four-year old returns, progeny of final releases in post-dam removal year 7). The first adult returns from the progeny of naturally spawning fall-run Chinook salmon in newly accessible habitat upstream of the location of Iron Gate Dam would be expected in post-dam removal year 3 (3-year old returns, progeny of post-dam removal year 1; Table 3.3-3). Therefore, between post-dam removal years 3 and 10, both hatchery returns and returns from newly accessible habitat would occur, potentially increasing the rate of reintroduction comparable to the effect of active reintroduction assumed in the EDRRA model. Impacts associated with hatcheries operations in relation to water diversions and minimum bypass flows for fish passage is discussed in

Potential Impact 3.3-23 (Iron Gate Hatchery) and Potential Impact 3.3-24 (Fall Creek Hatchery).

The amount of time required for the fall-run Chinook salmon population in the Klamath River to reach capacity under the Proposed Project would be a function of adult returns that volitionally recolonize new habitat, although there is no accurate means to predict how much longer it would take to reach full capacity without the active reintroduction modeled using EDRRA. Recolonization success and rate is a function of fish straying into newly available habitats (Pess 2009). For Chinook salmon, stray rates are around six percent (Hendry et al. 2004), and 95 percent of strays migrate less than 20 miles from their natal area (Quinn and Fresh 1984, Quinn et al. 1991). However, following major changes in environmental conditions (e.g., dam removal, high SSC), salmonid stray rates have been observed to increase. For example, Leider (1989) reported steelhead stray rates increasing from 16 percent to 45 percent during recolonization of streams following the Mt. Saint Helens eruption. The time period of colonization (historical or new habitat) has been reported to occur within five to thirty years, with most falling between one to two decades (Withler 1982, Bryant 1999, Burger et al 2000, Glen 2002, Pess et al. 2003, Milner et al. 2008, Kiffney et al. 2009). Rapid (less than one year) recolonization was observed for fall-run Chinook salmon following fish ladder installation at Landsburg Dam on the Cedar River, Washington (Kiffney et al. 2009) and within months of removal of Condit Dam on the White Salmon River, Washington (Allen et al. 2016). Fall-run Chinook salmon were observed to recolonize habitat upstream of the former location of the Elwha Dam within the first year of dam removal, and within five years of dam removal a majority of returning adults were spawning in newly accessible habitat upstream of the former dam location (Weinheimer et al. 2018). A ladder was placed on the Landsburg Dam in 2003, and Chinook salmon immediately (i.e., the first fall following ladder installation) accessed areas upstream of the dam, with juveniles of both species being observed during snorkel surveys the following year. By 2011, Chinook salmon occurred throughout nearly all accessible habitat upstream of the dam.

It is likely that following dam removal under the Proposed Project, recolonization of the 80 miles of habitat downstream of Keno Dam would be rapid, with a longer timeframe for habitat in the Upper Klamath River and connected waterbodies (and contingent on fish passage being provided at Keno Impoundment/Lake Ewauna). The EDRRA model prediction is that with dam removal there would be substantially more (median increase greater than 10,000) returning adult Chinook salmon in the Klamath Basin than without dam removal, where the prediction is based solely on access to habitat between Iron Gate and Keno dams.

Median escapements to the Klamath Basin are predicted to be higher (median increase greater than 30,000) with the Proposed Project than under existing conditions. The potential for ocean harvest is also predicted to be greater with the Proposed Project due to increased Chinook salmon adults in ocean, and the probability of low escapement leading to fishery closures was less under the Proposed Project. Modeling results of Hendrix (2011) indicated uncertainty in Chinook salmon stock recruitment dynamics due to the uncertainty in predicting smolt production based on habitat conditions, as well as uncertainty in escapement and harvest abundance forecasts based on habitat conditions. Despite the uncertainty, the results indicate that the Proposed Project would result in higher relative abundance of Chinook salmon.

In addition to the quantitative EDRRA modeling results, FERC (2007) and Hamilton et al. (2011) synthesized all available information and both concluded that increased habitat access following dam removal would result in an increase in the abundance of fall-run Chinook salmon population in the Klamath Basin.

Further, to help determine if the Proposed Project would advance restoration of the salmonid fisheries of the Klamath Basin, a Chinook Salmon Expert Panel was convened to attempt to answer specific questions that had been formulated by the KHSA (2016) stakeholders to assist with assessing the effects of the KHSA compared with existing conditions (Goodman et al. 2011). The Chinook Salmon Expert Panel concluded that Lower Klamath Project dam removal (and habitat restoration actions associated with the KBRA) would be a major step forward in conserving target fish populations in the Klamath Basin. The Chinook Salmon Expert Panel predicted that, based on the information provided to them, it was possible that Lower Klamath Project dam removal would provide a substantial increase in the abundance of naturally spawned Klamath River Chinook salmon above that expected under existing conditions in the reach between Iron Gate Dam and Keno Dam. In addition, the Chinook Salmon Expert Panel concluded that Lower Klamath Project dam removal offers greater potential than the existing conditions for Chinook salmon to tolerate climate change and changes in marine survival (Goodman et al. 2011). While the Chinook Salmon Expert Panel agreed that there was also evidence for potential dramatic increases in abundance associated with potential fish passage upstream of Keno Dam as well, they cautioned that achieving substantial gains in Chinook salmon abundance and distribution in the Klamath Basin is contingent upon successfully resolving key factors that would continue to affect the population, including water quality in Upper Klamath Lake and Keno Reservoir, disease, colonization of the Upper Klamath River Basin, harvest and escapement, hatchery interactions, predation by resident fish, climate change, instream flows, and impacts from dam removal. The anticipated influence of the Proposed Project on these factors (among others) within specific reaches is described below.

Upper Klamath River and Connected Waterbodies

As discussed above under 3.3.5.8 *Aquatic Habitat*, under the Proposed Project, removal of the Lower Klamath Project dams would allow fall-run Chinook salmon to regain access to around 360 miles within the upper Klamath River upstream of Upper Klamath Lake (DOI 2007, Hamilton et al. 2005, 2016). The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River, upstream to the Sprague, Williamson, and Wood rivers (Hamilton et al. 2005, 2016). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat upstream of Iron Gate Dam (DOI 2007), including access to groundwater-fed areas with relatively cold water that would be resistant to climate change-induced water temperature increases (Hamilton et al. 2011).

As discussed under Section 3.3.5.3 *Water Quality*, the Keno Impoundment/Lake Ewuana has the potential to be a habitat barrier during most years for fall-run Chinook due to poor water quality during the late summer, and therefore NMFS and USFWS have prescribed fish passage measures for the Keno Impoundment/Lake Ewuana to be used during periods of poor water quality (DOI 2007). If fish passage were not provided, fall-run Chinook salmon would be limited to the additional habitat access in the Hydroelectric Reach, as described in detail below. Over the long term, seasonal dissolved oxygen in the Keno Impoundment/Lake Ewauna would also be expected to improve as TMDL implementation projects continue. While it would be speculative at this point to identify the timing or scope of such improvements, it is reasonable to assume that the multiple water quality improvement projects would work to shorten the season of impairment in the reach (allowing early and/or later migrants to reach upstream spawning habitat) and to reduce the number of years in which Keno Impoundment/Lake Ewauna's poor water quality forms a barrier to migration.

Upper Klamath River - Hydroelectric Reach

The Proposed Project would restore fall-run Chinook salmon access to the Hydroelectric Reach, expanding their distribution to include historical habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek; including in Jenny, Shovel, and Fall creeks (Hamilton et al. 2005), totaling around 80 miles of potential habitat within the Hydroelectric Reach, including 21.2 miles of habitat currently inundated by Lower Klamath Project reservoirs (DOI 2007, Cunanan 2009). Historically, Chinook salmon (both fall- and spring-run) spawned and were abundant within this habitat (NMFS 2006a, Hamilton et al. 2016). Prior to construction of Iron Gate Dam, Coots and Wales (1952) observed about 300 Chinook salmon spawning in the Copco No. 2 Bypass Reach at around eight cfs, with additional spawning habitat available at the time of survey.

Adults would be able to access this reach starting in September of dam removal year 2 (Table 2.7-1). By fall of dam removal year 2, elevated SSCs from dam removal would have subsided (USBR 2012). Because of this, fall-run Chinook salmon would not be exposed to the elevated SSCs that would occur during dam removal in this reach. Most of the sediment stored within the river channels currently inundated by Lower Klamath Project reservoirs would likely be eroded by the end of spring of dam-removal year 2. The maximum deposition anticipated is minor (less than 0.5 foot), within pockets of the river reaches between reservoirs, settling into pool and other low-velocity habitats as water velocities decrease. This would constitute a negligible and temporary (less than six months following reservoir drawdown in dam removal year 1) reduction in the quality of habitat and would occur prior to the first adult salmon accessing newly available habitat in post-dam removal year 1.

River channel habitat within the reservoir reaches would be primarily low gradient habitat which is of critical importance for salmon spawning and rearing. For example, FERC (2007) described the Copco No. 2 bypassed reach and reaches inundated by Iron Gate and Copco reservoirs to be low gradient. For these reaches, they estimated that the density of Chinook salmon spawners per mile for mainstem habitat was twice that of high gradient habitat (FERC 2007). These river channels would likely excavate to their pre-dam elevations within six months, and revert to and maintain pool-riffle morphology due to restoration of riverine processes, creating holding, spawning, and rearing habitat for anadromous salmonids.

Modeling (USBR 2012) indicates that after dam removal, spawning gravel in all sections of the Hydroelectric Reach would be within the range usable for fall-run Chinook salmon, but the amount of sand in the bed within former reservoir sections could initially inhibit spawning success. The bed material within the reservoirs and from Iron Gate Dam to Cottonwood Creek is expected to have a high content (30 to 50 percent) of sand immediately following reservoir drawdown until a flushing flow moves the sand sized material out of the reach (USBR 2012). The flushing flow is expected to be at least 6,000 cfs and of several days to weeks to return the bed to a bed dominated by cobble and gravel with a sand content less than 20 percent. After the flushing flow, the bed is expected to maintain fractions of sand, gravel, and cobble which would be expected under natural conditions. Based on the historical record a sufficient flushing flow would likely occur within five years following dam removal (see Section 3.6.5.1 *Flood Hydrology*).

Habitat currently within inundated Lower Klamath Project reservoir that would be exposed following dam removal under the Proposed Project is anticipated to be used during the first spawning migration after dam removal (fall of dam removal year 2). A similar rapid recolonization of formally reservoir inundated habitat was observed at two dam removal sites in southern Oregon. Following removal of Savage Rapids Dam on the Rogue River in 2009, 91 redds from within the bounds of the former reservoir were documented where no redds had existed previously in 2010 (the first fall spawning season following dam removal), and more the following year (ODFW 2011). Following removal of the Gold Ray Dam on the Rogue River in 2010, 37 redds were documented from within the bounds of the former reservoir the fall after dam removal, with over twice that many the following year (ODFW 2011).

The Proposed Project would establish flow and water quality conditions that more closely mimics natural conditions by incorporating more variability in daily flows (described in Section 3.6.5.1 *Flood Hydrology*). The reservoir drawdowns would also allow tributaries and springs such as Fall, Shovel, and Spencer creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011).

In addition, as described in detail in Section 3.3.5.5 *Fish Disease and Parasites*, it is unlikely that the disease conditions that currently exist downstream of Iron Gate Dam would develop upstream of Iron Gate Dam under the Proposed Project.

Middle and Lower Klamath River

In the short term in this reach, the Proposed Project would decrease dissolved oxygen and release dam-stored sediment downstream to the Lower Klamath River. In the long term, the Proposed Project would restore a flow and sediment regime that more closely mimics natural conditions in the long term. Suspended sediment effects on fall-run Chinook salmon under the Proposed Project are described in detail in Appendix E.3.2.1, and summarized here.

During the fall and winter of dam removal year 1, under the least impacts on fish, most-likely impacts on fish, or worst impacts on fish scenario, no impact from suspended sediment is anticipated for all adult fall-run Chinook salmon migrating or spawning within tributaries to the Klamath River, or for juveniles rearing within tributaries (Appendix E, Table E-8). Under the most-likely impacts on fish or worst impacts on fish scenario, complete loss of eggs from the dam removal year 1 brood year deposited in the mainstem in fall of dam removal year 1 is predicted. Based on redd surveys from 1999 through 2009 (Magneson and Wright 2010), an average of around 2,100 redds could be affected in the mainstem. As described in detail in Appendix E.3.2.1, based on escapement estimates in the Klamath Basin from 2001 through 2009 (CDFG 2010, unpublished data) on average this would be around eight percent of all anticipated fall-run Chinook salmon redds in the Klamath River Basin in the fall spawning of dam removal year 1.

In dam removal year 2 suspended sediment could be high enough for long enough duration to cause moderate physiological stress for returning adults during the fall under a least impacts on fish scenario, impaired homing under a most-likely impacts on fish scenario, and major physiological stress under the worst impacts on fish scenario (Appendix E.3.2.1). For smolts, in dam removal year 2 suspended sediment is anticipated to have sublethal effects on Type I, Type II, and Type III outmigrants (Appendix E.3.2.1) and would not cause substantial reductions in abundance. The Type I smolts affected by increased SSCs during dam removal year 2 would be the progeny of the same cohort[94] of adult spawners potentially affected by dam removal. However, the Type-II and Type-III progeny of that same cohort of adults that successfully spawn in tributaries during dam removal year 2 would produce smolts that would outmigrate to the ocean a year after the spring pulse of suspended sediment in dam removal year 2 and should not be noticeably affected by the Proposed Project.

In the long term (by post-dam removal year 2), SSC in the Middle and Lower Klamath River are predicted to return to similar levels to existing conditions, and no substantial effect on fall-run Chinook salmon is anticipated.

In the short term, a higher proportion of sand in the mainstem channel bed surface may reduce the quality of spawning habitat in the mainstem Klamath River downstream of Iron Gate Dam. As described in detail in Appendix F, the dam removal year 2 fall-run Chinook salmon cohort could be affected by sediment deposits with higher levels of sand than under existing conditions. After a flushing flow of at least 6,000 cfs, the bed is expected to maintain fractions of sand, gravel, and cobble which would be expected under natural conditions, and suitable for fall-run Chinook salmon. Based on the historical record a sufficient flushing flow would likely occur within five years following dam removal. These effects would be most apparent in successive median or dry years following dam removal, but less apparent in successive wet years (Appendix F). Increased proportion of sand in the spawning substrate could reduce embryo survival-to-emergence (Chapman 1988) for fall-run Chinook salmon spawning during fall of dam removal year 1 (affecting fry that would emerge and smolt during dam removal year 2). Changes in bedload would be limited to the reach from Iron Gate Dam to Cottonwood Creek, a length of eight miles, or 4 percent of the channel length of the mainstem Klamath River downstream from Iron Gate Dam. The most severe effects would also be limited to a small proportion of the total channel length (0.5 miles, or less than one percent of the channel downstream from Iron Gate Dam), as sediment deposition would lessen downstream from Bogus Creek to Cottonwood Creek. At most, around eight percent of fall-run Chinook salmon in the Klamath Basin are expected to spawn in the mainstem downstream of Iron Gate Dam prior to dam removal, with an even smaller percentage expected to spawn within the 8-mile affected reach (described in Appendix E.3.2.1).

In the long term, the river would eventually exhibit enhanced habitat complexity due to increased sediment supply, a more natural flow regime, greater sediment transport rates, and more frequent bed mobilization that would increase spawning habitat availability and quality and improve early rearing habitat downstream from Iron Gate

[94] Cohort is a group of fish born during the same year.

Dam (see Appendix F). Bedload sediment movement and transport are vital to create and maintain functional aquatic habitat. An increased supply of gravel from upstream sources is predicted to improve spawning gravel quality and increase the amount of fall-run Chinook salmon spawning habitat downstream from Iron Gate Dam by decreasing the median substrate size to 1.5 to 2.4 in (USBR 2012), within the observed range for Chinook salmon spawning (0.6 to 2.8 in [Kondolf and Wolman 1993]). Pools would likely return to their pre-sediment release depth within one year (USBR 2012), and the river is predicted to revert to and maintain a pool-riffle morphology providing suitable habitat for fall-run Chinook salmon.

Short-term (less than two months) reductions in dissolved oxygen are anticipated to occur as a result of high organic SSCs following dam removal, as described in detail in Potential Impact 3.2-9. Despite predicted short-term increases in oxygen demand under the Proposed Project, dissolved oxygen concentrations would generally remain above the minimum acceptable level (5 mg/L) for salmonids of all life stages in this reach. Exceptions to this would occur four to eight weeks following drawdown of J.C. Boyle and Iron Gate reservoirs (i.e., in February dam removal year 2), when dissolved oxygen would remain below 5 mg/L for a distance approximately 48–71 miles downstream from Iron Gate Dam (approximately RM 145 to RM 122). Any incubating fall-Chinook salmon eggs in the river during this time are assumed to have already suffered 100 percent mortality caused by increased SSC during this time, and thus the decrease in dissolved oxygen is not anticipated to have an additional effect. No other life-stages are anticipated to occur in the mainstem Klamath River during this time, and thus no additional effects are expected.

By eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, the Proposed Project would support a flow regime that more closely mimics natural conditions in the Lower Klamath River. Flows under the Proposed Project are intended to benefit fall-run Chinook salmon and are anticipated to have positive consequences for Chinook salmon given their life cycle in the Klamath River.

As discussed in detail in Section 3.2.5.1 *Water Temperature*, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall and have diurnal variations more synchronized with historical migration and spawning periods (Hamilton et al. 2011). Under the Proposed Project, warmer springtime temperatures would result in fall-run Chinook salmon fry emerging earlier (Sykes et al. 2009), encountering favorable temperatures for growth sooner than under existing conditions (Figure 3.3-5), which could support higher growth rates and encourage earlier migration downstream, thereby reducing stress and disease (Bartholow et al. 2005, FERC 2007). A predicted earlier outmigration in response to elevated water temperatures in the spring is also supported by the scientific literature relating to increased growth rates and thermal response of outmigrating salmonids, as summarized by Hoar (1988). In addition, fall-run Chinook salmon spawning in the mainstem during fall would no longer be delayed by water temperatures (reducing prespawn mortality) (Figure 3.3-4), and adult migration would occur in lower water temperatures than under existing conditions (Figure 3.3-5). Overall, these changes would result in water temperatures more favorable for fall-run Chinook salmon in the mainstem Klamath River downstream from Iron Gate Dam.

As described in Section 3.3.5.5 *Fish Disease and Parasites*, the Proposed Project is expected to disrupt many of the existing congruence of factors that lead to high disease parasite concentrations at locations with multiple water quality stressors for fish and resulting high levels of fish disease.

As described in Section 3.3.5.6 *Fish Hatcheries*, operation of the Iron Gate Hatchery and Fall Creek Hatchery, at a combined reduced capacity for eight years following dam removal, would be likely to reduce hatchery Chinook salmon returns available for ocean or in-river harvest compared with existing conditions. However, naturally-spawning adult returns benefiting from dam removal are predicted to occur beginning in post-dam removal year 3 and the larger returns would begin to offset reductions due to lower hatchery capacity during the first eight years following dam removal and, ultimately, to hatchery closure in post-dam removal year 7.

Also, as described in Section 3.3.5.6 *Fish Hatcheries*, the cessation of juvenile fish releases from Iron Gate Hatchery after eight years may also significantly decrease the amount of competition for food resources and habitat space between hatchery-reared and natural origin smolts and yearlings in the Klamath River. This would result in higher growth rates for natural origin fish (McMichael et al. 1997), and thus larger size at ocean entry beginning in post-dam removal year 8 (first year of no hatchery releases; Table 3.3-11). Smolt size is correlated with increased marine survival for Chinook salmon (Scheuerell et al. 2009, Feldhaus et al. 2016) which, in conjunction with reduced competition with hatchery smolts in the marine environment (Sweeting et al. 2003), is anticipated to result in increased adult returns as soon as post-dam removal year 10 (three-year-old adult returns). In addition, incidences of disease are expected to be reduced by ending hatchery operations after eight years.

Klamath River Estuary and Pacific Ocean Nearshore Environment
Under the Proposed Project, habitat in the Klamath River Estuary and the Pacific Ocean nearshore environment could be affected by sediment releases during dam removal for approximately three months (January through March) under all scenarios. After this time, SSCs would return to levels similar to existing conditions (see Appendix E). SSCs in the Klamath River Estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, the increased SSCs predicted to occur in the estuary would not be of sufficient magnitude or duration to result in substantial sublethal or lethal effects on fall-run Chinook salmon individuals (Appendix E.3.2.1). While the magnitude of SSCs released to the Pacific Ocean nearshore environment would be within the range of natural conditions, the duration of elevated SSCs (i.e., weeks) would be greater than would occur under natural (i.e., storm) conditions (i.e., days). Therefore, there also would be elevated SSCs in the Pacific Ocean nearshore environment relative to existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, no Chinook salmon adults or juveniles are anticipated to occur within the nearshore environment during this period.

Summary
In the short term, reservoir drawdown under the Proposed Project would result in elevated SSCs, low dissolved oxygen, and altered sand and finer bedload sediment transport and deposition, and would adversely impact fall-run Chinook salmon primarily

in the Middle Klamath River downstream of Iron Gate Dam. Fall-run Chinook salmon use the mainstem Klamath River for spawning, rearing, and as a migratory corridor. Direct mortality is predicted for a proportion of fall-run Chinook salmon redds. However, the effect of SSCs from the Proposed Project on the fall-run Chinook salmon population, under all scenarios, is not expected to substantially reduce the population because of variable life histories, the timing of SSC pulses to avoid the most vulnerable fall-run Chinook life stages, the comparatively small number of fall-run Chinook salmon that spawn in the mainstem, the large majority of age 0 juveniles that remain in tributaries until later in the spring and summer, and because many of the fry that outmigrate to the mainstem come from lower-Basin tributaries (e.g., Salmon and Trinity rivers) and thus would be subject only to conditions in the Lower Klamath River, where SSCs resulting from the Proposed Project are expected to be lower due to dilution from tributaries (USBR 2012). Based on no predicted substantial short-term decrease in fall-run Chinook salmon abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to fall-run Chinook salmon under the Proposed Project in the short term.

Although this EIR finds no significant impact on fall-run Chinook salmon In the short term, the KRRC proposes aquatic resource measures AR-1 (Mainstem Spawning) and AR-2 (Juvenile Outmigration) which would further reduce the potential for short-term effects of SSCs on salmonid juveniles, smolts, and eggs, including fall-run Chinook salmon. In addition, although CEQA Guidelines Section 15126.4(a)(3) states that mitigation measures are not required for effects which are not found to be significant, mitigation measures AQR-1 and AQR-2, which would be implemented as a result of significant adverse impacts described for Potential Impact 3.3-1 and Potential Impact 3.3-4, would even further reduce the less than significant short-term effects of the Proposed Project on fall-run Chinook salmon by increasing certainty regarding the effectiveness of the KRRC's proposed aquatic resource measures. Aquatic resource measures are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan − Appendix I*. Proposed Aquatic Resource Measure AR-1 includes the development and implementation of a monitoring and adaptive management plan to offset the impacts of Lower Klamath Project dam removal on mainstem spawning. Proposed Aquatic Resource Measure AR-1 actions include a 2-year tributary confluence monitoring effort and addressing sediment and debris obstructions that block volitional upstream passage from the Klamath River into tributaries. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-1 Mainstem Spawning (detailed above), developed for this EIR, further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. Proposed Aquatic Resource Measure AR-1 also includes a spawning habitat evaluation on the Klamath River and tributaries in the Hydroelectric Reach. The spawning habitat actions of AR-1 are focused on offsetting impacts of the Proposed Project on Chinook salmon and steelhead. If spawning habitat conditions following dam removal do not meet target metrics[95] developed to offset the anticipated loss of Chinook salmon and steelhead redds due to the Proposed Project, spawning gravel augmentation would be

[95] Spawning gravel in the amount of 44,100 yd^2 for fall Chinook salmon and 4,700 yd^2 for steelhead

completed within the mainstem, with additional spawning habitat actions within tributaries. Tributary spawning habitat restoration actions to be completed in Jenny Creek, Shovel Creek, Fall Creek, and/or Spencer Creek could include removal of artificial fish passage barriers, or placement of large woody debris to trap and retain spawning gravels. Mitigation Measure AQR-1 Mainstem Spawning (detailed above) further specifies the range of actions that shall be conducted in tributaries to offset impacts to Chinook salmon spawning. Proposed Aquatic Resource Measure AR-1 and Mitigation Measure AQR-1 would reduce the less than significant short-term impacts of SSCs on fall-run Chinook salmon spawning in dam removal year 1 by improving access to tributary habitat where impacts from SSCs in the mainstem can be avoided, and by augmenting spawning gravel ensuring that suitable spawning habitat in mainstem and tributaries is available following dam removal.

Proposed Aquatic Resource Measure AR-2 includes three primary actions: (1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; (2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River; and (3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cold water tributaries or nearby off-channel ponds. Implementation of proposed Aquatic Resource Measure AR-2 would reduce the short-term effects of SSCs to fall-run Chinook salmon juveniles rearing in the mainstem during dam removal by actively transporting juveniles from vulnerable mainstem areas to off-channel ponds protected from the effects of the Proposed Project, thus offsetting water quality impacts to juvenile Chinook salmon. Seining efforts would be focused on coho salmon, but all captured juvenile Chinook salmon would also be relocated into tributary streams adjacent to the salvage locations. Proposed Aquatic Resource Measure AR-2 would also reduce the potential short-term effects of SSCs to fall-run Chinook salmon smolts by maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-2 Juvenile Outmigration (detailed below) developed for this EIR, further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. In addition, proposed Aquatic Resource Measure AR-2 would reduce the less than significant short-term effects of SSCs to migratory Chinook salmon smolts by rescuing and transporting smolts if mainstem SSC are high, and water temperatures within tributaries are too poor to provide safe refuge (a decision to be made in regular consultation with the ATWG).

These actions would effectively reduce the number of fall-run Chinook salmon juveniles and smolts potentially exposed to periods of high SSC in the mainstem following dam removal, and therefore off-set short-term impacts to the proportion of the population experiencing sub-lethal effects or mortality.

In the long term, removal of the Lower Klamath Project dams under the Proposed Project would increase habitat availability, restore a more natural flow regime by eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, restoring more natural seasonal water temperature variation, improve water quality, and reduce the likelihood of fish disease, all of which would be beneficial for fall-run Chinook salmon. As stated above, dam removal would also restore connectivity to hundreds of miles of potentially usable habitat in the Upper Klamath Basin and would create additional spawning and rearing habitat within the Hydroelectric Reach. It is anticipated that the Proposed Project would increase the abundance, productivity, population spatial structure, and genetic diversity of fall-run Chinook salmon in the Klamath Basin (Hendrix 2011). In general, free-flowing river conditions created by the Proposed Project would likely increase adult migration rate, decrease outmigrant delay, and increase adult escapement (Buchanan et al. 2011b). As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. In addition, under the Proposed Project diminished disease conditions and improved water quality in the mainstem Klamath River would likely improve the survival of smolts outmigrating from tributaries downstream from Iron Gate Dam (e.g., Scott and Shasta rivers). Finally, the loss of hatchery production following the closure of Iron Gate Hatchery and Fall Creek Hatchery following eight years of operation is anticipated to be offset by the increase in natural production from habitat upstream of Iron Gate Dam. If fish passage is not provided a Keno Impoundment/Lake Ewuana, restored habitat access to the Hydroelectric Reach and the multiple benefits of the Proposed Project would be beneficial for fall-run Chinook salmon in the long term. If fish passage were provided (per DOI [2007] fish passage prescriptions), an even greater magnitude of restored habitat access to the Upper Klamath River Basin and the multiple benefits of the Proposed Project would be beneficial for fall-run Chinook salmon in the long term.

Significance

No significant impact for fall-run Chinook salmon populations in the short term

Beneficial for fall-run Chinook salmon populations in the long term

Potential Impact 3.3-8 Effects on the spring-run Chinook salmon population due to short-term sediment releases and long-term changes in habitat quality, habitat quantity, and hatchery operations due to dam removal.

As discussed above for fall-run Chinook salmon, a Chinook Salmon Expert Panel was convened to attempt to answer specific questions that had been formulated by the project stakeholders to assist with assessing the effects of the Proposed Project compared with existing conditions (Goodman et al. 2011). While noting uncertainties based on existing data, the panel concluded that the prospects for the Proposed Project to provide a substantial positive effect for spring-run Chinook salmon were less certain than for fall-run Chinook salmon. The primary concern of the panel was that low abundance and productivity (return per spawner) of spring-run Chinook salmon could limit recolonization of habitats upstream of Iron Gate Dam.

There are a few basic mechanisms by which spring-run Chinook salmon could recolonize newly accessible habitat, including (1) straying of adults returning to the Salmon River, (2) adaptation of fall-run Chinook salmon to an early spring-run Chinook salmon life history, or (3) active reintroduction of spring-run Chinook salmon from another population. There are many examples of fall-run Chinook salmon rapidly recolonizing newly accessible habitat discussed in Potential Impact 3.3-7 above, and spring-run Chinook salmon were observed recolonizing habitat in the White Salmon

River, Washington, following removal of Condit Dam (Allen et al. 2016). Following the removal of Condit Dam most of the observed spring-run Chinook salmon spawning was upstream of the location of the former Condit Dam. The current spring-run Chinook salmon abundance in the Salmon River is low (Table 3.3-10), and the rate of recolonization could be slow as a result. However, under the Proposed Project water temperatures and instream flows in the Klamath River upstream of the confluence with the Salmon River are predicted to mimic more natural conditions, which could encourage increased straying into upstream habitat.

The potential for adaptation of fall-run Chinook salmon to a spring-run Chinook salmon life history was assessed by Thompson et al. (2018), and they concluded that based on the genetics of the fall-run Chinook salmon currently downstream of Iron Gate Dam, it was unlikely that this would occur. Active reintroduction of Chinook salmon with genetics suited to adapt to an early spring-run Chinook salmon life history may be successful strategy for recolonization (Thompson et al. 2018). The Proposed Project does not include an active reintroduction plan, although ODFW has been considering implementing active reintroduction of spring-run Chinook salmon following dam removal (T. Wise, ODFW, pers. comm., 2018).

Under the Proposed Project, steelhead, coho, and fall-run Chinook salmon yearlings and smolts would no longer be released from hatcheries in the Klamath River following post-dam removal year 7. Currently there are no releases of spring-run Chinook salmon from hatcheries into the Klamath River. Therefore, the closure of hatcheries eight years following dam removal is not anticipated to result in a decline in adult returns for spring-run Chinook. Impacts associated with hatcheries operations in relation to water diversions and minimum bypass flows for fish passage is discussed in Potential Impact 3.3-23 (Iron Gate Hatchery) and Potential Impact 3.3-24 (Fall Creek Hatchery).

The expected influence of the Proposed Project within specific reaches is described below.

Upper Klamath River and Connected Waterbodies

The Proposed Project would not result in changes to suspended or bedload sediment, flow-related habitat, or algal toxins in this reach. Under the Proposed Project, dam removal would allow spring-run Chinook salmon to regain access to the Upper Klamath River upstream of J.C. Boyle Reservoir (FERC 2007). The access would expand the Chinook salmon's current habitat to include historical habitat along the mainstem Klamath River and upstream to the Sprague, Williamson, and Wood rivers (Hamilton et al. 2005). This would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising hundreds of miles of additional potentially productive habitat (DOI 2007), including access to important thermal refugia within areas influenced by groundwater exchange that are more resistant to climate change (Hamilton et al. 2011). Some of these areas, such as the lower Williamson River, have habitat that would provide substantial holding areas for spring-run Chinook salmon (Hamilton et al. 2011). Other holding areas with suitable temperatures upstream of J.C. Boyle Reservoir include groundwater influenced areas on the west side of Upper Klamath Lake, and the Wood River (Gannett et al. 2007). Warmer winter water temperatures associated with groundwater input to the river would also be conducive to the growth of salmonids (Hamilton et al. 2011).

Poor water quality (e.g., severe hypoxia, temperatures exceeding 77°F, high pH) in the reach from Keno Dam to Link Dam might impede volitional fish passage at any time from late June through mid-November (Sullivan et al. 2009, USGS 2010; both as cited in Hamilton et al. 2011). However, available information indicates that Upper Klamath Lake habitat is presently suitable to support Chinook salmon for at least the period from October through May (Maule et al. 2009). Currently, adult spring-run Chinook migration takes place in approximately April through June. Historically, adult spring-run Chinook salmon migrated upstream of the current location of Iron Gate Dam perhaps as early as February and March (Fortune et al. 1966) and likely held over in large holding pools in the mainstem in tributaries fed by cool water, and in thermal refuge habitat upstream of Upper Klamath Lake (Snyder 1931, CDFG 1990c, Moyle 2002). One benefit of such early migration (similar to the spring-run Chinook salmon migration timing currently observed in the Klamath Basin) would be the avoidance of periods of poor water quality in the vicinity of Keno Impoundment/Lake Ewuana. The restored water temperature regime under the Proposed Project may restore the natural upstream migration timing of adult spring-run Chinook salmon because of the shift in water temperatures downstream from Iron Gate Dam (Bartholow et al. 2005). Either under the current migration timing or under a shift towards earlier migration, most or all of the spring-run Chinook salmon migrants would be able to pass upstream through the Keno Impoundment/Lake Ewuana area before seasonal water quality reductions would make passage restricted.

Huntington (2006) reasoned that spring-run Chinook salmon likely accounted for the majority of the Upper Klamath Basin's actual salmon production under historical conditions. Huntington (2006) cautioned that while access to the Upper Klamath Basin provides considerable promise of increasing spring-run abundance, the existing potential for Chinook salmon production within the basin upstream of Upper Klamath Lake is clearly much lower than his estimate of historical potential. However, Huntington (2006) did not fully account for the historical (and unknown) production potential of Upper Klamath Lake itself, which could have been considerable, as suggested by a recent experimental reintroduction into Upper Klamath Lake (Maule et al. 2009).

Upper Klamath River - Hydroelectric Reach

The Proposed Project would restore spring-run Chinook salmon access to the Hydroelectric Reach, including include historical habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek; including in Jenny, Shovel, and Fall creeks (Hamilton et al. 2005), comprising around 80 miles of potential habitat within the Hydroelectric Reach (DOI 2007, Cunanan 2009). Chinook salmon (both fall- and spring-run) historically spawned and were abundant within this habitat (NMFS 2006a, Hamilton et al. 2016). Adults would be able to access this reach beginning in spring of dam removal year 2 (Table 2.7-1); thus, short-term gains in flow-related habitat or habitat expansion may be limited to later cohorts. Elevated SSCs and bedload movement from dam removal may not have sufficiently dissipated in time for the first potential migrants, but by the second adult migrant season in post-dam removal year 1, would return to background levels similar to those under existing conditions and would not be expected to affect spring-run Chinook salmon using this area. Adult spring-run Chinook salmon do not currently occur upstream of the Salmon River, and would not be expected to be able to use the mainstem Klamath River upstream of Iron Gate Dam until conditions in the Hydroelectric Reach are suitable.

The Proposed Project would establish flow and water quality conditions that more closely mimics natural conditions by eliminating peaking flows, removing Lower Klamath

Project reservoirs, and incorporating more variability in daily flows. The removal of the reservoirs would allow Fall, Shovel, and Spencer creeks to flow directly into the mainstem Klamath River, along with Big Springs (in the J.C. Boyle Bypass Reach) and additional springs, which would provide fish with patches of cooler water as refugia during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011).

As described in detail in Section 3.3.5.5 *Fish Disease and Parasites*, it is unlikely that the disease conditions that currently exist downstream of Iron Gate Dam would develop upstream of Iron Gate Dam under the Proposed Project.

Middle and Lower Klamath River

The Proposed Project would release dam-stored sediment downstream to the Lower Klamath River Reach in the short term and would establish a flow and sediment regime that more closely mimics natural conditions in the Middle Klamath River in the long term.

Short-term effects of elevated SSCs on spring-run Chinook salmon under the Proposed Project are described in detail in Appendix E.3.2.2 and summarized here. Spring-run Chinook salmon are primarily distributed in the Salmon River and other tributaries downstream with limits their exposure to temporarily elevated concentrations of suspended sediment that would occur in the mainstem Klamath River under the Proposed Project. Under all scenarios, no impact from suspended sediment is anticipated for all spring-run Chinook salmon spawning and rearing, which occurs primarily within tributaries (Table E-9). Suspended sediment is anticipated to have sublethal effects on adult migration, primarily for those adults returning to the Salmon River (around five percent of all spring-run migrants). All outmigrating spring-run Chinook salmon smolts enter the Klamath River at the confluence with the Salmon River, where SSC are predicted to be much lower than further upstream, and where SSCs under existing conditions can be high from tributary contributions of suspended sediment. Therefore, only sublethal effects on outmigrants are predicted (Appendix E, Table E-9), which is similar to existing conditions (Appendix E, Table E-3).

Short- and long-term changes in channel bed elevations and grain size in response to increased bedload supply would be limited to the reach from Iron Gate Dam to Cottonwood Creek, a length of eight miles, or four percent of the mainstem Klamath River channel downstream from Iron Gate Dam (see Appendix F for details). The most severe effects would also be limited to a small proportion of the total channel length (0.5 miles, or less than one percent of the channel downstream from Iron Gate Dam), as sediment deposition would lessen downstream from Bogus Creek to Cottonwood Creek and, thus, would not affect the area currently used by spring-run Chinook salmon. Within one year (i.e., by spring of post-dam removal year 1), SSCs would have returned to existing conditions and the channel would likely have reverted to its previous pool-riffle morphology (Stillwater Sciences 2008).

By eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, the Proposed Project would support a flow regime that more closely mimics natural conditions in the Lower Klamath River, mostly upstream of the confluence of Scott Creek. Dam removal would cause water temperatures upstream of the Salmon River confluence to warm earlier in the spring and early summer and cool earlier in the late summer and fall and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperatures that are more favorable for salmonids in the mainstem upstream of the Salmon River confluence (Section 3.3.5.4 *Water Temperature*). Therefore, in the long term it is anticipated that improved mainstem migration conditions may increase migration of spring-run Chinook salmon upstream of the Salmon River towards newly accessible habitat.

Although disease incidence is predicted to decrease (resulting in increased salmonid smolt survival) under the Proposed Project (see Section 3.3.5.5 *Fish Disease*), these benefits would be most noticeable upstream of the confluence with the Salmon River, and thus are anticipated to have less of benefit for spring-run Chinook salmon than other salmonids in comparison with existing conditions.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Under the Proposed Project, habitat in the Klamath River Estuary could be affected by elevated sediment releases during dam removal for about three months (January through March) when spring-run Chinook salmon smolts could be within the estuary (see Section 3.3.5.1 *Suspended Sediment* and Appendix E). After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project* and Appendix E). However, the increased SSCs predicted to occur in the Klamath River Estuary would not be of sufficient magnitude or duration to result in substantial sublethal or lethal effects on spring-run Chinook salmon individuals (Appendix E.3.2.2). While the magnitude of SSCs released to the Pacific Ocean nearshore environment would be within the range of natural conditions, the duration of elevated SSCs (i.e., weeks) would be greater than would occur under natural (i.e., storm) conditions (i.e., days). Therefore, there also would be elevated SSCs in the Pacific Ocean nearshore environment relative to existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, no Chinook salmon adults or juveniles are anticipated to occur within the nearshore environment during this period.

Summary

In the short term, reservoir drawdown associated with dam removal under the Proposed Project would alter SSCs and bedload sediment transport and bedload deposition. The overall effect of suspended sediment from the Proposed Project on the spring-run Chinook salmon population is not anticipated to differ substantially from existing conditions. Suspended sediment conditions experienced by adult migrants would result in minor and only sublethal impacts. No impacts are anticipated for the spawning, incubation, and fry stages because they do not occur in the mainstem. Type I, II, and III outmigrants are expected to experience similar conditions under the Proposed Project as under existing conditions. Based on no predicted substantial short-term decrease in spring-run Chinook salmon abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to spring-run Chinook salmon under the Proposed Project in the short term.

Although this EIR finds no significant impact on spring-run Chinook salmon In the short term, the KRRC proposes Aquatic Resource Measures AR-2 (Juvenile Outmigration) which would further reduce the potential for short-term effects of SSCs on salmonid juveniles and smolts, including spring-run Chinook salmon. In addition, although CEQA

Guidelines Section 15126.4(a)(3) states that mitigation measures are not required for effects which are not found to be significant, Mitigation Measure AQR-2, which would be implemented as a result of significant adverse impacts described for Potential Impact 3.3-1 and Potential Impact 3.3-4, would even further reduce the potential for short-term, less than significant effects of the Proposed Project on spring-run Chinook salmon by increasing certainty regarding the effectiveness of the KRRC's proposed aquatic resource measure.

Aquatic resource measures are summarized in Section 2.7.8.1 and detailed in Appendix B: *Definite Plan − Appendix I*. AR-2 includes three primary actions: (1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; (2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River; and (3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cold water tributaries or nearby off-channel ponds. Implementation of AR-2 would reduce the short-term effects of SSCs to outmigrating juvenile spring-run Chinook salmon smolts by rescuing and transporting smolts if mainstem SSC are high, and water quality conditions within tributaries do not allow safe refuge. This action would effectively reduce the number of spring-run Chinook salmon smolts potentially exposed to periods of high SSC in the mainstem following dam removal, and therefore reduce the proportion of the population experiencing sub-lethal effects.

In the long term, removal of the Lower Klamath Project dams under the Proposed Project would increase habitat availability, restore a more natural temperature regime, improve water quality, and reduce the likelihood of fish disease, all of which would be beneficial for spring-run Chinook salmon. Dam removal would restore connectivity to hundreds of miles of potentially usable habitat in the Upper Klamath Basin, including additional habitat within the Hydroelectric Reach. Access to additional habitat would provide a long-term benefit to spring-run Chinook salmon populations. The expansion of habitat opportunities would allow increased expression of life-history variation and the restoration of an additional population of spring-run Chinook salmon to strengthen resiliency in the Klamath Basin, particularly because passage upstream of Iron Gate Dam would provide access to groundwater-fed thermal refugia during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). By providing an unimpeded migration corridor, the Proposed Project would provide the greatest possible benefit related to fish passage, hence, the highest survival and reproductive success (Buchanan et al. 2011b). As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods in the mainstem upstream of the confluence with the Salmon River (Hamilton et al. 2011). These changes would result in water temperatures more favorable for spring-run Chinook salmon in the mainstem, supporting any portion of the population that recolonizes Klamath River Basin habitat upstream of the Salmon River. It is anticipated that, as a result of the Proposed Project, the spring-run Chinook salmon population within the Klamath Basin would have an opportunity to increase in abundance, and would have increased productivity, population spatial structure, and genetic diversity. Implementation of the Proposed Project would be beneficial for spring-run Chinook salmon in the long term.

Significance

No significant impact for spring-run Chinook salmon populations in the short term

Beneficial for spring-run Chinook salmon populations in the long term

Potential Impact 3.3-9 Effects on coho salmon populations due to short-term sediment releases and long-term changes in habitat quality, habitat quantity, and hatchery operations due to dam removal.

The Coho Salmon and Steelhead Expert Panel was convened and charged with answering specific questions that had been formulated to assist with assessing the effects of the Proposed Project on coho salmon (Dunne et al. 2011). While noting the constraints of the Coho Salmon and Steelhead Expert Panel to arrive at conclusions within a short time, and without adequate quantitative or synthesized information, the conclusion of the Coho Salmon and Steelhead Expert Panel was that, in the short term, the difference between the Proposed Project and existing conditions is expected to be small. The Coho Salmon and Steelhead Expert Panel stated that larger (moderate) increases in abundance are possible under the Proposed Project if additional restoration actions are implemented, and mortality caused by the pathogen *C. shasta* is reduced. The Coho Salmon and Steelhead Expert Panel predicted a small increase in the population from a modest increase in habitat area usable by coho salmon, small changes in conditions in the mainstem, and positive but un-quantified changes in tributary habitats where most coho spawn and rear. The Coho Salmon and Steelhead Expert Panel also noted the potential for increased disease risk and low ocean survival to offset gains in production in the new habitat, although no evidence for either increased disease risk or reduced ocean survival was presented.

Under the Proposed Project, hatchery coho salmon smolts would be released from Fall Creek Hatchery into the Klamath River at current (75,000 smolts annually) production goals for eight years following dam removal. During that eight-year period no change to the coho salmon population resulting from hatchery operations relative to existing conditions is anticipated. Eight years following dam removal, all hatchery coho salmon releases would cease (final releases would occur in dam removal year 7). Based on production goals, ceasing operations after eight years would likely result in a reduction of up to 75,000 coho salmon smolts per year beginning in post-dam removal year 8 (Table 3.3-11). Based on the current low abundance of coho salmon in the upper Klamath River population unit, a conservation focus for the coho salmon hatchery program has been deemed necessary to protect the remaining genetic resources of that population unit (CDFW 2014). Coho salmon adult returns to Iron Gate Hatchery have significantly and steadily declined from a high of 2,466 adults in the 2001/2002 return year to 38 in the 2015/2016 return year, with an average of 866 annually (CDFW 2016b). Assuming smolts are released for the last time in post-dam removal year 7, adults of hatchery progeny would continue to return through post-dam removal year 9 (as age 3 adults). Based on the average coho salmon smolt-to-adult survival ratio of 0.99 percent estimated for current coho salmon Iron Gate Hatchery operations (CDFW 2014), a reduction in the release of 75,000 coho salmon smolts following closure of Fall Creek Hatchery could result in a decline of around 743 adult returns on average annually starting in post-dam removal year 10. These adults would return to the Fall Creek Hatchery, but also stray and spawn naturally. Between 2004 and 2011 an average of 46 coho salmon hatchery adults per year strayed into Bogus Creek (CDFW 2014). Impacts associated with hatcheries operations in relation to water diversions and minimum bypass flows for fish passage is discussed in Potential Impact 3.3-23 (Iron Gate Hatchery) and Potential Impact 3.3-24 (Fall Creek Hatchery).

As described in Section 3.3.5.6 *Fish Hatcheries* and summarized in CDFW (2014), there are potential adverse hatchery-related effects on the coho salmon population, including straying of hatchery fish into important tributaries such as Bogus Creek (first three years) and Fall Creek (years four through ten) with the potential to reduce the reproductive success of the natural population (Mclean et al. 2003, Chilcote 2003, Araki et al. 2007) and negatively affect the diversity of the Klamath River coho salmon populations via outbreeding depression[96] (Reisenbichler and Rubin 1999). The current Hatchery Genetic Management Plan for Iron Gate Hatchery coho salmon (HGMP, CDFW 2014) operates to assist in the basin's coho salmon recovery efforts by conserving a full range of the existing genetic, phenotypic, behavioral, life history, and ecological diversity of the run. The intent of this program is to use genetic analysis in brood stock selection and rearing and release techniques improve fitness and reduce straying of hatchery fish to natural spawning areas.

Under the Proposed Project, dam removal and the associated habitat improvements are anticipated to result in an increase in coho salmon abundance. The first adults that could potentially access newly available habitat upstream of Iron Gate Dam would be in dam removal year 2 (Table 3.3-11) and produce age 1 smolts benefiting from improved river function (e.g., reduced disease in the Middle Klamath River). Therefore, the first adult returns that could reflect improved conditions would be in post-dam removal year 4 (as age 3 adults). Under existing conditions, CDFW (2014) estimates that greater than 30 percent of the total adult returns to the upper Klamath River are of hatchery origin, including greater than 70 percent of returns to the hatchery, around 34 percent of returns to Bogus Creek, and around 16 percent of returns to tributaries such as the Shasta and Scott rivers. Between post-dam removal years 4 and 10, both hatchery returns and returns from newly accessible habitat, would occur (Table 3.3-11) providing a likelihood of increased abundance and recolonization of the newly accessible habitat.

As described in Section 3.3.5.6 *Fish Hatcheries*, outmigrant smolt mortality from disease would be reduced under the Proposed Project starting in post-dam removal year 8 with the end of Chinook and coho salmon hatchery releases. The cessation of juvenile fish releases may also significantly decrease the amount of competition for food resources and habitat space between hatchery-reared and natural origin smolts in the Klamath River. This would result in higher growth rates for natural origin fish (McMichael et al. 1997), and thus larger size at ocean entry beginning in dam removal year 8. Smolt size is correlated with increased marine survival for coho salmon (Holtby et al. 1990), which in conjunction with reduced competition with hatchery smolts in the marine environment (Sweeting et al. 2003) is anticipated to result in increased adult returns as soon as post-dam removal year 10 (3-year-old adult returns). Although existing data are not available for a quantitative prediction, it is anticipated that benefits from dam removal and cessation of hatchery operations would increase adult returns by more than the loss of hatchery progeny.

Upper Klamath River and Connected Waterbodies

Available data suggests that coho salmon were in both mainstem and tributary reaches of the Klamath River upstream to and including Spencer Creek at RM 232.6 (Figure 3.3-

[96] Outbreeding depression is progeny that are less adapted to the environment than parents.

1, NRC 2004, as cited in NMFS 2007a, Hamilton et al. 2005). It is not anticipated that under the Proposed Project coho salmon would begin to occupy habitat within the Upper Klamath River and connected waterbodies, and therefore this reach is not analyzed for effects on coho salmon.

Upper Klamath River – Hydroelectric Reach

The Proposed Project would restore access for the Upper Klamath River Population coho salmon to the Hydroelectric Reach, expanding their distribution to include historical habitat along the mainstem Klamath River and all tributaries upstream at least as far as Spencer Creek; including in Jenny, Shovel, and Fall creeks (Hamilton et al. 2005), comprising around 80 miles of potential habitat within the Hydroelectric Reach (DOI 2007, Cunanan 2009). Coho salmon downstream from Iron Gate Dam belonging to the Upper Klamath River Population Unit would migrate upstream of the dam if access was provided (NMFS 2006a). Over time, access to habitat upstream of Iron Gate Dam would benefit the Upper Klamath River Population Unit by: a) extending the range and distribution of the species thereby increasing the coho salmon's reproductive potential; b) increasing genetic diversity in the coho stocks; and c) reducing the species' vulnerability to the impacts of degradation. These benefits would cumulatively result in an increase in the abundance of the coho salmon population (NMFS 2006a). The National Research Council (NRC) of the National Academy of Sciences reviewed causes of decline and strategies for recovery of endangered and threatened fishes of the Klamath Basin. The NRC concluded that "removal of Iron Gate Dam...could open new habitat, especially by making available tributaries that are now completely blocked to coho" (NRC 2004). Coho salmon recolonization of newly accessible habitat was observed following fish ladder installation at Landsburg Dam on the Cedar River, Washington (Kiffney et al. 2009), and following removal of Condit Dam on the White Salmon River, Washington (Allen et al. 2016). The Landsburg Dam was laddered in 2003, and coho salmon were observed within areas upstream of the dam within the first year. By 2011 salmon (with coho salmon being most abundant) occurred within nearly all of the accessible habitat upstream of the dam. Pess (et al. 2011) predicted that within the habitat upstream of Landsburg Dam juvenile coho salmon would establish a population that outnumbered resident salmonid species (e.g., rainbow trout, cutthroat trout) by 40 percent within five years of colonization, suggesting a strong ability of coho salmon to successfully occupy newly accessible habitat.

By eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, the Proposed Project would support a flow regime that more closely mimics natural conditions in the Lower Klamath River. The reservoir drawdowns would also allow tributaries and springs such as Fall, Shovel, and Spencer creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011). As described in Section 3.3.5.5 *Fish Disease and Parasites*, risk of fish disease and parasites for coho salmon would decrease.

Adults would be able to access the Hydroelectric Reach beginning in fall of dam removal year 2. By this time, elevated SSCs from dam removal would likely have dissipated, returning to background levels similar to those of existing conditions. Most sediment released from the reservoirs would likely be eroded within the first six months after dam removal (by June of dam removal year 2), returning sections of river currently inundated by the Lower Klamath Project reservoirs and riverine sections between reservoirs to pool-riffle morphology. Within this reach, coho salmon would generally spawn in tributaries and not within the mainstem Klamath River, but might rear in and migrate through the Hydroelectric Reach. Dam removal would result in the provision of suitable rearing habitat for juveniles and spawning habitat for the few individual coho that might spawn in the mainstem Klamath River. Access to the cooler waters associated with spring inputs in the Hydroelectric Reach would benefit coho salmon rearing in the mainstem (Hamilton et al. 2011). Removal of the Lower Klamath Project reservoirs would result in more favorable water temperature for coho salmon adult migrants, juveniles, and smolts. As described in detail in Section 3.3.5.5 *Fish Disease and Parasites*, it is unlikely that the disease conditions that currently exist downstream of Iron Gate Dam would develop upstream of Iron Gate Dam under the Proposed Project. Access to this reach and the habitat conditions within it would benefit the Upper Klamath River coho salmon population.

Middle and Lower Klamath River

The Proposed Project would release dam-stored sediment downstream to the Lower Klamath River Reach in the short term and would establish a flow and sediment regime that more closely mimics natural conditions in the long term. Suspended sediment effects on coho salmon under the Proposed Project are described in detail in Appendix E.3.2.3, and summarized here.

There are nine coho salmon population units in the Klamath Basin (see the coho salmon subsection of Section 3.3.2.1 *Aquatic Species*). Only negligible effects from suspended sediment would be expected on the three population units in the Trinity River, and on the Lower Klamath River Population Unit. Effects on the Salmon River Population Unit are anticipated to remain similar to existing condition (SEV ranging from 5.4 to 8.4 with sublethal physiological stress) even under a worst impacts on fish scenario (Appendix E.3.2.3, Table E-10), due to dilution of suspended sediment from tributaries in the Middle Klamath River. Effects on the Upper Klamath River, Mid-Klamath River, Shasta River, and Scott River population units under all scenarios are anticipated to be sublethal on most life-stages (Appendix E.3.2.3). Under all scenarios, the small proportion of coho salmon from the Upper Klamath River Population Unit that spawn in the mainstem, as well as their progeny, would suffer 60 to 80 percent mortality due to the effects of suspended sediment on these life stages. This compares to existing conditions high rate of mortality for this small proportion of mainstem spawners predicted to be from 20 to 60 percent depending on severity of conditions (Appendix E.3.1.3). It is believed by experts in the watershed that progeny of mainstem spawning coho salmon experience reduced survival compared to fish produced from tributary spawners (Simondet 2006), since rearing and growth conditions within tributaries are more favorable than in the mainstem. Based on spawning surveys conducted from 2001 through 2017 (Magneson and Gough 2006, Hentz and Wickman 2016, Dennis et al. 2017), from 0 to 13 redds could be affected in dam removal year 1 during the Proposed Project. Many of these redds are thought to be from returning hatchery fish (NMFS 2010a), and thus may be only selecting this habitat after failing to locate the hatchery collection site. Based on the range of escapement estimates of Ackerman et al. (2006), 13 redds (the highest number observed) would be much less than one percent of the natural and hatchery returns to the Klamath River Basin. The Upper Klamath River Population Unit would be expected to recover from these losses in the long term, given the benefits to the population.

Coho salmon smolts from the dam removal year 1 cohort are expected to outmigrate to the ocean beginning in late February, although most natural origin smolts outmigrate to the mainstem Klamath River during April and May (Wallace 2004). Coho smolt releases from Iron Gate Hatchery typically occur in the first three weeks of April (CDFW 2014). Numerous field and laboratory studies have shown that juvenile salmonids actively avoid exposure to high (> 150 mg/L) SSCs, including altering migratory patterns to seek lower turbidity (Bisson and Bilby 1982, Berg and Northcote 1985, Redding et al. 1987, Servizi and Martens 1992, Bash et al. 2001, Carlson et al. 2001, Kemp et al. 2011, Kjelland et al. 2015). Therefore, it is assumed that coho salmon outmigration during the spring of dam removal year 2 would occur within the period of typical outmigration with the lowest predicted SSC. Once in the mainstem Klamath River, coho salmon smolts move downstream fairly quickly (Stutzer et al. 2006). Under the Proposed Project, SSCs would be slightly higher during spring than under existing conditions, and coho salmon smolts are likely to suffer moderate to major stress and reduced feeding depending on scenario (Appendix E.3.2.3, Table E-10).

Under existing conditions, coho salmon smolts outmigrating from the Upper Klamath River, Scott River, and Shasta River populations currently have high mortality rates (35 to 70 percent) presumably as a result of poor water quality and disease (Beeman et al. 2007, 2008), which, in conjunction with physiological stress and reduced growth resulting from the Proposed Project, could result in higher mortality than under existing conditions in the spring of dam removal year 2.

Based on the results of coho salmon outmigrant trapping by the USFWS (2001) on the mainstem Klamath River compared with trapping in the Trinity River from 1997 to 2000 (USFWS 2011), most (greater than 80 percent) coho smolts originate from the Trinity River and Lower Klamath River populations. For the majority of coho salmon smolts, produced from tributaries downstream from Orleans, effects of the Proposed Project would be similar to existing conditions by late April.

The Proposed Project would also result in the release of coarse sediment, as described in Section 3.11 *Geology, Soils, and Mineral Resources* and Appendix F of this EIR. Impacts associated with the release of coarse sediment are expected to affect the same individuals described for suspended sediment above. For example, coarse sediment is predicted to bury redds constructed in fall of dam removal year 1, which are the same redds expected to suffer from suspended sediment (potentially from 0 to 13 redds). In addition, sediment deposition could aggrade pools or overwhelm other habitat features that coho salmon use for adult holding or juvenile rearing. However, the sediment impact on habitat is anticipated to be short term, and pools would likely return to their pre-sediment release depth within one year (USBR 2012).

Additionally, as described in Potential Impact 3.2-1 and Potential Impact 3.2-2, water quality improvements are anticipated to reduce stress to smolts, improving fitness and survival. As discussed in detail in Section 3.2.5.1 *Water Temperature*, dam removal would cause water temperatures to become warmer earlier in the spring and early summer and cooler earlier in the late summer and fall and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for coho salmon and other salmonids in the mainstem. Cooler water temperatures during fall would benefit upstream migrant adults during fall upstream migration and juvenile redistribution to overwintering habitats by providing a broader window of suitable habitat, starting in dam-removal year 2. A predicted earlier outmigration in response to elevated water temperatures in the spring is also supported by of the scientific literature relating to increased growth rates and thermal response of outmigrating salmonids, as summarized by Hoar (1988). Spring outmigrants could therefore begin an earlier outmigration starting in post-dam-removal year 1, potentially reducing their susceptibility to disease. Coincident with increased with SSCs, in the short term, migrating adults and juveniles rearing or migrating in the mainstem would be exposed to reductions in dissolved oxygen due to the Proposed Project. The risk of sublethal physiological stress and avoidance behavior predicted for migrating adults and juveniles rearing or migrating in the mainstem after dam removal resulting from increased suspended sediment is anticipated to be further exacerbated by reductions in dissolved oxygen.

As described in Section 3.3.5.5 *Fish Disease and Parasites*, the Proposed Project is expected to disrupt many of the existing congruence of factors that lead to high disease parasite concentrations at locations with multiple water quality stressors for fish and resulting high levels of fish disease.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Under the Proposed Project, habitat in the Klamath River Estuary could be affected by elevated sediment during dam removal for about three months (January through March) when a low abundance of coho salmon smolts could be within the estuary during their outmigration to the ocean. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.3.5.1 *Suspended Sediment*). However, the increased SSCs predicted to occur in the estuary would not be of sufficient magnitude or duration to result in substantial sublethal or lethal effects on coho salmon individuals (Appendix E.3.2.3). While the magnitude of SSCs released to the Pacific Ocean nearshore environment would be within the range of natural conditions, the duration of elevated SSCs (i.e., weeks) would be greater than would occur under natural (i.e., storm) conditions (i.e., days). Therefore, there also would be elevated SSCs in the Pacific Ocean nearshore environment relative to existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, no coho salmon adults or juveniles are anticipated to occur within the nearshore environment during this period.

Summary

In the short term, reservoir drawdown associated with dam removal under the Proposed Project could alter SSCs and bedload sediment transport and deposition, causing both lethal and sub-lethal impacts to coho salmon at all life stages. In general, the wide distribution and use of tributaries by both juvenile and adult coho salmon would likely protect the population from the worst short-term impacts of the Proposed Project. A small amount of direct mortality is anticipated for redds from the Upper Klamath Population Unit, and no mortality is anticipated for the other population units under all scenarios. Based on no predicted substantial short-term decrease in coho salmon abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to coho salmon under the Proposed Project in the short term.

Although this EIR finds no significant impact on coho salmon In the short term, the KRRC proposes aquatic resource measures AR-1 (Mainstem Spawning), AR-2 (Juvenile Outmigration), and AR-4 (Iron Gate Hatchery Management) which would further reduce the potential for short-term effects of SSCs on coho salmon eggs, juveniles, and smolts (natural and hatchery production). In addition, although CEQA Guidelines Section 15126.4(a)(3) states that mitigation measures are not required for effects which are not found to be significant, mitigation measures AQR-1 and AQR-2, which would be implemented as a result of significant adverse impacts described for Potential Impact 3.3-1 and Potential Impact 3.3-4, would even further reduce the potential for short-term effects of the Proposed Project on coho salmon by increasing certainty regarding the effectiveness of the KRRC's proposed aquatic resource measures. Aquatic resource measures are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan − Appendix I*. Proposed Aquatic Resource Measure AR-1 includes the development and implementation of a monitoring and adaptive management plan to offset the impacts of Lower Klamath Project dam removal on mainstem spawning. Proposed Aquatic Resource Measure AR-1 actions include a 2-year tributary confluence monitoring effort and addressing sediment and debris obstructions that block volitional upstream passage from the Klamath River into tributaries. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-1 Mainstem Spawning (detailed in Potential Impact 3.3-1 above) further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. Proposed Aquatic Resource Measure AR-1 also includes a spawning habitat evaluation on the Klamath River and tributaries in the Hydroelectric Reach. Most coho salmon spawning occurs in tributaries, and very few coho salmon have been observed spawning in the mainstem Klamath River. Therefore, the spawning habitat actions of Proposed Aquatic Resource Measure AR-1 are focused on offsetting impacts of the Proposed Project on Chinook salmon and steelhead. However, due to the similar spawning habitat requirements of coho salmon to both species, these actions would benefit them as well. If mainstem spawning habitat conditions following dam removal do not meet target metrics[97] developed to offset the anticipated loss of Chinook salmon and steelhead redds due to the Proposed Project, spawning gravel augmentation would be completed within the mainstem, with additional spawning habitat actions within tributaries. Tributary spawning habitat restoration actions to be completed in Jenny Creek, Shovel Creek, Fall Creek, and/or Spencer Creek could include removal of artificial fish passage barriers, or placement of large woody debris to trap and retain spawning gravels. Mitigation Measure AQR-1 Mainstem Spawning (detailed in Potential Impact 3.3-1 above) further specifies the range of actions that shall be conducted in tributaries to offset impacts to coho salmon spawners. Implementation of Proposed Aquatic Resource Measure AR-1 and Mitigation Measure AQR-1 would reduce the short-term potential impacts of SSCs on coho salmon spawning in dam removal year 2 by improving access to tributary habitat where impacts from SSC on habitat in the mainstem can be avoided, and by augmenting spawning gravel ensuring that suitable spawning habitat in mainstem and tributaries is available following dam removal.

Proposed Aquatic Resource Measure AR-2 includes three primary actions: (1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; (2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and

[97] Spawning gravel in the amount of 44,100 yd^2 for fall Chinook salmon and 4,700 yd^2 for steelhead

the Klamath River; and (3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cold water tributaries or nearby off-channel ponds. Implementation of AR-2 would reduce the short-term effects of SSCs to coho salmon juveniles rearing in the mainstem during dam removal by actively transporting up to 500 coho salmon juveniles from vulnerable mainstem areas to off-channel ponds protected from the effects of the Proposed Project, thus offsetting water quality impacts to these coho salmon individuals. Proposed Aquatic Resource Measure AR-2 would also reduce the potential short-term effects of SSCs to migrating coho salmon smolts by maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-2 Juvenile Outmigration (detailed in Potential Impact 3.3-1 above) further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. In addition, proposed Aquatic Resource Measure AR-2 would reduce the potential short-term effects of SSCs to migrating coho salmon smolts by rescuing and transporting smolts if mainstem SSC are high, and water temperatures within tributaries are too poor to provide safe refuge (a decision to be made in regular consultation with the ATWG). These actions would effectively reduce the number of coho salmon juveniles and smolts potentially exposed to periods of high SSC in the mainstem habitat following dam removal, and therefore reduce the proportion of the population experiencing sub-lethal effects or mortality.

The Proposed Project would shift all production of Iron Gate Hatchery coho salmon (75,000 yearling goal) to Fall Creek Hatchery. In the short term, transfer of coho salmon production from Iron Gate Hatchery to Fall Creek Hatchery would have no impact on adult returns. In addition, proposed Aquatic Resource Measure AR-4 proposes that hatchery-reared yearling coho salmon to be released in the spring of dam removal year 2 be held at Iron Gate Hatchery or Fall Creek Hatchery until water quality conditions in the mainstem Klamath River improve to sublethal levels. This would reduce the short-term effects of SSCs to coho salmon smolt released from the hatchery by decreasing the probability that they would be exposed to peak SSC levels, and would increase survival during downstream migration in dam removal year 2.

In the long term, removal of the Lower Klamath Project dams under the Proposed Project would increase habitat availability, restore a more natural flow regime by eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, restoring more natural seasonal water temperature variation, improve water quality, and reduce the likelihood of fish disease, all of which would be beneficial for coho salmon populations. Substantial declines in abundance resulting from effects of the Proposed Project are not anticipated for more than one year class (i.e., one generation). Dam removal would restore connectivity to habitat on the mainstem Klamath River up to and including Spencer Creek and would create additional habitat within the Hydroelectric Reach. Dam removal would also cause water temperatures to become warmer earlier in the spring and early summer, cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem.

In the long term, increased adult returns resulting from newly accessible habitat upstream of Iron Gate Dam would offset reductions in adult returns due to cessation of hatchery operations eight years following dam removal. It is anticipated that as a result of the Proposed Project, the coho salmon population would experience an increase in abundance, productivity, population spatial structure, and genetic diversity. In general, free flowing river conditions under the Proposed Project would likely increase adult migration efficiency, decrease outmigrant delay, and increase adult escapement (Buchanan et al. 2011b). The Proposed Project would provide multiple benefits to coho salmon from all Klamath River population units in the long term.

Significance

No significant impact for coho salmon populations in the short term

Beneficial for coho salmon populations in the long term

Potential Impact 3.3-10 Effects on the steelhead population due to short-term sediment releases and long-term changes in habitat quality, habitat quantity, and hatchery operations due to dam removal.

The Coho Salmon and Steelhead Expert Panel was convened and charged with answering specific questions that had been formulated to assist with assessing the effects of the Proposed Project on steelhead (Dunne et al. 2011). The conclusion of the Coho Salmon and Steelhead Expert Panel was that the Proposed Project could increase the spatial distribution and abundance of steelhead. This assessment is based on the observations that steelhead would be able to access a substantial extent of new habitat, steelhead are relatively tolerant to warmer water (compared to coho salmon), steelhead are similar to other species (resident redband/rainbow trout) that are currently thriving in upstream habitats, and that while steelhead are currently at lower abundances than historical values, they currently migrate to habitat directly downstream of Iron Gate Dam (e.g., Bogus Creek), and are not yet rare. It is likely that steelhead recolonization would occur rapidly, as was observed for similar steelhead populations following fish ladder installation at Landsburg Dam on the Cedar River, Washington (Kiffney et al. 2009), and following removal of Condit Dam on the White Salmon River, Washington (Allen et al. 2016). Steelhead recolonization of habitat upstream of Condit Dam was notable, with steelhead spawning observed in upper basin tributaries within five years of dam removal.

Under the Proposed Project, steelhead, coho, and fall-run Chinook salmon yearlings and smolts would no longer be released from hatcheries in the Klamath River following post-dam removal year 7. Currently there are no releases of steelhead from hatcheries into the Klamath River. Therefore, the closure of hatcheries eight years following dam removal is not anticipated to result in a decline in adult returns for steelhead. Impacts associated with hatcheries operations in relation to water diversions and minimum bypass flows for fish passage is discussed in Potential Impact 3.3-23 (Iron Gate Hatchery) and Potential Impact 3.3-24 (Fall Creek Hatchery).

The impacts of the Proposed Project on steelhead populations within specific reaches are described below.

Upper Klamath River and Connected Waterbodies

Under the Proposed Project, dam removal would allow steelhead to regain access to the Upper Klamath River upstream of J.C. Boyle Reservoir. Under the Proposed Project, the population's distribution would likely expand to include historical habitat along the mainstem Klamath River upstream to the Sprague, Williamson, and Wood rivers (Hamilton et al. 2005). As discussed under Section 3.3.5.3 *Water Quality*, in some years poor water quality in the Keno Impoundment/Lake Ewuana reach may prevent the latest migrants of the summer steelhead run and the earlier migrants from the fall run from accessing upstream spawning habitat in these upper reaches. If no upstream trap and haul is provided at Keno, these fish would be likely to spawn in habitat downstream of Keno Dam in the Hydroelectric Reach (described below), or, in the case of fall-run steelhead, hold below the dam until conditions become passable. However, the majority of the summer steelhead adult migration, much of the fall-run adult steelhead migration, and all of the winter adult steelhead migration is anticipated to occur outside the mid-June to mid-November timeframe in which water quality in the Keno Impoundment/Lake Ewuana reach is typically so poor as to present a migration barrier to adult salmonids. Similarly, juvenile outmigration and run-backs also occur outside this timeframe. Under the Proposed Project, there would be a potential increase in access to 49 significant tributaries in the Upper Klamath Basin, comprising around 360 miles of additional potentially productive habitat (Huntington 2006, DOI 2007, NMFS 2007b).

Upper Klamath River - Hydroelectric Reach

In the long term, the Proposed Project would restore steelhead access to habitat upstream of Iron Gate Dam and below J.C. Boyle, including an estimated 80 miles of habitat within the Hydroelectric Reach (DOI 2007, Cunanan 2009). Reaches currently inundated by reservoirs and reaches between reservoirs would likely return to a pool-riffle morphology, which would benefit steelhead.

In the short term, adults could first access this reach in winter (summer steelhead) or fall (winter steelhead) of dam removal year 2. Steelhead could use this reach as a migration corridor, as most sediment released from the reservoirs would likely be eroded within the first six months after reservoir drawdown (by June of dam removal year 2) and would not impede upstream movement. By late spring of removal year 2, elevated SSCs resulting from dam removal would likely have returned to low levels unlikely to impact steelhead.

By eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, the Proposed Project would support a flow regime that more closely mimics natural conditions in the Lower Klamath River. The reservoir drawdowns would also allow tributaries and springs such as Fall, Shovel, and Spencer creeks and Big Springs to flow directly into the mainstem Klamath River, creating patches of cooler water that could be used as temperature refugia by fish during summer and fall, as well as providing slightly warmer winter water temperatures conducive to the growth of salmonids (Hamilton et al. 2011).

Middle and Lower Klamath River

The Proposed Project would release dam-stored sediment downstream to the Lower Klamath River in the short term and restore a flow regime that more closely mimics natural conditions in the long term. Short-term suspended sediment effects on steelhead populations under the Proposed Project are described in detail in Appendix E.3.2.4, and summarized here.

Under all scenarios, sublethal effects from suspended sediment are anticipated for adult migrants, all spawning (which occurs primarily in tributaries), and outmigrating smolts

(Appendix E.3.2.4, Table E-11). As detailed in Appendix E.3.2.4, mortality is anticipated for the following steelhead life-stages:

- Half-pounder adult: Mortality ranging from just under 20 percent of those present in the mainstem under a least impacts on fish or most-likely impacts on fish scenario, to just over 20 percent under a worst impacts on fish scenario (data on half pounder adult abundance is lacking). Majority remain in tributaries and would not be affected. Some would enter tributaries if conditions within the mainstem were adverse.
- Juvenile age 0: No mortality under a least impacts on fish or most-likely impacts to fish scenario, up to 20 percent mortality of those present in the mainstem under a worst impacts on fish scenario (up to 843 juveniles or around 3 percent of population basin-wide age 0 production in a worst impacts on fish scenario).
- Juvenile age 1: 0 to 20 percent of those present in the mainstem under a least impacts on fish scenario, or up to 40 percent mortality under the most-likely impacts to fish or worst impacts on fish scenario (up to 6,314 juveniles or around 11 percent of population basin-wide age 1 production).
- Juvenile age 2: 0 to 20 percent of those present in the mainstem under a least impacts on fish scenario, or up to 40 percent mortality under the most-likely impacts to fish or worst impacts on fish scenario (up to 5,303 juveniles or around 10 percent of population basin-wide age 2 production in a worst impacts on fish scenario).

As described in detail in Section 3.11 *Geology, Soils, and Mineral Resources* and Appendix F, dam-released sediment associated with the Proposed Project might aggrade pools or overwhelm other habitat features currently used for adult holding and juvenile rearing upstream of Cottonwood Creek. The effect would be short term (less than one year), as pools would quickly return to their pre-sediment release depth (USBR 2012). Within six months the river would revert to and maintain the pool-riffle morphology that currently exists. In the long term, under the Proposed Project, bedload sediment transport would restore vital aquatic habitat for steelhead.

As discussed in detail above, dam removal would cause water temperatures to warm earlier in the spring and early summer, cool earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods. These changes would result in water temperatures that are more favorable for salmonids occurring in the mainstem. Migrating adults and juveniles rearing or migrating in the mainstem after dam removal would be exposed to low dissolved oxygen due to the Proposed Project, but these effects would be short term and of limited spatial extent, and not likely to be of sufficient magnitude to exacerbate effects substantially beyond those anticipated for increased suspended sediment. Long-term effects of the Proposed Project would benefit steelhead using the Lower Klamath River.

The Iron Gate Hatchery does not currently produce steelhead smolts, and no steelhead releases are included under the Proposed Project. Therefore, discontinuing hatchery operations under the Proposed Project would not have a direct effect on the steelhead population, although it would eliminate the potential for additional hatchery production were sufficient numbers of steelhead to enter the hatchery again. As described in Section 3.3.5.6 *Fish Hatcheries*, and 3.3.5.5 *Fish Disease and Parasites*, incidences of disease are expected to be reduced under the Proposed Project through changes to a number of factors underlying disease prevalence. Reducing polychaete habitat would likely reduce the prevalence of *P. minibicornis* infection, although the benefit to the steelhead would not be as great as for coho and Chinook salmon because they are resistant to *C. shasta*.

Klamath River Estuary and Pacific Nearshore Environment

Under the Proposed Project, habitat in the estuary could be affected by elevated sediment releases during dam removal for about three months (January through March) when a low abundance of steelhead juveniles and smolts could be within the Klamath River Estuary. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.3.5.1 *Suspended Sediment*). However, the increased SSCs predicted to occur in the estuary would not be of sufficient magnitude or duration to result in substantial sublethal or lethal effects on steelhead salmon individuals (Appendix E.3.2.3). While the magnitude of SSCs released to the Pacific Ocean nearshore environment would be within the range of natural conditions, the duration of elevated SSCs (i.e., weeks) would be greater than would occur under natural (i.e., storm) conditions (i.e., days). Therefore, there also would be elevated SSCs in the Pacific Ocean nearshore environment relative to existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, no steelhead adults or juveniles are anticipated to occur within the nearshore environment during this period.

Summary

In the short term, reservoir drawdown associated with dam removal under the Proposed Project could alter SSCs and affect steelhead. In general, the short term impacts of suspended sediment resulting from the Proposed Project on steelhead are likely to be substantial for any juveniles rearing in the mainstem. However, there are several aspects of steelhead life history in the Klamath River Watershed that would ameliorate these impacts, and only a limited proportion of the rearing juveniles would be affected. The broad spatial distribution of steelhead in the Klamath Basin and their flexible life history suggests that some juveniles that would otherwise be in the mainstem would avoid the most serious effects of the Proposed Project by: (1) remaining in tributaries for extended rearing, (2) rearing farther downstream where SSC should be lower due to dilution (e.g., the progeny of the adults that spawn in the Trinity River Basin or tributaries downstream from the Trinity River), and/or (3) moving out of the mainstem into tributaries and off-channel habitats during winter. In addition, the life-history variability (e.g., regularly smolting at age 0+, 1+, or 2+) observed in steelhead means that not all individuals in any given year class would smolt during spring of dam removal year 2 and be exposed to the effects of the Proposed Project. Those that do not smolt would remain in tributaries and be unaffected by sediment release. Based on no predicted substantial short-term decrease in steelhead abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to steelhead under the Proposed Project in the short term.

Although this EIR finds no significant impact on steelhead In the short term, the KRRC proposes aquatic resource measures AR-1 (Mainstem Spawning) and AR-2 (Juvenile Outmigration) which would further reduce the potential for short-term effects of SSCs on salmonid juveniles and eggs, including steelhead. In addition, although CEQA Guidelines Section 15126.4(a)(3) states that mitigation measures are not required for effects which are not found to be significant, mitigation measures AQR-1 and AQR-2, which would be implemented as a result of significant adverse impacts described for Potential Impact 3.3-1 and Potential Impact 3.3-4, would even further reduce the potential for short-term effects of the Proposed Project on steelhead by increasing certainty regarding the effectiveness of the KRRC's proposed aquatic resource measures. Aquatic resource measures are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan − Appendix I*. Proposed Aquatic Resource Measure AR-1 includes the development and implementation of a monitoring and adaptive management plan to offset the impacts of Lower Klamath Project dam removal on mainstem spawning. Proposed Aquatic Resource Measure AR-1 actions include a 2-year tributary confluence monitoring effort and addressing sediment and debris obstructions that block volitional upstream passage from the Klamath River into tributaries. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-1 Mainstem Spawning (detailed in Potential Impact 3.3-1) further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. Proposed Aquatic Resource Measure AR-1 also includes a spawning habitat evaluation on the Klamath River and tributaries in the Hydroelectric Reach. If spawning habitat conditions following dam removal do not meet target metrics[98] developed to offset the anticipated loss of Chinook salmon and steelhead redds due to the Proposed Project, spawning gravel augmentation would be completed within the mainstem, with additional spawning habitat actions within tributaries. Tributary spawning habitat restoration actions to be completed in Jenny Creek, Shovel Creek, Fall Creek, and/or Spencer Creek could include removal of artificial fish passage barriers, or placement of large woody debris to trap and retain spawning gravels. Mitigation Measure AQR-1 Mainstem Spawning (detailed in Potential Impact 3.3-1) further specifies the range of actions that shall be conducted in tributaries to offset impacts to steelhead spawning. Implementation of proposed Aquatic Resource Measure AR-1 and Mitigation Measure AQR-1 would reduce the short-term potential impacts of SSCs on steelhead spawning habitat in dam removal year 2 by improving access to tributary habitat where impacts from SSC on habitat in the mainstem can be avoided, and by augmenting spawning gravel, ensuring that suitable spawning habitat in mainstem and tributaries is available following dam removal. Therefore, it is anticipated that steelhead spawning would not be substantially reduced as a result of the Proposed Project.

Proposed Aquatic Resource Measure AR-2 includes three primary actions: (1) salvaging mainstem overwintering juvenile salmonids prior to reservoir drawdown; (2) maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River; and (3) developing a water quality monitoring network, trigger thresholds, and plan for salvaging and relocating juvenile fish from tributary confluence areas to cold water tributaries or nearby off-channel ponds. Implementation of Proposed Aquatic Resource Measure AR-2 would reduce the short-term effects of SSCs on juvenile steelhead rearing in the mainstem during dam removal by actively transporting juveniles from vulnerable mainstem areas to off-channel ponds protected from the effects of the Proposed Project. Seining efforts would be focused on coho salmon juveniles, but other native fish captured during the seining and trapping effort, including

[98] Spawning gravel in the amount of 44,100 yd^2 for fall Chinook salmon and 4,700 yd^2 for steelhead

juvenile steelhead, would be relocated into tributary streams adjacent to the salvage locations. Proposed Aquatic Resource Measure AR-2 would also reduce the potential short-term effects of SSCs to steelhead smolts by maintaining tributary-mainstem connectivity to ensure volitional fish passage between tributaries and the Klamath River. Monitoring would occur regularly for the two years following dam removal. Additionally, any 5-year flow event of 10,895 cfs or greater on the Klamath River recorded at the USGS Klamath River Below Iron Gate Dam CA gage (No. 11516530) within the first two years following reservoir drawdown would trigger a monitoring effort. Mitigation Measure AQR-2 Juvenile Outmigration (detailed in Potential Impact 3.3-1) further specifies that monitoring shall also be conducted following a significant flow event, even if that flow event occurs more than two years following dam removal. In addition, Proposed Aquatic Resource Measure AR-2 would reduce the potential short-term effects of SSCs to steelhead smolts by rescuing and transporting smolts if mainstem SSCs are high, and water temperatures within tributaries are too poor to provide safe refuge (a decision to be made in regular consultation with the ATWG). These actions would effectively reduce the number of steelhead juveniles and smolts potentially exposed to periods of high SSC in the mainstem following dam removal, and therefore reduce the proportion of the population experiencing impacts.

In the long term, removal of the Lower Klamath Project dams under the Proposed Project would increase habitat availability, restore a more natural flow regime by eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, restoring more natural seasonal water temperature variation, improve water quality, and reduce the likelihood of fish disease, all of which would be beneficial for steelhead in the long term. Dam removal would restore connectivity to hundreds of miles of historical habitat in the Upper Klamath Basin and would create additional habitat within the Hydroelectric Reach. FERC (2007) concluded that implementing fish passage would help to reduce adverse effects to steelhead associated with lost access to upstream spawning habitats. Hamilton et al. (2011) also concluded that access to additional habitat in the Upper Klamath Basin would benefit steelhead runs. In general, dam removal would likely result in the restoration of more reproducing populations, increased abundance, higher genetic diversity, the opportunity for variable life histories, and use of new habitats (Hamilton et al. 2011). In general, free flowing conditions would likely increase adult migration rate, decrease outmigrant delay, and increase adult escapement (Buchanan et al. 2011b). As discussed in detail above, dam removal would also cause water temperatures to become warmer earlier in the spring and early summer, cooler earlier in the late summer and fall, and have diurnal variations more in sync with historical migration and spawning periods (Hamilton et al. 2011). These changes would result in water temperature more favorable for salmonids in the mainstem. The multiple benefits of the Proposed Project would be beneficial for steelhead populations in the long term.

Significance

No significant impact for steelhead populations in the short term

Beneficial for steelhead populations in the long term

Potential Impact 3.3-11 Effects on the Pacific lamprey population due to short-term sediment releases and long-term changes in habitat quality and quantity due to dam removal.

The Lamprey Expert Panel (Panel) was convened and charged with answering specific questions that had been formulated to assist with assessing the effects of the Proposed Project on lamprey (Close et al. 2010). The conclusion was that the Proposed Project could increase Pacific lamprey habitat by up to 14 percent with access to habitat upstream of Iron Gate Dam, and even more potential habitat if Pacific lamprey gain access to habitat upstream of Keno Dam. However, the Panel concluded that larval lamprey habitat within much of the newly accessible habitat is of less quality that current larval habitat downstream of Iron Gate Dam, and therefore there might be roughly a total increase of production of outmigrant lamprey (and hence harvest potential) in the range of 1 to 10 percent relative to existing conditions, lower than the percent increase in habitat access. The Panel expects that adult Pacific lamprey would recolonize newly accessible habitat after dam removal, as was observed for Pacific lamprey following fish ladder installation at Landsburg Dam on the Cedar River, Washington (Kiffney et al. 2009), and for Pacific lamprey following removal of Condit Dam on the White Salmon River, Washington (Allen et al. 2016). Larval rearing capacity downstream from Iron Gate Dam is expected to increase after dam removal because a large amount of fine sediment—a major component of larval rearing habitat—would be released through dam removal. The available burrowing habitat for larvae would subsequently decrease over time, but would likely remain higher than under existing conditions because sediment input and transport processes would be restored (Close et al. 2010). In addition, the return to a temperature regime and flows that more closely mimic natural patterns would likely benefit Pacific lamprey, which evolved under those conditions.

Access to habitat would benefit Pacific lamprey by increasing their viability through: (a) extending the range and distribution of the species; (b) providing additional spawning and rearing habitat; (c) increasing the genetic diversity of the species; and (d) increasing the abundance of the Pacific lamprey population (NMFS 2006a). The FERC EIS (2007) concluded that “Removal of Iron Gate Dam provides the greatest potential to expand the range of Pacific lamprey, a species of cultural importance to the tribes, to potential habitat upstream of Iron Gate Dam.”

In a 2015 USFWS regional implementation plan for measures to conserve Pacific lamprey in northern California and the Klamath River Basin, Goodman and Reid (2015) conclude that while there remains some uncertainty about the historical extent of Pacific lamprey in the Upper Klamath Watershed, the removal of the dams and restoration of natural hydrologic flow regimes to the Klamath River would have the greatest positive influence on Pacific Lamprey in the Upper Klamath River. The influence of the Proposed Project on Pacific lamprey populations within specific reaches on the Klamath River is described below.

Upper Klamath River and Connected Waterbodies

Pacific lamprey occurred historically at least to Spencer Creek (Hamilton et al. 2005), and there are no predictions that under the Proposed Project Pacific lamprey would occur in the Upper Klamath River and connected waterbodies.

Upper Klamath River - Hydroelectric Reach

Under the Proposed Project, it is anticipated that Pacific lamprey would migrate upstream of the location of Iron Gate Dam (NMFS 2006a). The Proposed Project would provide Pacific lamprey with access to the Hydroelectric Reach and to the mainstem Klamath River and its tributaries upstream at least as far as Spencer Creek, including Jenny, Shovel, and Fall creeks (Hamilton et al. 2011). Most sediment released from the reservoirs would likely be eroded within the first six months after dam removal (by June of dam removal year 2), returning sections of river currently inundated by reservoirs, and riverine sections between reservoirs, to a pool-riffle morphology. After erosion of dam-stored sediment, the Hydroelectric Reach would likely contain gravel suitable for lamprey spawning.

By eliminating peaking flows in the Hydroelectric Reach and removing the Lower Klamath Project reservoirs, the Proposed Project would support a flow regime that more closely mimics natural conditions. Drawing-down the reservoirs would also allow tributaries and springs such as Fall, Shovel, and Spencer creeks and Big Springs to flow directly into the mainstem Klamath River. These changes would result in more favorable water temperatures for native fishes, and improved water quality. These changes would provide a long-term benefit to Pacific lamprey populations that would occur within the Hydroelectric Reach.

Middle and Lower Klamath River

The Proposed Project would release dam-stored organic sediment and reduce dissolved oxygen downstream to the Lower Klamath River in the short term, and improve water quality and restore a flow regime that more closely mimics natural conditions in the long term. Suspended sediment effects on Pacific lamprey populations under the Proposed Project are described in detail in Appendix E.3.2.5, and summarized here.

Under the most-likely impacts to fish scenario or worst impacts on fish scenario, sub-lethal effects from suspended sediment are anticipated for outmigrants, and for Pacific lamprey migrating to or from the Trinity River or tributaries farther downstream (Appendix E.3.2.5, Table E-13). High rates of mortality are predicted for ammocoetes (lamprey larvae) in the mainstem Klamath River during winter and spring of dam removal year 2. However, there is little information on the effects of suspended sediment on Pacific lamprey. This analysis used the effects of suspended sediment on salmonids to predict effects on Pacific lamprey, with the assumption that effects on Pacific lamprey are equivalent or less severe than on salmonids. In general, most life stages of Pacific lamprey appear more resilient to poor water quality conditions (such as suspended sediment) than salmonids (Zaroban et al. 1999), so this is likely a conservative assessment (an overestimate) of potential effects. In addition, Goodman and Hetrick (2017) report that in a 2008 ammocoete survey within the Klamath Basin no Pacific Lamprey were detected in the reach from Iron Gate Dam downstream to the confluence with the Shasta River (RM 179.5), and the densities did not approach levels observed elsewhere in the watershed until the confluence with the Scott River (RM 145.1). Therefore, the proportion of the Pacific lamprey population in the Klamath River potentially exposed to the highest SSCs during dam removal is low. In addition, recent genetic analysis of Pacific lamprey (Goodman and Reid 2012) indicates a high degree of historical gene flow even across expansive distances of the northern Pacific Rim as a result of low fidelity of Pacific lamprey progeny to their natal stream. This suggests that impacts to Pacific lamprey in the Klamath River are unlikely to affect the metapopulation.

As described for salmonid species above, the Proposed Project would affect spawning and incubation in the short term in the area between Iron Gate Dam and Cottonwood Creek by burying gravel in dam-released sediment and increasing the proportion of sand in the bed. This could reduce the quality of spawning habitat In the short term, but also may increase suitability of habitat for rearing ammocoete (Close et al. 2010). After a flushing flow of at least 6,000 cfs, the bed is expected to maintain fractions of sand, gravel, and cobble which would be expected under natural conditions (suitable for Pacific lamprey spawning). Based on the historical record a sufficient flushing flow would likely occur within five years following dam removal.

The Proposed Project would establish a flow regime that more closely mimics natural conditions in the Lower Klamath River Reach. Dam removal would cause water temperatures to have natural diurnal variations. These changes would result in water temperatures that are more similar to those that Pacific lamprey evolved with and would improve water quality. These long-term changes would likely provide a benefit to Pacific lamprey in the Lower Klamath River.

Klamath River Estuary and Pacific Ocean Nearshore Environment
Under the Proposed Project, habitat in the estuary could be affected by sediment releases during dam removal for about three months (January through March) when a low abundance of Pacific lamprey ammocoetes could be within the estuary during outmigration. After this time, SSCs would return to levels similar to existing conditions. SSCs in the Klamath River Estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.3.5.1 *Suspended Sediment*). However, the increased SSCs predicted to occur in the estuary would not be of sufficient magnitude or duration to result in substantial sublethal or lethal effects on Pacific lamprey individuals (Appendix E.3.2.5). While the magnitude of SSCs released to the Pacific Ocean nearshore environment would be within the range of natural conditions, the duration of elevated SSCs (i.e., weeks) would be greater than would occur under natural (i.e., storm) conditions (i.e., days). Therefore, there also would be elevated SSCs in the Pacific Ocean nearshore environment relative to existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, few Pacific lamprey adults (and no juveniles) are anticipated to occur within the nearshore environment during this period.

Summary
In the short term, reservoir drawdown associated with dam removal under the Proposed Project would alter SSCs and bedload sediment transport and deposition and could affect Pacific lamprey. The Proposed Project would have short-term effects related to SSCs, bedload sediment transport and deposition, and water quality (particularly dissolved oxygen). As described in detail in Appendix E.3.2.5, Pacific lamprey use the mainstem Klamath River for several aspects of their life history. Because multiple year classes of Pacific lamprey rear in the mainstem Klamath River at any given time, and since adults would migrate upstream over the entire year, including January of dam removal year 2 when effects from the Proposed Project would be most pronounced, effects on Pacific lamprey adults and ammocoetes could be much higher in the mainstem Klamath River than under existing conditions. However, because of their wide spatial distribution and low observed occurrence downstream of Iron Gate Dam, most of the population would likely avoid the most severe suspended sediment pulses resulting from the Proposed Project and a substantial reduction in abundance is not anticipated. In addition, Pacific lamprey are considered to have low fidelity to their natal streams (FERC 2007), and may not enter the mainstem Klamath River if environmental

conditions are unfavorable in dam removal year 2. Migration into the Trinity River and other Lower Klamath River tributaries may also increase during dam removal year 2 because of poor water quality in the mainstem Klamath River. Low fidelity also increases the potential that Pacific lamprey can recolonize mainstem habitat if ammocoetes rearing there suffer high mortality. In addition, the geographic range of the Pacific lamprey population is very large and disperse (Goodman and Reid 2012), and thus the percentage of adult and larval Pacific lamprey that would be affected by the Proposed Project relative to the population as a whole would be minor (although no data are available to estimate percentage of population affected). Based on no predicted substantial short-term decrease in Pacific lamprey abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the Pacific lamprey population under the Proposed Project in the short term.

Although this EIR finds no significant impact on Pacific lamprey In the short term, the KRRC proposes aquatic resource measures AR-1 (Mainstem Spawning) which would further reduce the potential for short-term effects of SSCs on Pacific lamprey spawners. In addition, although CEQA Guidelines Section 15126.4(a)(3) states that mitigation measures are not required for effects which are not found to be significant, Mitigation Measures AQR-1, which would be implemented as a result of significant adverse impacts described for Potential Impact 3.3-1 and Potential Impact 3.3-4, would even further reduce the potential for short-term effects of the Proposed Project on Pacific lamprey by increasing certainty regarding the effectiveness of the KRRC's proposed aquatic resource measure. Aquatic resource measures are summarized in Section 2.7.8.1 and detailed in Appendix B: *Definite Plan − Appendix I*. Proposed Aquatic Resource Measure AR-1 includes the development and implementation of a monitoring and adaptive management plan to offset the impacts of Lower Klamath Project dam removal on mainstem spawning. Proposed Aquatic Resource Measure AR-1 actions include a 2-year tributary confluence monitoring effort and addressing sediment and debris obstructions that block volitional upstream passage from the Klamath River into tributaries. Implementation of AR-1 would reduce the short-term impacts of SSCs on Pacific lamprey spawning in dam removal years 1 and 2 by improving access to tributary habitat where impacts from SSC in the mainstem can be avoided. Therefore, it is anticipated that fewer Pacific lamprey would spawn in the mainstem prior to and following the Proposed Project, further decreasing the proportion of the population exposed to high SSC.

In the long term, the Proposed Project would provide access to habitat upstream of Iron Gate Dam at least as far as Spencer Creek. It is anticipated that as a result of the Proposed Project the Pacific lamprey population within the Klamath Basin would have an increase in abundance and productivity due to increases in habitat availability, and improved flow regime, water quality, and temperature variation. Based on no predicted substantial long-term decrease in Pacific lamprey abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the Pacific lamprey population under the Proposed Project in the long term. Furthermore, implementation of the Proposed Project would be beneficial for Pacific lamprey in the long term.

Significance

No significant impact for Pacific lamprey populations in the short term

Beneficial for Pacific lamprey populations in the long term

Potential Impact 3.3-12 Effects on the green sturgeon population due to short-term sediment releases and long-term changes in habitat quality due to dam removal.
Southern DPS Green Sturgeon may enter the Klamath River Estuary to forage during the summer months. They would not be present when the most severe effects of dam removal are occurring and are not expected to be affected by the Proposed Project. The remainder of this section focuses on the effects of the Proposed Project on the Northern Green Sturgeon DPS. Northern Green Sturgeon are an anadromous species that enter the Klamath River to spawn from March through July (Table 3.3-9). Green sturgeon spawn primarily in the lower 67 miles of the mainstem Klamath River (downstream from Ishi Pishi Falls), in the Trinity River, and occasionally in the lower Salmon River. Since green sturgeon do not occur upstream of Ishi Pishi Falls, they would only be affected by Proposed Project effects that would extend downstream of these falls.

Middle and Lower Klamath River
The Proposed Project would release dam-stored sediment downstream to the Lower Klamath River in the short term. There is not extensive literature on the effects of suspended sediment on green sturgeon. This analysis is based on available information of the effects of SSC on salmonids, with the assumption that effects of suspended sediment on sturgeon are likely less than or equal to those on salmonids. Suspended sediment effects on Northern Green Sturgeon populations under the Proposed Project are described in detail in Appendix E.3.2.6 and summarized here.

As described in Appendix E.3.2.6, green sturgeon in the Klamath River spawn approximately every four years. The result of this life history pattern is that up to 75 percent of the mature adult green sturgeon population (as well as 100 percent of sub-adults) can be assumed to be in the ocean during dam removal year 2 and avoid effects associated with the Proposed Project. For the 25 percent of the adult population that could be in the Klamath River during dam removal year 2, only slightly higher impacts are predicted for adults than under existing conditions under all scenarios (Appendix E.3.2.6, Table E-14), mostly because Northern Green Sturgeon distribution within the mainstem Klamath River is primarily limited to areas downstream from Orleans, where the effects of SSC resulting from the Proposed Project are more diluted from tributary accretion. Green sturgeon females are broadcast spawners that lay thousands of adhesive eggs that settle into the spaces between cobble substrates. Eggs in the mainstream Klamath River are vulnerable to suspended sediment under existing conditions as a result of the contributions of multiple tributaries in the Middle Klamath River (Appendix E 3.1.6). From 40 to 60 percent mortality is predicted for incubating eggs and larval life stages under all scenarios.

Juvenile green sturgeon typically rear for one year in the Klamath River system (M. Belchik, pers. comm., 2008), but may rear for up to three years before they migrate to the estuary and the ocean, usually during summer and fall. Moderate physiological stress is predicted for rearing juveniles under a least impacts on fish scenario. Under a most-likely impacts to fish or worst impacts on fish scenario major physiological stress is predicted (Appendix E.3.2.6). Around 30 percent of green sturgeon juveniles rear in the Trinity River and would not be exposed to SSC from the Proposed Project.

Bedload sediment effects related to dam-released sediment would not extend as far downstream to Ishi Pishi Falls (USBR 2012) and would not affect Northern Green Sturgeon.

The Proposed Project would improve water quality, and reduce instances of algal toxins. These long-term effects would benefit Northern Green Sturgeon in the Lower Klamath River.

Klamath River Estuary and Pacific Ocean Nearshore Environment

Rearing for more than one year is rarely observed in the mid-Klamath River (M. Belchik, pers. comm., 2008), but juvenile green sturgeon may rear for additional months or years in the estuary before migrating to the ocean. Under the Proposed Project, habitat in the Klamath River Estuary could be affected by elevated suspended sediment during dam removal for about three months during winter, when juvenile green sturgeon could be rearing in the estuary. After this time, SSCs would return to levels similar to existing conditions. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial, and would be higher than the extreme values estimated by the sediment transport model for existing conditions (see Section 3.3.5.1 *Suspended Sediment*). However, the increased SSCs predicted to occur in the estuary would not be of sufficient magnitude or duration to result in substantial sublethal or lethal effects on green sturgeon juveniles (Appendix E.3.2.6). While the magnitude of SSCs released to the Pacific Ocean nearshore environment would be within the range of natural conditions, the duration of elevated SSCs (i.e., weeks) would be greater than would occur under natural (i.e., storm) conditions (i.e., days). Therefore, there also would be elevated SSCs in the Pacific Ocean nearshore environment relative to existing conditions (see Section 3.2.5.2 *Suspended Sediments*). However, few green sturgeon adults or juveniles are anticipated to occur within the nearshore environment during this period.

Summary

In the short term, reservoir drawdown associated with dam removal under the Proposed Project would alter water quality and SSCs and could affect Northern Green Sturgeon. Overall the effects of the Proposed Project are most likely to include physiological stress, inhibited growth, and high mortality for incubating eggs. Northern Green Sturgeon in the Klamath Basin have the following traits likely to enhance the species' resilience to impacts of the Proposed Project:

- Most of the Northern Green Sturgeon population (sub-adult and adult) would be in the ocean during the year of the Proposed Project (dam removal year 2) and would be unaffected (Appendix E.3.2.6).
- Approximately 30 percent of the Northern Green Sturgeon population that spawn and rear in the Trinity River and would be unaffected.
- Much of the spawning and rearing of Northern Green Sturgeon occurs downstream from the Trinity River, where sediment concentrations would be similar to existing conditions.

Northern Green Sturgeon are long-lived (greater than 40 years) and are able to spawn multiple times (approximately 8 times in their lifetime) (Klimley et al. 2007), so effects on the spawning effort of a proportion of adults for one year are anticipated to have little influence on the population as a whole. Because there would be no predicted substantial short-term decrease in green sturgeon abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the green sturgeon population under the Proposed Project in the short term.

In the long term, suspended sediment levels would return to levels similar to existing conditions, and removal of dams would result in improvements in water quality, temperature variation, and algal toxins which could affect Northern Green Sturgeon. Because there would be no predicted substantial long-term decrease in green sturgeon abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the green sturgeon population under the Proposed Project in the long term.

Significance

No significant impact for green sturgeon populations in the short term

No significant impact for green sturgeon populations in the long term

Potential Impact 3.3-13 Effects on Lost River and shortnose sucker populations due to short- and long-term changes in habitat quality and quantity due to dam removal.

A Resident Fish Expert Panel (Panel) was convened to compare the potential effects of the Proposed Project and existing conditions on resident fish, including sucker populations (Buchanan et al. 2011a). The Panel noted that the populations of Lost River and shortnose sucker in Upper Klamath lake are currently self-sustaining, whereas the populations in the Hydroelectric Reach (Iron Gate and Copco reservoirs) are not self-sustaining. The Panel concluded that most factors limiting the production of Lost River and shortnose sucker populations occur in Upper Klamath Lake (e.g., poor water quality, nonnative fish predation and competition, lack of emergent vegetation rearing habitat), upstream of the Area of Analysis for aquatic resources.

Upper Klamath River and Connected Waterbodies

The Proposed Project has no elements that would substantially alter habitat conditions for Lost River and shortnose sucker populations in the Upper Klamath River upstream of Keno/Lake Ewuana. Facilitating the movement of anadromous fish presents a relatively low risk of introducing pathogens to sucker species upstream of Iron Gate Dam (NMFS 2006a). Generally, with the exception of *F. columnaris* and Ich, pathogens associated with anadromous fish do not impact non-salmonids (e.g., suckers) (NMFS 2006a). In the most recent review of effects of interactions between reintroduced anadromous fish and federally listed suckers, the USFWS concludes that indirect effects of removal of the Lower Klamath Project dams is "not likely to adversely affect" listed suckers (Roninger 2012).

Upper Klamath River - Hydroelectric Reach

Lost River and shortnose sucker individuals are found within Lower Klamath Project reservoirs in the Hydroelectric Reach (Desjardins and Markle 1999). The Proposed Project would eliminate reservoir habitat, and as dams within the Hydroelectric Reach were removed, sediment would move downstream. However, the Lost River and shortnose suckers in these reservoirs are considered by the USFWS (2013) as "sink populations", as they are not likely self-sustaining because of low recruitment due to the lack of access to spawning habitats, citing Moyle (2002), and NRC (2004). Buettner et al. (2006) conclude that since little or no reproduction occurs downstream from Keno Dam, and there is no potential for interaction with upstream populations, they are not considered to substantially contribute to the achievement of conservation goals or recovery. This is also consistent with the findings of Hamilton et al. (2011), and NRC

(2004). In addition, Miller and Smith (1981) asserted that sucker hybridization was most pronounced in these reservoirs, prompting Buettner et al. (2006) and others to caution against relocating individuals from Iron Gate and Copco reservoirs into the Upper Klamath Lake population.

Middle and Lower Klamath River, Estuary, and Pacific Ocean Nearshore Environment
No Lost River or shortnose suckers have been documented to occur downstream of Iron Gate Dam and therefore these reaches are not considered in the potential impact analysis for this EIR.

Summary
In the short term, reservoir removal associated with dam removal under the Proposed Project could alter habitat availability and affect Lost River and shortnose suckers in Iron Gate and Copco reservoirs. All individual suckers occurring within these reservoirs would likely be lost within dam removal year 2; however, these individuals are not considered to substantially contribute to the achievement of conservation goals or recovery, since little or no reproduction occurs downstream from Keno Dam (Buettner et al. 2006), and there is no potential for interaction with upstream populations (Hamilton et al. 2011). Although both species are fully protected species under California Fish and Game Code, Assembly Bill Number 2640 (Wood 2018) added Section 2081.11 to the Fish and Game Code to allow the take of both sucker species resulting from impacts attributable to the decommissioning and removal of the Lower Klamath Project facilities, consistent with CDFW take provisions. Based on the best available estimates of Lost River and shortnose sucker abundance in the Lower Klamath Project reservoirs, there are likely fewer than 1,000 adult suckers of both species in all reservoirs combined (USFWS 2012, Desjardins and Markle 1999), with a combined suitable sucker area of less than 2,500 acres. The populations in Upper Klamath Lake are estimated at 50,000 to 100,000 Lost River sucker (USFWS 2013b), and up to 25,000 shortnose suckers (USFWS 2013c), within around 79,000 acres of suitable habitat in Upper Klamath Lake and connected water bodies. Therefore, a loss of the suckers in Lower Klamath Project reservoirs represents around less than 1.5 percent of the total sucker population, and a loss of less than 3.5 percent of the total suitable sucker habitat. Based on no predicted substantial (< 1.5 percent) short-term decrease in Lost River and shortnose suckers' abundance of a year class, or substantial decrease in habitat quality or quantity (<1.5 percent), the Proposed Project would not cause a significant impact to the Lost River and shortnose sucker populations in the short term.

In the long term, reservoir removal associated with dam removal under the Proposed Project would eliminate habitat availability and affect Lost River and shortnose suckers in Lower Klamath Project reservoirs. All individual suckers occurring within these reservoirs would likely be lost within the short term and would not be replaced in the long term. However, as described above, these individuals are not considered to substantially contribute to the achievement of conservation goals or recovery of the populations (Hamilton et al. 2011). In addition, and as described above, the loss of the sucker population and suitable habitat in the Lower Klamath Project reservoirs is a minor proportion of the total sucker population and suitable habitat area. Based on no predicted substantial long-term decrease in Lost River and shortnose suckers' abundance of a year class, or substantial decrease in habitat quality or quantity, the Proposed Project would not cause a significant impact to the Lost River and shortnose sucker populations in the long term.

Although this EIR finds no significant impact on Lost River and shortnose suckers in the short-or long-term, the Proposed Project includes aquatic resource measure AR-6 (Suckers) to reduce the short- and long-term effects of reservoir removal. Aquatic resource measures are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan − Appendix I*. AR-6 includes two primary actions including reservoir and river sampling to estimate the abundance of suckers in the Hydroelectric Reach and conduct genetic testing for hybridization, and sucker salvage and release into waterbodies isolated from the Upper Klamath Lake Populations. As discussed above, Section 2081.11 was added to the Fish and Game Code to authorize take of Lost River and shortnose suckers, subject to certain conditions. CDFW (2018b) has reviewed AR-6 and preliminarily agreed that the Proposed Project with implementation of AR-6 potentially meets the standards for take authorization under Fish and Game Code, section 2081.11. The proposed actions are anticipated to increase the survival of individual Lost River and shortnose suckers currently inhabiting the Hydroelectric Reach, without increasing exposure of the Upper Klamath Lake population to adults with a high degree of hybridization. The number of translocated fish would not exceed 3,000 fish, which is the capacity of the currently-identified recipient waterbody (Tule Lake). Tule Lake currently supports both sucker species and has suitable habitat for translocation site. In addition, Tule Lake is isolated from the sucker population in Upper Klamath Lake, and thus this measure would not risk influencing the sucker populations designated as recovery populations in Upper Klamath Lake.

Significance

No significant impact for Lost River and shortnose sucker populations in the short term

No significant impact for Lost River and shortnose sucker populations in the long term

Potential Impact 3.3-14 Effects on the redband trout population due to short-term sediment releases and long-term changes in habitat quality and quantity due to dam removal.

A Resident Fish Expert Panel (Panel) was convened to compare the potential effects of the Proposed Project and existing conditions on resident fish, including redband trout (Buchanan et al. 2011a). The Panel predicted that following the Proposed Project, the abundance of redband trout in the free-flowing reach between Keno Dam and Iron Gate Dam could increase significantly. In addition, the Panel expects the existing trout and colonizing anadromous steelhead to co-exist (or even for the redband to produce anadromous progeny), as they do in other watersheds, although there may be shifts in abundance related to competition for space and food. The effects of implementing the Proposed Project on redband trout populations within specific reaches of the Klamath River are described below.

Upper Klamath River and Connected Waterbodies

Under the Proposed Project, redband trout would be able to migrate more successfully from the Hydroelectric Reach to the Upper Klamath Basin (Hamilton et al. 2011) than under existing conditions. Redband trout could be affected by increased predation from reintroduced anadromous salmonids, but this loss might be offset by an increase in available food sources (e.g., eggs, fry, and juveniles of reintroduced salmonids) (Hamilton et al. 2011). Furthermore, anadromous steelhead trout and resident rainbow/redband trout co-existed and intermingled prior to the construction of Copco No. 1 Dam in 1917. There are many examples from nearby river systems in the Pacific Northwest showing that wild anadromous salmon and resident rainbow/redband trout can co-exist and maintain abundant populations without negative consequences. The Deschutes River in Oregon, the Yakima River in Washington, and the river systems in Idaho are examples (NMFS 2006a).

Facilitating the movement of anadromous fish presents a relatively low risk of introducing pathogens to resident fish upstream of Iron Gate Dam (NMFS 2006a).

Upper Klamath River - Hydroelectric Reach

Under existing conditions, redband trout are found within the California portion of the Area of Analysis within the Hydroelectric Reach, including within all riverine areas and reservoirs. Spawning primarily occurs within Shovel and Spencer creeks. Redband trout are currently prevented from migrating between some tributaries and the reservoirs to complete their life cycle because of poorly functioning fishways at J.C. Boyle Dam (DOI 2007, NMFS 2007b). Under the Proposed Project, redband trout would be able to migrate more successfully than under existing conditions (Hamilton et al. 2011). Approximately 4 mi (6.4 km) of habitat has been adversely affected by the dewatered flows in the Bypass Reach, and 17 mi (27.4 km) of habitat has been adversely affected by the daily fluctuating flows in the Peaking Reach (NMFS 2006a). In addition, the NMFS (2006a) finding regarding J.C. Boyle flow operations stated, “Current Project operations, particularly sediment blockage at the J.C. Boyle Dam, the flow regime, and peaking operations, negatively affect the redband trout fishery.”

Under the Proposed Project, the establishment of a flow regime that more closely mimics natural conditions, eliminates hydroelectric peaking and associated negative aquatic impacts, would benefit the redband trout populations in the Hydroelectric Reach. Redband trout throughout this reach of the mainstem would be affected by high SSCs for a period of three to four months during reservoir drawdown associated with the Proposed Project. Redband trout in riverine reaches between the reservoirs in the Hydroelectric Reach would be vulnerable to effects of sediment released during dam removal and bedload deposition (Newcombe and Jensen 1996, Buchanan et al. 2011a). However, SSCs would be the result of sediment stored in J.C. Boyle and Copco reservoirs, which is relatively small potential impact (USBR 2012), and a large proportion of the adult redband trout population should be already spawning in Spencer or Shovel creeks during the dam removal. Juvenile redband trout outmigrating from Spencer Creek would be expected to recolonize the mainstem by late spring or summer when water conditions become suitable. Those in the affected area could move to tributaries for refuge.

The Proposed Project would eliminate reservoir habitat, returning sections of river currently inundated by reservoirs and riverine sections between reservoirs to a pool-riffle morphology. Although most redband trout are anticipated to continue to spawn in tributaries, modeling data indicate that after dam removal, spawning gravel in all sections of the Hydroelectric Reach would be within the range usable for redband trout, but the amount of sand within the bed within former reservoir sections might inhibit spawning success in the short term. Riverine sections between reservoirs would be expected to contain gravel with very little sand, suggesting high-quality spawning habitat would become available within a few years following dam removal. The initial movement of coarse and fine sediment after drawdown would likely create unfavorable conditions for redband trout within the mainstem Klamath River, but these conditions would be short term. Buchanan et al. (2011a) estimate that 43 miles of additional riverine habitat would be available to resident redband trout as a result of the Proposed Project. The adfluvial individuals within this reach would likely adopt a fluvial[99] life history, which is unlikely to affect the sustainability of the population. Overall migratory opportunities would increase for redband trout, increasing resiliency to disturbance over the short and long-term. The Proposed Project would also increase the number of thermal refugia available to redband trout as they would have access to more tributaries, as well as to the cold water areas near the mouths of tributaries and the many springs in this reach.

Middle and Lower Klamath River
No redband trout occur downstream of Iron Gate Dam, and therefore these reaches are not considered in the potential impact analysis for this EIR. However, in the long term redband trout would have access to habitat in the Middle Klamath River, and they are anticipated to use cold-water tributaries and portion of the mainstem river. The resident trout currently within the Middle Klamath River (rainbow trout) are genetically very similar to the redband trout currently present upstream of Iron Gate Dam; these two populations that are currently isolated would revert to a connected and sustainable population (Buchanan et al. 2011a).

Summary
In the short term, the Proposed Project would have impacts related to SSCs and bedload movement. However, very little sediment is stored in J.C. Boyle Reservoir, and only a small proportion of the redband population is expected to be exposed to short-term effects. Based on no predicted substantial short-term decrease in redband trout abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the redband trout population under the Proposed Project in the short term.

In the long term, dam removal would restore connectivity among the Middle Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. Based on a long-term substantial increase in redband trout habitat quality and quantity, the Proposed Project would be beneficial for redband trout in the long term.

Significance
No significant impact for redband trout population in the short term

Beneficial for redband trout population in the long term

Potential Impact 3.3-15 Effects on the eulachon population due to short-term sediment releases and long-term changes in habitat quality due to dam removal.
The Proposed Project would release dam-stored sediment downstream to the Lower Klamath River and Estuary. SSCs in the estuary would be less than 40 percent of the peak concentrations that are anticipated to occur immediately downstream from Iron Gate Dam. These peaks would still be substantial (>500 mg/L) and would be higher than the extreme values estimated by the sediment transport model for existing conditions. Predicted increases in SSCs under the most-likely impacts to fish scenario are within the range of existing extreme conditions (Appendix E.4). Under a worst impacts on fish scenario SSCs could be higher than typically occur within the estuary (>1,000 mg/L) for a period of weeks. Adult eulachon entering the Klamath River in the

[99] Fluvial life history is resident trout spawning in tributaries and maturing within a larger mainstem river.

winter and spring of dam removal year 2 may be exposed to high SSCs for a portion of their migration period. Although no analysis of the effects of SSCs on eulachon is available, based on application of the Newcombe and Jensen (1996) approach using studies of the effects on other estuary species, it is predicted that under a most-likely impacts to fish or worst impacts on fish scenario mortality of eulachon adults would occur under the Proposed Project, unless individuals migrate out of the estuary to avoid poor water quality conditions (as has been observed in the Columbia River watershed, NMFS 2010b). Mortality is also predicted for spawning, incubation, and larval life stages under the Proposed Project. However, eulachon have a relatively long period of the year when they could potentially spawn in the Klamath River (January through April; Larson and Belchik 1998), and a relatively short duration of occurrence within freshwater (around one month), increasing the probability that most of the population would migrate and spawn either before or after the largest pulses of SSCs (predicted to be over 1,000 mg/L for the month of January under a worst impacts on fish scenario, Appendix E.4). Therefore, no substantial reduction in the abundance of a year class is predicted. Based on no predicted substantial short-term decrease in eulachon abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the eulachon population under the Proposed Project in the short term. Within a short duration (< 6 months) SSCs within the Klamath River Estuary are predicted to return to existing levels (Appendix E.4). There is no predicted substantial long-term decrease in eulachon abundance of a year class, or substantial decrease in habitat quality or quantity, and thus there would not be a significant impact to the eulachon population under the Proposed Project in the long term.

Significance

No significant impact for eulachon population in the short term and long term

Potential Impact 3.3-16 Effects on the longfin smelt population due to short-term sediment releases and long-term changes in habitat quality due to dam removal.

The Proposed Project would release dam-stored sediment downstream to the Klamath River Estuary. Longfin smelt entering the Klamath River in the winter and spring of dam removal year 2 may be exposed to high SSCs for a portion of their migration period. Although no analysis of the effects of SSCs on longfin smelt is available, based on application of the Newcombe and Jensen (1996) approach using studies of the effects on other estuary species, it is predicted that under a most-likely impacts to fish or worst impacts on fish scenario mortality would be higher under the Proposed Project than under existing conditions for a period of weeks. However, as described for eulachon above, the protracted migration season for longfin smelt (throughout the year), and relatively short duration of occurrence in the estuary (less than two months), increases the probability that most of the population would migrate and spawn either before or after the largest pulses of SSCs (predicted to be two weeks in duration or less). Based on no predicted substantial short-term decrease in longfin smelt abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the longfin smelt population under the Proposed Project in the short term. Within a short duration (< 6 months) SSC within the Klamath River Estuary are predicted to return to existing levels (Appendix E.4), and thus there is no predicted substantial long-term decrease in longfin smelt abundance of a year class, or substantial decrease in habitat quality or quantity, and there would not be a significant impact to the longfin smelt population under the Proposed Project in the long term.

Significance

No significant impact for longfin smelt population in the short term and long term

Potential Impact 3.3-17 Effects on species interactions between introduced resident fish species and native aquatic species due to short- and long-term changes in habitat quality and quantity due to dam removal.

Introduced fish species threaten the diversity and abundance of native fish species through competition for resources, predation, interbreeding with native populations, and causing potential physical changes to the invaded habitat (Moyle 2002). Introduced resident species occur in Lake Ewuana and Upper Klamath Lake, but the Proposed Project would not affect populations in this area.

As described in detail in Section 3.20.2.3 *Lower Klamath Project Reservoir-based Recreation*, the reservoirs currently provide a recreational fishery for non-native fishes including largemouth bass, trout, catfish, crappie, and sunfish (Hamilton et al. 2011). Fishing is popular in Copco No. 1 and Iron Gate reservoirs, especially for yellow perch (Hamilton et al. 2011). Adults yellow perch are opportunistic predators that feed on small fish, potentially including native fish species. Juvenile and adult largemouth bass tend to feed on larger invertebrates and fish as well, potentially including native species. The Proposed Project would eliminate reservoir habitat upstream of Iron Gate Dam, and thus the abundance of introduced resident species would decline substantially or be eradicated (Buchanan et al. 2011a), providing a benefit to native aquatic species.

A few introduced resident species occur in the Middle and Lower Klamath River, but water velocities within riverine habitat are too high for the introduced species that in general are adapted to the lotic conditions in the reservoirs in which they were introduced. Under the Proposed Project, conditions would be expected to become even less suitable for introduced resident species. This effect would be beneficial for native aquatic species in the short and long term.

Significance

Beneficial for the effects of introduced resident fish species on aquatic species in the short term and long term

Potential Impact 3.3-18 Effects on aquatic species from interactions among fish species due to short- and long-term changes in habitat quantity due to dam removal.

The Proposed Project would restore access for anadromous salmon and steelhead to habitat upstream of Iron Gate Dam, as described in detail above. Restoration of access would result in anadromous salmon and steelhead potentially interacting with resident redband trout and bull trout, with the potential for competition and predation. These species evolved together in the Upper Klamath Basin of the Klamath River, and co-existed prior to the construction of dams (Goodman et al. 2011).

Anadromous salmonids currently co-exist with resident rainbow trout and resident cutthroat trout downstream from Iron Gate Dam, without any obvious detriment to these native species or the aquatic ecosystem in which they reside. While there is little information on the nature of any competitive interactions between steelhead and resident trout in the Klamath Basin, research does suggest that in some circumstances, resident trout may have a competitive edge over steelhead (NMFS 2006a). Conversely, research has shown that hatchery salmon supplementation can negatively impacted resident trout abundance and salmonid biomass in a Washington watershed (Pearsons and Temple 2010). However, competition between steelhead and currently present indigenous species such as redband trout are not assumed to be a major limiting factor since these species historically co-evolved (Hooton and Smith 2008). There are many examples from nearby river systems in the Pacific Northwest that show wild anadromous steelhead and resident rainbow/redband trout can co-exist and maintain abundant populations without adverse consequences. The Deschutes River in Oregon, the Yakima River in Washington, and the river systems in Idaho are examples (NMFS 2006a). As noted by Buchanan et al. (2011a), existing trout and colonizing anadromous steelhead are expected to co-exist in the Klamath Basin, as they do in other watersheds, although there may be shifts in abundance related to competition for space and food. Overall, there is no predicted substantial short-term or long-term decrease in native aquatic species abundance of a year class, or substantial decrease in habitat quality or quantity, and there would not be a significant impact to the aquatic species populations under the Proposed Project in the short term or long term.

Significance

No significant impact for effects to aquatic species from interactions among fish species in the short term and long term

Potential Impact 3.3-19 Effects on freshwater mollusks populations due to short-term sediment releases and long-term changes in habitat quality due to dam removal.

Four species of native freshwater mussels have been observed within the Klamath Basin, including Oregon floater (*A. oregonensis*), California floater (*A. californiensis*), western ridged mussel (*G. angulata*), and western pearlshell mussel (*M. falcata*).Oregon floater and California floater (commonly referred together “floater mussels,” or “*Anodata spp*.”) occur in the mainstem Klamath River in the Hydroelectric Reach, within Lower Klamath Project reservoirs, in a reach (<15 miles) directly downstream of Iron Gate Dam, and within the Upper Shasta River. *M. falcata* are common in the mainstem Klamath River from Iron Gate Dam downstream to the confluence with the Trinity River, and within Middle Klamath tributaries such as Bogus Creek, and Shasta, Scott, and Salmon rivers. *G. angulata* is more widely distributed and more abundant than the other species and has been observed in high densities from Keno Dam downstream to the confluence with the Trinity River, and within the Shasta and Scott rivers (Davis et al. 2013). Mussel abundance also generally declines with increasing distance downstream from Iron Gate Dam, suggesting the effects of the increasing hydrologic variability of the Klamath River with distance from Iron Gate. Davis et al. (2013) concluded that habitats located further downstream had lower probabilities of supporting mussels due to more variable conditions.

Seven to eight species of fingernail clams and peaclams (Family: Sphaeriidae) also occur in the Hydroelectric Reach and from Iron Gate Dam to Shasta River. This evaluation focuses on freshwater mussels because of their similar distribution to other freshwater mollusks, similar habitat requirements, their longer life-span, and lack of information regarding the effects of sediment on clams and other mollusks.

Suspended Sediment Concentrations

Under the Proposed Project, in the Hydroelectric Reach between J.C. Boyle Dam and Copco No.1 SSCs are predicted to exceed 600 mg/L (the minimum SSC level that would be considered detrimental to freshwater mussels), for short periods of time (1–5 days) during spikes in SSCs. SSCs are expected to be higher than under existing conditions and would likely exceed 600 mg/L for two to four months after removing the dams from Copco No 1. Dam downstream to the Klamath River Estuary; however, the highest levels, well in excess of 1,000 mg/L, would occur between Seiad Valley and Iron Gate Dam. Within six months of dam removal SSCs in the mainstem Klamath River are predicted to return to levels observed under existing conditions. Under existing conditions, SSCs in the mainstem Klamath River often exceed 600 mg/L, although these spikes generally occur for a few days as opposed to several months (see also Potential Impact 3.2-3).

Predicted increases in SSC within the Hydroelectric Reach under the Proposed Project are anticipated to result in major physiological stress to *Anodata spp*., and *G. angulata*, including mortality of at least a proportion of the individuals. The most significant impacts would occur downstream from Iron Gate Reservoir, especially to those individual freshwater mussels or freshwater mussel beds upstream of Orleans and closest to Iron Gate Dam. For populations occurring downstream of the confluence with the Salmon River (*M. falcata* and *G. angulata*) dilution from tributaries would limit exposure to SSCs likely to be sublethal. Because freshwater mussels found within the Klamath River can be so long lived (from 10 to more than 100 years, depending on the species) and sexual maturity might not be reached until four years of age or more, even relatively short term (e.g., for more than five consecutive days) SSCs in excess of 600 mg/L, would be expected to be detrimental for freshwater mussel populations within the mainstem Klamath River upstream of the Salmon River confluence, in the short term. This would impact all four-mussel species, most notably *Anodata spp*., due to their limited distribution in the proximity of Iron Gate Dam. *M. falcata* and *G. angulata* are less likely to experience a substantial decline in abundance In the short term, due to their broader distribution downstream of Iron Gate Dam in the mainstem, and strong populations in tributaries.

Freshwater clams can live buried in the substrate, and are expected to suffer less impact than freshwater mussels. In addition, they are relatively short-lived (one to three years) and bear young several times throughout the spring and summer which would support rapid recovery within the short term to impacts from suspended sediment.

In the long term (i.e., greater than five years), it is anticipated that mainstem Klamath *M. falcata* and *G. angulata* populations would rebound from suspended sediment impacts, recolonizing through the transport of larvae (glochidia) by host fish from downstream populations less affected by excessive SSCs or from populations within tributaries, such as Bogus, Shasta, Scott, and Salmon rivers. *Anodata spp*. are anticipated to recover more slowly from suspended sediment impacts, due to a narrower distribution downstream of Iron Gate Dam, and limited distribution within tributaries (i.e., only found in upper Shasta River).

Changes in Bed Elevation

Silt and fine material make up the largest proportion of the volume of sediment stored behind the dams and would be transported downstream primarily as suspended sediment under the Proposed Project. Coarser material (larger than 0.063 mm) would also be transported downstream and would likely be deposited in the river channel, changing riverbed elevations from the existing conditions for approximately eight miles between Iron Gate Dam and Cottonwood Creek. The 182 miles of mainstem downstream from Cottonwood Creek are not predicted to have any substantial aggradation. Therefore, *Anodonta spp*. populations closest to Iron Gate Dam are likely to be most affected by aggradation of sediments under the Proposed Project, whereas *M. falcata* and *G. angulata* with broad distributions are unlikely to be substantially affected. It is not known how well any of these species could tolerate deposition of sediment and whether they could move upward through deposited material to the surface to breathe and feed. It is reasonable to assume that some percentage of Klamath River freshwater mussels buried under 0.5 to 3.0 feet of new sediment would not survive, especially since these same population would be exposed to the increased SSCs described above. *G. angulata* have a demonstrated ability to withstand burial in sediment and are likely to be the least affected.

Freshwater clams can live buried in the substrate and are expected to avoid impacts from bed deposition.

Changes in Bed Substrate

Removal of the Lower Klamath Project dams under the Proposed Project would result in the erosion of accumulated reservoir sediments and changes in substrate characteristics within the Klamath River, especially within the current reservoir reaches. The reformation of river channels in the reservoir reaches is expected to occur within six months (Potential Impact 3.11-5) following removal of the dams. The reformation of river channels between Iron Gate Dam and the upstream reaches of J.C. Boyle Reservoir would benefit *M. falcata* and *G. angulata* and clams in the long term by providing more suitable substrates (i.e., large gravel, cobble, and boulder) than currently exists, especially within the current reservoir reaches. However, conversion of reservoirs to riverine habitat is anticipated to have a short- and long-term impact on *Anodonta spp*., which currently occur within reservoirs, and are adapted to low-flow variability habitat.

Changes in Habitat Accessibility

In addition, the Proposed Project would also open access to river reaches upstream of Iron Gate Dam to migratory fish species, which serve as host fish for parasitic freshwater mussel larvae (glochidia). *M. falcata* in particular may benefit from the increased distribution of anadromous salmonids, which are a primary host species for their larvae. As a result, in the long term suitable habitats upstream of Iron Gate Dam might be colonized or recolonized by all four freshwater mussel species, transported as glochidia from downstream reaches by migratory fish species.

Summary

In the short term, *G. angulata* have a demonstrated ability to withstand burial in sediment and are a widespread and abundant mussel species, including within the Hydroelectric Reach, and within key tributaries upstream and downstream of Iron Gate Dam. Therefore, a relatively small proportion of their population would be directly impacted by sediment released during dam removal. Based on no predicted substantial short-term decrease in *G. angulata* abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the *G. angulata* population under the Proposed Project in the short term.

M. falcata have a broad distribution downstream of Iron Gate Dam in the mainstem, and strong populations in several tributaries in the Middle Klamath River. Therefore, a relatively small proportion of their population would be directly impacted by sediment released during dam removal. Based on no predicted substantial short-term decrease in *M. falcata* abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the *M. falcata* population under the Proposed Project in the short term.

Anodonta spp. would likely be impacted by the Proposed Project due to their close proximity to Iron Gate Dam, and preference for stable flows that currently exist in Lower Klamath Project reservoirs and downstream of Iron Gate Dam. *Anodonta spp*. likely only occurs downstream of Iron Gate Dum under existing conditions as a result of the altered hydrograph (Davis et al. 2013). Under natural conditions they would be unlikely to occur in the mainstem Klamath River downstream. Based on their limited distribution in the mainstem Klamath River, Lower Klamath Project reservoirs, and small presence in the Upper Shasta River, *Anodonta spp*. would likely decline substantially in abundance within the first six months of dam removal as a result of suspended sediment releases. In addition, their habitat would likely substantially decline in quality in the short term. Based on predicted substantial short-term decrease in *Anodonta spp* abundance of a year class, and substantial decrease in habitat quality, there would be a significant impact to the *Anodonta spp* population under the Proposed Project in the short term.

However, the Proposed Project includes aquatic resource measure AR-7 (Freshwater Mussels) to reduce the short-term effects of sediment transport during dam removal on *Anodonta spp*. Aquatic resource measures are summarized in Section 2.7.8.1 *Aquatic Resource Measures* and detailed in Appendix B: *Definite Plan – Updated AR-7, October 2018 Update*. Proposed Aquatic Resource Measure AR-7 includes salvage and relocation plan prior to Lower Klamath Project dam removal and completing a reconnaissance of existing freshwater mussels from Iron Gate Dam to Cottonwood Creek and potential relocation habitat between the upstream extent of J.C. Boyle Reservoir and Keno Dam. Freshwater mussels would be salvaged and relocated in dam removal year 1 prior to the reservoir drawdown. Approximately 15,000 to 20,000 mussels (primarily *Anodonta spp.)* are planned for translocation. There are currently multiple large-scale mussel relocation projects occurring nationwide (Zimmerman et al. 2017, USDA Forest Service 2016, Illinois Department of Natural Resources 2016). Initial findings from these and previous studies indicate that with planning, mussel relocation can be successful. USDA Forest Service (2016) has found that 71 percent of the translocated mussels were found a year later and that only two mussels (0.22 percent) were confirmed dead. Fernandez (2013) found that Between 55 percent and 95 percent of the transplanted *M. falcata* mussels could be accounted for in individual streams one to three years after relocation. Therefore, it appears likely that these measures could be successful. Sites considered for translocation include areas downstream from the Trinity River confluence (RM 43.4), and between J.C. Boyle Dam (RM 230.6) and Copco No. 1 Reservoir (RM 209.0). These areas would have less impact from increased SSCs but would not be completely protected from short-term effects. The areas downstream of the Trinity River confluence do not currently support *Anodonta spp*. and are unlikely to in the future (Davis et al. 2013). The reach between J.C. Boyle Dam and Copco No. 1 Reservoir does not currently support *Anodonta spp.* Therefore, translocation efforts described in proposed Aquatic Resource Measure AR-7 are anticipated to be potentially successful for *G. angulata* and *M. falcata* (based on suitable habitat in translocation sites), but is unlikely to be successful for *Anodonta spp.* With this aquatic resource measure, there would likely still be a substantial reduction in the abundance of *Anodonta spp.* species In the short term, and impacts would be significant with for *Anodonta spp.* in the short term. For development of proposed Aquatic Resource Measure AR-7, the KRRC explored several approaches to salvaging and relocating *Anodonta spp*. prior to dam removal, as described Appendix B: *Definite*

Plan − Updated AR-7, October 2018 Update. However, options such as translocating mussels to tributaries, or other reaches upstream of Iron Gate Dam were rejected after surveys suggesting that most locations would not provide suitable habitat, and the concern of risking healthy and abundant mussels populations in tributaries by translocating mussels from the mainstem reach with unknown disease risk. Therefore, the short-term significant impact on *Anodonta spp*. due to the Proposed Project cannot be avoided or substantially decreased through feasible mitigation.

Freshwater clams can live buried in the substrate and are expected to suffer less impact than freshwater mussels. In addition, they are relatively short-lived (one to three years) and bear young several times throughout the spring and summer which would support rapid recovery within the short term to impacts from suspended sediment. Based on no predicted substantial short-term decrease in freshwater clam abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the freshwater clam populations under the Proposed Project in the short term.

In the long term, dam removal would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach for *M. falcata* and *G. angulata*. Based on no predicted substantial long-term decrease in *M. falcata* and *G. angulata* abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the *M. falcata* and *G. angulata* populations under the Proposed Project in the short term.

Conditions would also improve in the long term in the Hydroelectric Reach for *Anodonta spp.* with reduced flow variability downstream of J.C. Boyle Dam, potentially creating conditions more similar to the reach downstream of Keno Dam, where *Anodonta spp*. are currently found (Byron and Tupen 2017). This additional habitat is unlikely to offset the long-term habitat lost from increased flow variability within Lower Klamath Project reservoirs and downstream of Iron Gate Dam. The current populations of *Anodonta spp*. in the Lower Klamath Project reservoirs and downstream of Iron Gate Dam are artifacts of an altered hydrology and geomorphology. The reversion of these conditions to more natural river environment (e.g., natural flow regime and increased sediment scour) would no longer support *Anodonta spp*., and the suitable habitat supporting their populations would be revert to natural spring-fed stable flow conditions, such as the Upper Shasta River. Based on predicted substantial long-term decrease in *Anodonta spp.* abundance of a year class, and substantial decrease in habitat quality and quantity, there would be a significant impact to the *Anodonta spp.* population under the Proposed Project in the long term. Because reversion of the Klamath River within and downstream of the Lower Klamath Project to more natural river conditions would be an inevitable consequence of the Proposed Project, the long-term significant impact on *Anodonta spp*. due to the Proposed Project cannot be avoided or substantially decreased through feasible mitigation.

Based on no predicted substantial long-term decrease in freshwater clam abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to the freshwater clam populations under the Proposed Project in the long term.

Significance

No significant impact for *M. falcata* and *G. angulata* in the short or long term

Significant and unavoidable impact for *Anodonta spp.* in the short and long term

No significant impact for freshwater clams in the short or long term

Potential Impact 3.3-20 Effects on fish species from alterations to benthic macroinvertebrates due to short-term sediment releases and long-term changes in habitat quality due to dam removal.

Benthic macroinvertebrates (BMI) are small aquatic animals and the aquatic larval stages of insects. BMI are the primary food source for most freshwater fish species, and therefore, changes in abundance, distribution, or community structure can affect fish populations. A diminished food supply can limit growth of salmonids, and this is especially true at higher temperatures because as water warms, a fish's metabolic rate increases, and it needs more food to sustain growth. Growth is critical to juvenile salmonids because a larger size fish often has a survival advantage during the overwintering period, smolt outmigration, and ocean residence.

In the short term, the Proposed Project could alter SSCs and bedload sediment transport and deposition and thereby negatively affect benthic macroinvertebrates. Increases in suspended sediment and increased bedload deposition following dam removal under the Proposed Project are anticipated to result in a reduction in abundance of BMIs within the first few months of dam removal year 2 in the reach from Iron Gate Dam to confluence with the Salmon River, and SSC increases may decrease growth rates of fish rearing and feeding in the mainstem Klamath River downstream of Iron Gate Dam to around the Salmon River confluence. Short-term reductions in the abundance and diversity of BMIs has been observed following disturbance due to suspended sediment (Reid and Anderson 2000, Orr et. al 2008). During the period of greatest impact (winter of sediment release dam removal years 1 and 2), food availability related to BMI production would likely decrease in the reach downstream of Iron Gate Dam around the confluence with the Salmon River. However, within this reach a reduction in feeding by fish species is already predicted to occur in response to increased SSCs, which is a sub-lethal effect from which fish populations are anticipated to recover. In addition, salmonids typically reduce feeding during winter in response to lower water temperature and decreased metabolic demand (Bustard and Narver 1975).

While a large proportion of the BMI population in the Hydroelectric Reach and in the mainstem Klamath River downstream from Iron Gate Dam would be reduced in the short term, their populations would be expected to recover quickly because of the many sources for recolonization and their rapid dispersion through drift or aerial movement of adults. Full recovery of BMI communities is typically observed within a year following disturbance (Tsui and McCart 1981, Anderson et al. 1998). The constant "flushing" action of the Klamath River is anticipated to speed BMI recovery from negative impacts resulting from sediment deposition. Tullos et al. (2014) found that BMI communities downstream of the Brownsville (Calapooia River, Oregon) and Savage Rapids (Rogue River, Oregon) dams resembled upstream control sites within a year after dam removal. Foley et al. (2017) summarizes the effects of multiple dam removal studies and found that researcher reported that following dam removal downstream BMI abundance tends to increase and species assemblages transition to resemble sites upstream of the former dam, noting that some BMI species can double their population size in days to weeks, and quickly (within months) recover once the initial sediment pulse has passed. There, the effects of reduced BMI populations on food availability for fish species is anticipated to be of insufficient magnitude or duration to substantially effect fish species in the short term. Based on no predicted substantial short-term decrease in fish abundance of a year class, or substantial decrease in habitat quality or quantity supporting a fish species, there would not be a significant impact to fish populations under the Proposed Project in the short term from effects to BMIs.

In the long term, the Proposed Project would restore connectivity among the Lower Klamath Basin, the Hydroelectric Reach and its tributaries, and the Upper Klamath Basin, and would rehabilitate and increase availability of riverine habitat within the Hydroelectric Reach. The reformation of river channels in the reservoir reaches upstream of Iron Gate Dam, and the reversion to unimpeded sediment transport downstream of Iron Gate Dam under the Proposed Project, would benefit BMIs by providing more suitable substrates (e.g., gravel) than currently exist. Thus, suitable habitats formed upstream of Iron Gate Dam might be opened to additional colonization by BMIs through rapid dispersal by drift from upstream populations within current riverine reaches and/or dispersion of adult life stages. In addition, recolonization would occur rapidly from established BMI populations within the many tributary rivers and streams of the Klamath River. BMI populations would be expected to recover quickly and provide food availability to fish from short-term impacts because of the many sources for recolonization and their rapid dispersion through drift or aerial movement of adults.

Under the Proposed Project, peaking operations would no longer kill, through stranding, large numbers of aquatic invertebrates that are the primary prey food for resident trout in the reach between J.C. Boyle Powerhouse and Copco No. 1 Reservoir (NMFS 2006a). Based on increased habitat availability and improved habitat quality, the effect of the Proposed Project on BMI as a food source for fish species would be beneficial in the long term. Based on no predicted substantial long-term decrease in fish abundance of a year class, or substantial decrease in habitat quality or quantity supporting a fish species, there would not be a significant impact to fish populations under the Proposed Project in the long term from effects to BMIs.

Significance

No significant impact for effects of alterations to benthic macroinvertebrates on fish species in the short term

Beneficial for effects of alterations to benthic macroinvertebrates on fish species in the long term

Potential Impact 3.3-21 Effects on aquatic resources due to short-term noise disturbance and water quality alterations from construction and deconstruction activities.

This analysis relates to the potential impact to aquatic resources from various construction and deconstruction activities associated with the Proposed Project, outside of the release of reservoir sediments discussed more thoroughly above, and the relocation of the City of Yreka's water supply pipeline, discussed below as Potential Impact 3.3-23.

Disturbance to the river channel during construction related to the Proposed Project could affect aquatic species. The Proposed Project would require demolition of the dams and their associated structures, removal of power generation facilities and transmission lines, installation of cofferdams, road upgrading, hauling, reservoir restoration, and other activities (as described in Section 2.7.1 *Dam and Powerhouse Deconstruction*). These actions would include the use of heavy equipment, and blasting as necessary, and have the potential to disturb aquatic species. Activities at the Lower Klamath Project dams would affect the riverine and introduced resident species in the Hydroelectric Reach. At Iron Gate Dam and Iron Gate Hatchery, anadromous species could also be affected. These potential effects could include shockwaves associated with breaking down the dam structures using explosives or heavy equipment, potential crushing of aquatic species from operation of heavy equipment in the river, sedimentation, and release of oil, gasoline, or other toxic substances from construction sites.

Several deconstruction activities are schedule to occur prior to reservoir drawdown, including road improvements (e.g., bridge upgrades), temporary road crossings, Iron Gate modifications, Fall Creek Hatchery modifications, etc. In-water demolition of the dams and their associated structures, power generation facilities, and other activities, are scheduled to occur nearly simultaneously within the first nine months of reservoir drawdown during dam removal year 2 (see Table 2.7-1), and during the peak SSCs associated with reservoir drawdown in dam removal year 2. The aquatic resources impacts of this reservoir drawdown SSC peak are discussed earlier in this section. It is anticipated that this release of sediment during initial drawdown would result in the nearly immediate displacement of most mobile aquatic species from the mainstem into tributaries or farther downstream prior to the prolonged deconstruction or in-water work activities (e.g., cofferdam installation or removal). Native aquatic species (e.g., redband trout) that occur in the Hydroelectric Reach would have less potential refuge in the mainstem from deconstruction impacts, but would have access to key tributaries as refigure, including Jenny, Fall, and Shovel creeks. For non-mobile aquatic resources, like mussels, the impacts are anticipated to be well within the range of what is discussed for reservoir sediment release, as it is assumed that construction and deconstruction-related impacts would be of small magnitude, short duration, and low intensity when compared to those that would occur as a result of release of sediments stored behind the dams.

For aquatic species that occur within reservoirs, the effect of deconstruction is already subsumed by the impact of conversion of reservoir to riverine habitat, as described in multiple potential impacts above. For example, the reservoir habitat that supports Lost River and shortnose suckers (Potential Impact 3.3-13) would be removed, as addressed by the Aquatic Resource Measure AR-6 to salvage and relocate suckers prior to reservoir drawdown, or impacts associated with deconstruction.

To minimize potential construction impacts from crushing, sediment release, toxins, noise, etc., construction areas would be isolated from the river where possible. The Klamath River would be bypassed around the construction area while the isolated portion of the dam is removed. After a work area is isolated, fish rescue and relocation efforts, to remove any native fish trapped in the work area, would be conducted. Fish would be relocated to an area of suitable habitat within the Klamath River.

In addition, proposed soil erosion and sedimentation control and stormwater pollution prevention (Section 2.7.8.7 *Water Quality Monitoring and Construction BMPs*) measures would minimize effects of construction related toxins, soil erosion, and associated water quality effects on aquatic species downstream from the work area, during and after construction. Further, the State Water Board has issued a draft water quality certification which sets forth multiple conditions to monitor the effects of deconstruction on water quality (e.g., suspended sediment, dissolved oxygen, toxicity, etc.), and to protect aquatic resources through proper disposal of materials. Based on no predicted substantial short- or long-term decrease in aquatic species abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to aquatic resources under the Proposed Project in the short term or long term from deconstruction effects.

Significance
No significant impact for aquatic resources from deconstruction in the short term or long term

Potential Impact 3.3-22 Effects on aquatic species due to short-term noise disturbance and water quality alterations from deconstruction activities and long-term fish screen upgrades from the relocation of the City of Yreka Water Supply Pipeline under the Proposed Project.
The existing water supply pipeline for the City of Yreka passes under the upstream end of Iron Gate Reservoir and would have to be relocated prior to decommissioning the Iron Gate Dam to prevent damage from deconstruction activities or increased water velocities and pipeline exposure once the reservoir has been drawn down. Additionally, the water supply intake screens located in Fall Creek may need to be replaced or upgraded to meet regulatory criteria. Native species currently residing in Iron Gate Reservoir that could be affected from the construction-impacts of removal of the existing pipeline and the installing of a new one in the short term would include redband trout, cutthroat trout, chub species, sucker species, and sculpin species. In the long term anadromous fish accessing habitat upstream of Iron Gate Dam could also be affected by improved screens at the water supply intakes. If the existing fish screens for the water supply intakes do not meet current regulatory agency screen criteria for anadromous fish, improved screened intakes presumably would meet criteria. As described in Section *2.7.8.7 Water Quality Monitoring and Construction BMPs,* standard construction best management practices would reduce the likelihood and extent of aquatic impacts to a less-than-significant level for water quality purposes. These levels are set for protection of aquatic resources. Therefore, based on no predicted substantial short- or long-term decrease in aquatic species abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to aquatic resources under the Proposed Project in the short term or long term from the relocation of the City of Yreka water supply pipeline and intake screens.

Significance
No significant impact to aquatic resources from the relocation of the City of Yreka water supply pipeline and intake screens in the short or long-term

Potential Impact 3.3-23 Effects on anadromous salmonid populations due to short-term and long-term Bogus Creek flow diversions for the Iron Gate Hatchery.
Under the Proposed Project, up to 8.75 cfs of water would be diverted from Bogus Creek to operate Iron Gate Hatchery for eight years (dam removal year 2 through post-dam removal year 7), as described in Section 2.7.6 *Hatchery Operations*. This diversion would replace the current water supply from Iron Gate Reservoir. Specific diversion rates from Bogus Creek would be as follows:

- 6.50 cfs October through November
- 8.75 cfs in December
- 3.50 cfs January through March
- 8.25 cfs April through May
- 0.00 cfs June through September

To reduce the potential adverse effects of diverting water from Bogus Creek on naturally spawning and rearing salmon, the KRRC proposes to construct the pump station for the hatchery water supply would be constructed as far downstream toward the Klamath River confluence as practicable (within 1,000 feet, Figure 2.7-10). This would result in up to a 1,000-foot reach in lower Bogus Creek that would experience lower fall, winter, and spring flows than under existing conditions (Figure 2.7-11). As further discussed below, CDFW and NMFS have proposed monitoring and adaptation of operations to minimize habitat impacts.

Based on adult migrant monitoring (Knechtle and Chesney 2011, 2016, 2017), fall-run Chinook salmon are observed to return to Bogus Creek to spawn from mid-September to early November, coho salmon adults return from late October to early January, and steelhead from November through March. Therefore, flow diversions of 6.5 cfs during October and November, and 8.75 cfs in December could affect upstream migration of adult salmonids into Bogus Creek through the lower reach. The volume of flow required for adult salmonids to migrate upstream through lower Bogus Creek has not been directly assessed. Depending on stream gradient, channel width, and other geomorphic conditions, flows below the diversion may continue to be sufficient for upstream passage, or they could result in conditions that restrict passage at times, particularly in early October prior to increased precipitation. The geomorphic conditions that determine passage are subject to change as precipitation events alter the streambed.

Based on two years of recent migration observations in Bogus Creek (Knechtle and Chesney 2016, 2017) during the low flow years of 2015 and 2016, fall-run Chinook salmon were observed migrating at flows as low as 4.5 cfs in September 2016, and 8 fish were observed migrating at flows between 4.5 and 5 cfs. During the fall-run Chinook salmon migration peak in 2015 and 2016, flows were between 10 and 20 cfs. Based on this data, flows greater than around 4.5 cfs enabled at least some upstream migration in the past. If this flow was sufficient for Chinook salmon, it would also be sufficient for coho salmon and steelhead, which have less restrictive passage requirements. Long-term flow monitoring data are not available for Bogus Creek. However, the available data from 2013–2016 includes severe and extreme drought conditions and are therefore likely appropriate to observe minimum flows to support passage. Based on four years of available data (Figure 2.6-8), proposed water diversions could result in flow reductions during the adult migratory period of around 10 to 40 percent in the affected reach during fall-run Chinook salmon migration, potentially resulting in flows less than 4.5 cfs in at least some years, for at least a few days. By the time coho salmon and steelhead are migrating flows are high enough to provide greater than 4.5 cfs, based on the data available. Based on available data it appears that under the Proposed Project insufficient flows for Chinook salmon passage could result in delays for up five days in some years. Delay of migration for even one day has been observed to increase disease risk by increasing the density of holding adults and increasing mortality of adults prior to spawning (McLaughlin et al. 2012, Connor et al. 2018). Temporary increasing in crowding may be similar to similar to what is observed under existing conditions during periods of low rainfall, but could be exacerbated by decreasing flows in lower Bogus Creek. These impacts are anticipated to effect a small proportion of migrants during the 14-week fall-run Chinook salmon migration period (Table 3.3-3). In addition, any redds that are deposited along channel margins (shallow water areas) downstream of the diversion may be susceptible to stranding when diversion rates increase (e.g., primarily December, as well as March), although the affected reach is relatively short (< 1,000 feet). Rearing fish (mobile) are unlikely to be affected by the relatively low magnitude of flow fluctuations.

As described in detail in Section 2.7.6 *Hatchery Operations*, the proposal for Iron Gate Hatchery operation includes protection for fish passage in Bogus Creek (Appendix B: *Definite Plan – Section 7.8.3*, NMFS and CDFW 2018). To minimize effects of Bogus Creek diversions on fish habitat, NMFS and CDFW would coordinate to ensure that at least 50 percent of the flow would remain in Bogus Creek at the point of diversion, conduct an assessment to determine that the habitat below the diversion provides connectivity for fish spawning and rearing habitat, identify appropriate flow levels or percentages of diversion permitted each month, and establish reporting specifications (Section 2.7.6 *Hatchery Operations*).

Based on the potential for low flows (i.e., less than 4.5 cfs) in the Bypass Reach during the salmonid migration periods in some years resulting in delayed migration and increased crowding, the uncertainty in the migration flow levels in Bogus Creek, and the uncertainty in the commitment to ensure flows to protect anadromous salmon volitional migration, the flow diversions from Bogus Creek could decrease the abundance of multiple (up to eight) year classes of anadromous salmonids produced from spawning activity in Bogus Creek. However, only a portion of the fall-run migration could be affected, and the total potential production from redds in Bogus Creek is a low proportion of all the production from the Klamath River Basin for Chinook salmon, coho salmon, and steelhead. Based on the less than substantial decrease in abundance of a year class and habitat quality that could occur under the Proposed Project in the short- and long-term, the effect of reduced instream flows in Bogus Creek under the Proposed Project would not be significant in the short- and long-term.

Although CEQA Guidelines Section 15126.4(a)(3) states that mitigation measures are not required for effects which are not found to be significant, Mitigation Measure AQR-3 would even further reduce the potential for short- and long-term effects of reduced instream flows in lower Bogus Creek under the Proposed Project on anadromous salmon by increasing certainty that fish passage conditions are projected. Mitigation Measure AQR-3 below includes additional components beyond those listed as part of the Proposed Project which would further reduce the potential short-term impacts on migrating anadromous salmonids resulting from hatchery operations. With Mitigation Measure AQR-3, the potential effect of instream flow diversions is further reduced.

Mitigation Measure AQR-3 – Bogus Creek Flow Diversions.
Implementation of Iron Gate Hatchery operations plan (Described in Appendix B: *Definite Plan – Section 7.8.3*) shall include a minimum flow in Bogus Creek of 4.5 cfs, unless a study is conducted that determines an alternative minimum flow is required to provide volitional fish migration for Chinook salmon, coho salmon, and steelhead. If the hatchery diversions cause a flow within Bogus Creek downstream of the bypass that is less than 4.5 cfs (or the minimum flow identified for each species during their migration

period), then hatchery operations shall be adjusted, in coordination with NMFS and CDFW, to reduce the percentage of flow diverted from Bogus Creek to be protective of anadromous fish passage.

Significance

No significant impact with mitigation on Chinook salmon, coho salmon, or steelhead in the short term or long term

Potential Impact 3.3-24 Effects on anadromous salmonid populations due to short-term and long-term Fall Creek flow diversions for the Fall Creek Hatchery .

Under the Proposed Project, up to 9.24 cfs of water would be diverted from Fall Creek to operate Fall Creek Hatchery for eight years (through post-dam removal year 7), as described in Section 2.7.6 *Hatchery Operations*. Specific diversion rates from Fall Creek would be as follows:

- 8.48 cfs in October
- 9.24 cfs in November
- 6.32 cfs in December
- 5.77 cfs in January
- 1.47 cfs in February
- 1.76 cfs in March
- 1.84 cfs in April
- 1.08 cfs in May
- 0.58 cfs in June
- 1.01 cfs in July
- 1.48 cfs in August
- 2.29 cfs in September

In addition, the City of Yreka maintains a water right to divert up to 15 cfs from Fall Creek for municipal purposes (City of Yreka 2012). The primary water intake for this water pipeline is located along the PacifiCorp Fall Creek powerhouse return canal at Dam A (Figure 2.7-17), which is upstream of the proposed Fall Creek Hatchery water diversion. Under the Proposed Project no fish passage would be possible past the existing Dam A or Dam B on Fall Creek (Figure 2.7-8; Appendix B: *Definite Plan – Section 7.8.3*), approximately one mile upstream from the projected confluence of Fall Creek with the Klamath River. Depending on final site selection, discharge from the hatchery would re-enter Fall Creek from between 0.08 and 0.36 miles upstream from the confluence with the Klamath River. Therefore, most of the one mile of spawning and rearing habitat for salmonids in Fall Creek, from Dam A and Dam B to the confluence with the Klamath River, would be subject to reduced flows as a result of Fall Creek Hatchery water diversions.

Based on historical records and current assessments of habitat suitability, Fall Creek likely has the potential to provide around one mile of spawning and rearing habitat for fall-run and spring-run Chinook salmon, coho salmon, steelhead, and Pacific lamprey following the removal of the fish passage barrier of Iron Gate Dam (NMFS 2006a, Hamilton et al. 2005, 2011).

The City of Yreka is required to bypass a minimum flow of 15 cfs or the natural flow of Fall Creek, whenever the natural flow is less than 15 cfs. Under existing conditions Yreka uses less than the 15 cfs allocation, but the City has used the full allocation in the past, and for this analysis it is assumed that the City of Yreka would use their full water right of up to 15 cfs. The Fall Creek Hatchery diversion and return flow points would occur between the City of Yreka water supply intake and the City's compliance point for the Fall Creek minimum flow, which is at the Fall Creek USGS gage (USGS No. 11512000). Between the Fall Creek Hatchery diversion and return flow points, the flow remaining in Fall Creek after the diversions for the City of Yreka and the Fall Creek Hatchery would usually be greater than 15.0 cfs, but it could occasionally be slightly less than 15.0 cfs in late summer to early fall (i.e., mid-July to mid-September) when natural Fall Creek flows reach a minimum. Fall Creek Hatchery diversion flows during the late summer would be 1.01 to 2.29 cfs, potentially reducing flows within the hatchery diversion affected reach to less than 15 cfs in dry water years with particularly low flows. However, this slight reduction during late summer is not anticipated to have a substantial effect on habitat availability or fish passage, due to the volume of instream flows remaining in the reach. During periods of the year when hatchery diversions would be higher (e.g., October through January), typically flows greater than 20 cfs would occur in this section of Fall Creek (Figure 2.7-13), which based on the habitat and channel morphology in Fall Creek is anticipated to provide suitable migratory, rearing, and spawning conditions. Any redds that are deposited downstream of the diversion along channel margins (shallower water) during fall may be susceptible to stranding (i.e., reduced egg-to-emergence survival) when diversion rates increase (e.g., primarily October and November). Rearing fish (mobile) are unlikely to be affected by the relatively low magnitude of flow fluctuations.

Under the Proposed Project anadromous salmonids would have increased habitat access upstream of Iron Dam, including within around one mile of habitat within Fall Creek that is currently inaccessible. Overall, a relatively small diversion of water from Fall Creek relative to existing creek flows would occur under the Proposed Project. In addition, the proportion of anadromous salmonids anticipated to use the habitat in Fall Creek is relatively minor in comparison with the totality of newly accessible habitat upstream of Iron Gate Dam under the Proposed Project. Therefore, based on no predicted substantial short- or long-term decrease in anadromous salmonid population abundance of a year class, or substantial decrease in habitat quality or quantity, there would not be a significant impact to anadromous salmonids under the Proposed Project in the short term or long term from Fall Creek Hatchery flow diversions.

Significance

No significant impact on Chinook salmon, coho salmon, or steelhead in the short term or long term

3.4 Phytoplankton and Periphyton

This section focuses on potential effects of the Proposed Project on the phytoplankton and periphyton communities in the Klamath River. For the purposes of this EIR the following terms have the following meanings:

- Phytoplankton: aquatic microscopic organisms, including algae, bacteria, protists, and other single-celled plants, that obtain energy through photosynthesis and float in the water column of still or slowly flowing waters such as lakes or reservoirs.
- Periphyton: aquatic organisms including aquatic plants, algae, and bacteria that live attached to underwater surfaces such as rocks on a riverbed.
- Algae: common name for photosynthesizing organisms that are a component of phytoplankton and/or periphyton (see above definitions) where algae typically include diatoms, green algae, and blue-green algae.
- Blue-green algae: common name for a type of phytoplankton that can produce toxic compounds that have harmful effects on fish, shellfish, mammals, bird, and people. Though blue-green algae are a type of cyanobacteria they are commonly referred to as algae. Cyanobacteria toxins are often referred to as "algal toxins". For readability, and to reduce confusion, this EIR will primarily refer to cyanobacteria as blue-green algae, with the exception of referencing source material.

In a balanced ecosystem, phytoplankton and periphyton supply base energy for the food web, because they convert energy from the sun (through photosynthesis) into biomass. In addition to sunlight, water and air, phytoplankton and periphyton also rely on nutrients from the water (primarily nitrogen and phosphorus). An excessive nutrient load in the water can allow phytoplankton and periphyton to overwhelm the ecosystem, causing negative impacts to water quality and other environmental resources. In addition to water quality and environmental impacts, blue-green algae can produce toxic compounds that have harmful effects on fish, shellfish, mammals, birds, and people.

The State Water Board received several comments related to blue-green algae during the NOP public scoping process (Appendix A), including comments indicating that dam removal would reduce the incidence of blue-green algae blooms and associated toxins in the Klamath River system. Commenters related numerous instances in which they linked health impacts to water contact in the presence of blue-green algae toxins, and they described having to limit recreation and avoid water contact due to blue-green algae despite the cultural importance of the river. Several commenters also noted that they no longer eat fish from the Klamath River due to concerns about consuming blue-green algae toxins with the fish. Other comments indicated that blue-green algae growth would continue to occur in the Klamath River in the absence of the Lower Klamath Project reservoirs. There were also several comments regarding periphyton, suggesting that dam removal would reduce the prevalence of attached algae in the Klamath River, which could reduce parasite rates in anadromous fish. A detailed summary of comments received during the NOP public scoping process, as well as individual comments, are presented in Appendix A.

Discussion of blue-green algae toxins and their impact on water quality are addressed in Section 3.2 *Water Quality*. Discussion of the relationship between periphyton and fish disease is addressed further with respect to aquatic organisms in Section 3.3.2.3.5 *Disease and Parasites*. Discussion of blue-green algae and its impact on recreation are addressed in Section 3.20 *Recreation*. Discussion of tribal cultural resources impacts of blue-green algae are addressed in Section 3.12 *Historical Resources and Tribal Cultural Resources* and Appendix V to this EIR.

3.4.1 Area of Analysis

The Area of Analysis for phytoplankton and periphyton includes multiple reaches of the Klamath River, as listed below and shown in Figure 3.4-1.

Upper Klamath Basin

- Hydroelectric Reach (upstream end of J.C. Boyle Reservoir to Iron Gate Dam)

Mid-Klamath Basin

- Klamath River from Iron Gate Dam downstream to the confluence with the Salmon River
- Klamath River from the confluence with the Salmon River to the confluence with the Trinity River

Lower Klamath Basin

- Lower Klamath River from the confluence with the Trinity River to the Klamath River Estuary
- Klamath River Estuary
- Pacific Ocean nearshore environment

Note that the portion of the Hydroelectric Reach that extends into Oregon (i.e., from the Oregon-California state line [RM 214.1] to the upstream end of J.C. Boyle Reservoir) is only being considered in this chapter to the extent that conditions in this reach influence phytoplankton and periphyton communities downstream in California.

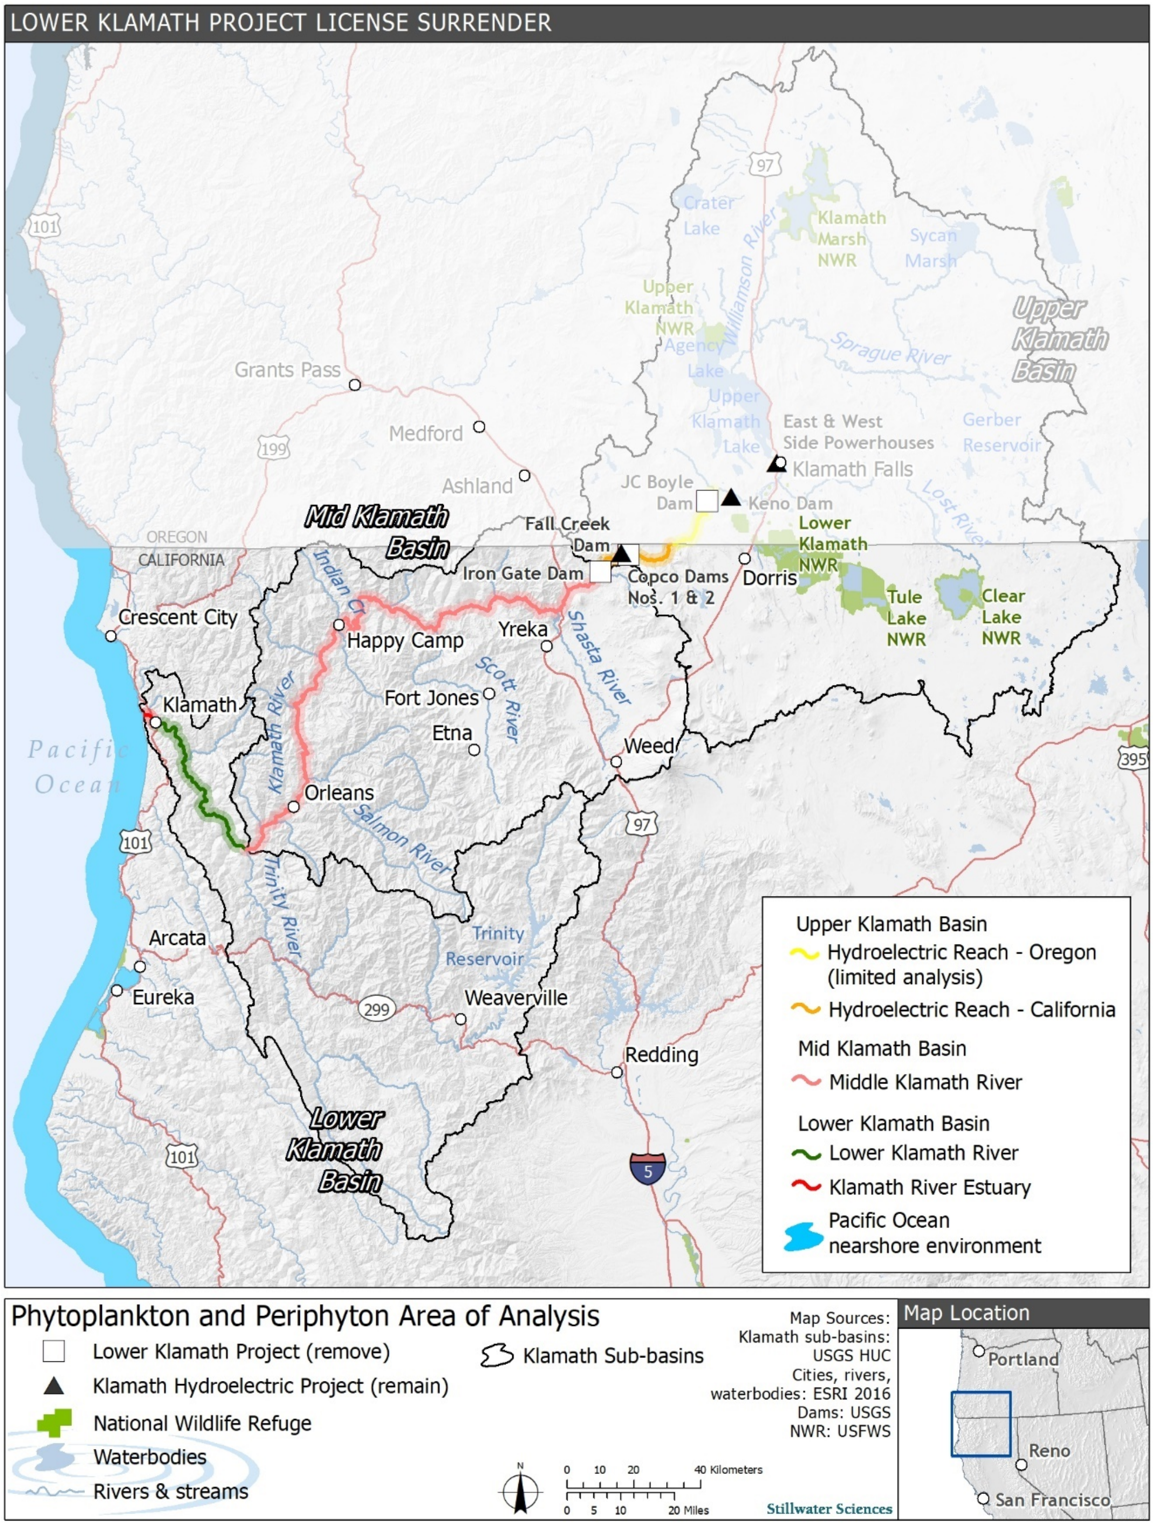

Figure 3.4-1. Klamath River Reaches Included in the Area of Analysis for Phytoplankton and Periphyton.

3.4.2 Environmental Setting

Phytoplankton and periphyton (defined in bullets at the beginning of in Section 3.4) are the two primary groups of algae (i.e., algal communities) in the Area of Analysis. Phytoplankton, including blue-green algae, compose the majority of the algal community in the reservoirs since phytoplankton prefer relatively still water. In the Klamath Basin, blue-green algae frequently reach nuisance levels within Upper Klamath Lake, Copco No. 1 Reservoir, and Iron Gate Reservoir. In addition, blue-green algae can be found in portions of the Klamath River (e.g., backwater eddies and near shore shallows) where blue-green algae cells from upstream lakes and the Lower Klamath Project reservoirs have drifted downstream. These portions of the river can also support nuisance levels of blue-green algae under certain conditions. Typically, most of the riverine portions of the Klamath River are dominated by periphyton, which include diatoms, green algae, fungi, and bacteria that attach to the stream bed and/or other underwater surfaces. Larger aquatic plants may also be present in quiet backwater areas in the Klamath River; however, no known quantitative or species-specific information about these plants has been collected in the phytoplankton and periphyton Area of Analysis. Since no surveys have been conducted to determine the relative distribution or biomass[100] of large aquatic plants in the Klamath River, they are not discussed further in this section. Wetland and riparian habitat, along with associated plant species, are discussed in Section 3.5 *Terrestrial Resources*.

3.4.2.1 Phytoplankton

A number of different groups of organisms contribute to the phytoplankton communities in the Klamath River and mainstem reservoirs, including diatoms, green algae, and blue-green algae. The composition of the phytoplankton communities shifts seasonally in response to changing temperature, light, and nutrient levels. Phytoplankton form the base of the food web in lakes and reservoirs throughout the world; they are consumed by zooplankton, insects, and some small fish, which are fed upon by larger fish, birds, mammals, and humans. Diatoms and green algae are generally considered to be beneficial components of phytoplankton communities based on their important role supplying nutrients to the food web. When phytoplankton communities reach high concentrations in the water column (e.g., greater than 10 to 15 micrograms per liter [ug/L] of water), the species composition often shifts from the more beneficial green algae species to nuisance blue-green algae species. The shift in species composition can happen quickly (i.e., in days) due to blue-green algae's relatively fast reproductive rates.

At high biomass levels, phytoplankton can create nuisance water quality conditions. A primary driver of nuisance conditions is extreme diel (daily) fluctuations in dissolved oxygen and pH due to the process of photosynthesis (the consumption of carbon dioxide and waste production of oxygen) and cellular respiration (the consumption of oxygen and waste production of carbon dioxide). During daylight hours, phytoplankton use sunlight to conduct photosynthesis, increasing the dissolved oxygen concentrations in water. Photosynthesis stops in the evening when sunlight is not available. During the night, cellular respiration consumes dissolved oxygen and results in decreases in dissolved oxygen concentrations in the water column. During both daylight and evening hours, dead and decaying phytoplankton are consumed by aerobic bacteria, using

[100] The total mass of organisms in a given area or volume.

dissolved oxygen from the water column and at times contributing to decreases in dissolved oxygen levels below those sufficient to support aquatic organisms (e.g., fish). The pH of water fluctuates with daily variations in photosynthesis and respiration. Photosynthesis consumes carbon dioxide in the water, such that when photosynthesis dominates during the day the pH increases. Cellular respiration releases carbon dioxide that, in contact with water, forms carbonic acid, decreasing the pH during the evening. Microbial decomposition of dead phytoplankton can also release free ammonia into the water column as cellular nitrogen is converted into ammonia, especially after a bloom when a high concentration of dead phytoplankton cells is being decomposed. Variations in dissolved oxygen, pH, and ammonia due to phytoplankton are primarily driven by the availability of sunlight and the resulting variations in the amount of photosynthesis and respiration. As more sunlight is available during summer months, there is generally more for photosynthesis at this time of year and a higher potential for larger variations in dissolved oxygen and pH in lakes, reservoirs, and rivers. In addition to dissolved oxygen, pH, and at times ammonia, high concentrations of blue-green algae species, such as *Anabaena flos-aquae* and *Microcystis aeruginosa,* can produce nuisance levels of algal toxins (e.g., anatoxin-a and microcystin) that are harmful to fish, mammals, and humans (see also Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*).

The stable lacustrine[101] environment created by Copco No. 1 and Iron Gate dams, coupled with high nutrient availability and high water temperatures in summer and fall months, provides ideal conditions for phytoplankton growth, especially the growth of blue-green algae species (Figure 3.4-2 and Figure 3.4-3). While cyanobacteria [blue-green algae] can be found in a variety of lake, reservoir, river, and estuarine environments, the cyanobacteria [blue-green algae] species *Anabaena flos-aquae* and *Microcystis aeruginosa* thrive in warm, high nutrient, and stable water column conditions (Konopka and Brock 1978; Kann 2006; Asarian and Kann 2011), where they can out-compete other beneficial algae species such as diatoms and green algae (Visser et al. 2016). While they do not thrive in fast-moving water, diatoms and green algae do not regulate their buoyancy, and thus they rely on mixing in the water column (e.g., from wind, convection, or slow currents) to remain suspended near the water surface where light is available for photosynthesis. In reservoirs with warm water and a stable water column, diatoms and green algae tend to settle out of the water column away from sunlight. Cyanobacteria [blue-green algae] cells contain gas sacs (vesicles[102]), so they can control their buoyancy and remain near the water surface to obtain light for photosynthesis (Walsby et al. 1997). The ability to control their density and position in the water column gives blue-green algae better access to light and they can shade phytoplankton lower in the water column. Thus, blue-green algae are able to outcompete diatoms and/or green algae under lower mixing conditions in reservoirs. *Microcystis aeruginosa* can dominate the phytoplankton community in calm, stable lacustrine conditions, when their ability to float exceeds the rate of turbulent mixing in the water column (Huisman et al. 2004). However, blue-green algae abundance in the phytoplankton community decreases compared to diatoms and green algae when water column mixing in a water body increases (McDonald and Lehman 2013; Visser et al. 2016).

Figure 3.4-3. Blue-green algae bloom along the Copco No. 1 shoreline on 7/13/2005. Source: Kann and Corum 2006.

As discussed above, blooms of floating algae (i.e., phytoplankton) can have negative impacts on water quality related to daily fluctuations in dissolved oxygen, pH, and nutrients such as ammonia. In the Klamath River, nuisance water quality conditions associated with phytoplankton are dominated by blooms of cyanobacteria [blue-green algae] species for both reservoir (Copco No. 1 and Iron Gate) and river portions of the Klamath River, particularly in the summer months (Asarian and Kann 2011; Gibson 2016). Within the phytoplankton and periphyton Area of Analysis, blue-green algae productivity is locally and seasonally associated with extreme daily fluctuations in dissolved oxygen levels (high during the day and low at night), elevated pH (above 8 s.u.), and free ammonia concentrations. Blue-green algae have a high cellular nitrogen content, so microbial decomposition of dead blue-green algae after a bloom can generate a relatively high amount of free ammonia and result in a further decrease in the water column's pH. Multiple reaches of the Klamath River from the Oregon-California state line to the Klamath River Estuary are included on the Clean Water Act (CWA) Section 303(d) list of water bodies with water quality impairments for water temperature, organic enrichment/dissolved oxygen, nutrients, and microcystin concentration (USEPA 2010) (Table 3.2-3). Organic enrichment and dissolved oxygen depressions are particularly problematic during the summer and fall months when water temperatures are relatively high.

Nuisance and/or noxious algal blooms that occur in the phytoplankton and periphyton Area of Analysis are primarily composed of three species of blue-green algae: *Aphanizomenon flos-aquae*, *Anabaena flos-aquae*, and *Microcystis aeruginosa*. While these blue-green algae species are a natural part of aquatic systems in California, including the Klamath River, environmental conditions that favor the growth and bloom of these blue-green algae species have been created by human modifications to the Klamath River (e.g., dams on the Klamath River that form slow-moving or stagnant water and additional inputs of nutrients above natural conditions). Blooms of these blue-green algae species can cause water quality and human health concerns because these species have been associated with the release of algal toxins (State Water Board et al. 2010, updated 2016).

Aphanizomenon flos-aquae

Aphanizomenon flos-aquae is a filamentous (thread-like), nitrogen-fixing cyanobacteria [blue-green algae] that is common in the Klamath Basin, especially in Upper Klamath Lake where it can comprise more than 90 percent of blue-green algae bloom biovolume (Figure 3.4-4 and Figure 3.4-5; Kann 1997; Eldridge et al. 2012). Nitrogen fixation is a cellular process where nitrogen gas in the air is converted into a biologically useful form of nitrogen for cellular growth. *Aphanizomenon flos-aquae* can thus provide its own source of nitrogen for algal growth, giving it a competitive advantage over non-nitrogen fixing algae species when phosphorus is abundant, but nitrogen is not. *Aphanizomenon flos-aquae* accounted for approximately 39 percent of the total phytoplankton biovolume measured between June and November 2007 at 21 sites in the Klamath Basin from the Upper Klamath Lake to Turwar, including Copco No. 1 and Iron Gate reservoirs (Raymond 2008). In a study of phytoplankton abundance at nine reservoir and river sites in the Hydroelectric Reach (i.e., Klamath River upstream of J.C. Boyle Reservoir to Iron Gate Dam), *Aphanizomenon flos-aquae* made up approximately 26 percent of the total phytoplankton biovolume measured in 106 samples collected during 14 sampling events in January and May through December 2009 (Raymond 2010). While members of the *Aphanizomenon* genus have been shown to produce cylindrospermopsin[103] and several neurotoxins in laboratory cultures, they have not been shown to produce microcystin. Thus, while *Aphanizomenon flos-aquae* is commonly found in the Klamath Basin, it is not likely to be the source of microcystin in the Klamath River (Eldridge et al. 2012). Nitrogen fixation by *Aphanizomenon flos-aquae* can provide a new nitrogen source within lakes and rivers when *Aphanizomenon flos-aquae* cells die and decay releasing fixed nitrogen and other nutrients contained in their cells. The additional nitrogen released can provide nutrients for *Microcystis aeruginosa,* potentially promoting *Microcystis aeruginosa* growth later in the season (discussed further below).

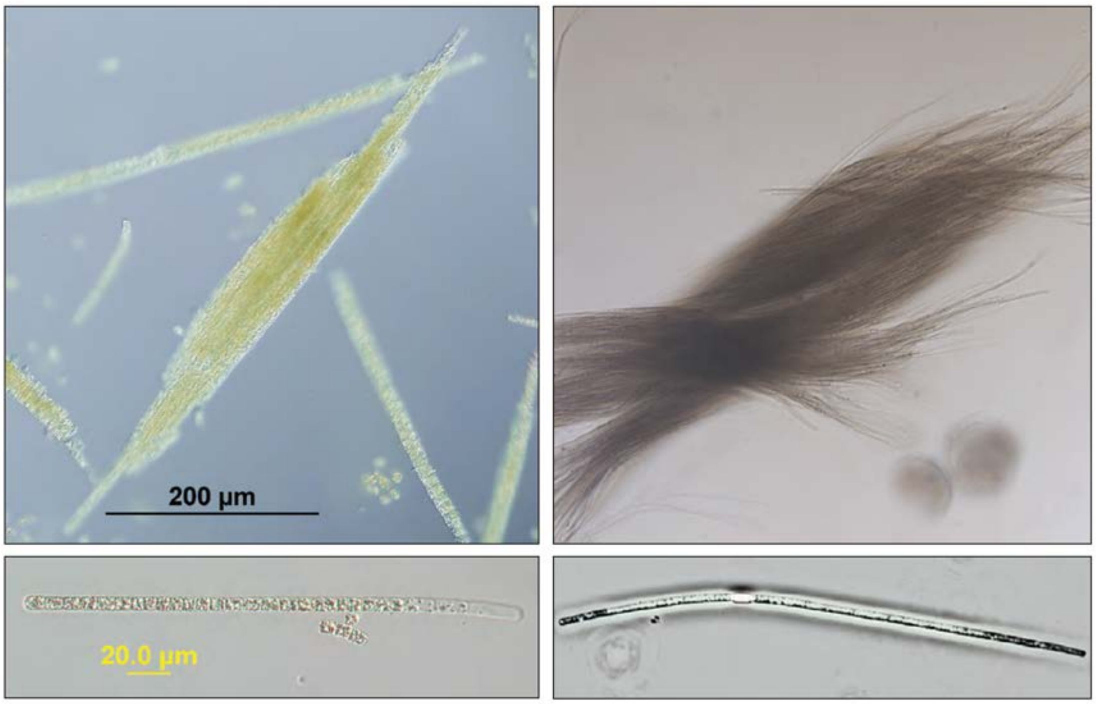

Figure 3.4-4. Microscopic View of *Aphanizomenon flos-aquae* Showing it in Bundles (upper left and right images) and Individual Filaments (lower left and right images). Photographs: Left, Barry H. Rosen; Right, Ann St. Amand. Source: Rosen and St. Amand 2015.

[103] An algal toxin associated with adverse health effects such as gastrointestinal, liver inflammation and hemorrhage, pneumonia, dermatitis, malaise, and long-term liver failure (Lopez et al. 2008). Cylindrospermopsin were only detected near or less than the method detection limit (<0.05 parts per billion) in the Upper Klamath Lake (Eldridge et al. 2012).

Figure 3.4-5. *Aphanizomenon flos-aquae* bloom. Photograph: Jacob Kann. Source: Rosen and St. Amand 2015.

***Anabaena flos-aquae*[104]**

Anabaena flos-aquae is also a filamentous (thread-like) nitrogen-fixing blue-green algae that occurs in the Klamath Basin (Figure 3.4-6; Kann 1997; Eldridge et al. 2012). Similar to *Aphanizomenon flos-aquae, Anabaena flos-aquae* can provide its own source of nitrogen for growth through nitrogen fixation and thus it has a competitive advantage over non-nitrogen fixing phytoplankton species under high phosphorous and low nitrogen conditions in streams or reservoirs. In phytoplankton sampling between June and November 2007, at 21 sites in the Klamath Basin from the Upper Klamath Lake to Turwar, including Copco No. 1 and Iron Gate reservoirs, *Anabaena flos-aquae* occurrence was low (i.e., less than 10 percent of samples). It was primarily found in Copco No. 1 and Iron Gate reservoirs, but it typically had low biovolumes on the order of 10,000 cubic micrometers per milliliter (um^3/mL) (Raymond 2008). In 2009, *Anabaena flos-aquae* comprised approximately 0.2 percent of the total phytoplankton biovolume measured in 106 samples collected during 14 sampling events at nine reservoir and river sites in the Hydroelectric Reach in January and May through December (Raymond 2010). Photographs of an algae bloom composed of primarily *Anabaena flos-aquae* are not available for the Klamath Basin, since it has not been found in isolation and has occurred at such low biovolumes.

Anabaena flos-aquae can produce several types of toxins, including anatoxin-a and microcystin (Lopez et al. 2008). Anatoxin-a is a neurotoxin which can cause irritation,

[104] *Anabaena flos-aquae* was recently renamed *Dolichospermum flos-aquae*. However, this EIR continues to use the *Anabaena* name since it was more frequently used in the literature cited and it is still commonly used in descriptions of this species.

muscle twitching, paralysis, and death. It was detected in September 2005 during one sampling event in Iron Gate Reservoir, at levels ranging from 22 to 34 µg/L (T. Mackie, pers. comm., 2005). Additional details about anatoxin-a concentrations measured in the Klamath River are found in Section 3.2.2.7 *Chlorophyll-a and Algal Toxins* and Appendix C – Section C.6 *Chlorophyll-a and Algal Toxins*. While anatoxin-a has been measured in the Klamath Basin, the extent of anatoxin-a production by *Anabaena flos-aquae* in the Area of Analysis for phytoplankton and periphyton is largely unknown due to the limited sampling to date. Toxin production by some strains of *Anabaena flos-aquae* appears to be sporadic, and the circumstances which prompt toxin production are unknown. While *Anabaena flos-aquae* have also been found to produce the algal toxin microcystin (Lopez et al. 2008), it is widely assumed that the severe blooms of *Microcystis aeruginosa* in the Area of Analysis are responsible for the detected concentrations of microcystin rather than *Anabaena flos-aquae* because the measured biovolume of *Anabaena flos-aquae* is typically much less than the *Microcystis aeruginosa* biovolume. The relative proportion of microcystin contributions from *Anabaena flos-aquae* versus *Microcystis aeruginosa* has not been documented for the Klamath Basin.

Figure 3.4-6. Microscopic view of *Anabaena flos-aquae,* recently renamed *Dolichospermum flos-aquae*. Source: Kudela Lab 2018.

Microcystis aeruginosa

Microcystis aeruginosa is a round- or oval-shaped unicellular, colony-forming cyanobacteria [blue-green algae] (Figure 3.4-7 and Figure 3.4-8; Eldridge et al. 2012). *Microcystis aeruginosa* are not capable of nitrogen fixation, unlike *Aphanizomenon flos-aquae* or *Anabaena flos-aquae*, so this species is dependent on ammonia and other nitrogen sources for growth, and the availability of nitrogen in the water column may limit their occurrence in portions of the Klamath Basin (Eldridge et al. 2012). In phytoplankton sampling conducted in Iron Gate and Copco No. 1 reservoir ranging from 2005 through 2010, *Microcystis aeruginosa* accounted for up to approximately 78 percent of the total phytoplankton biovolume in some samples collected at open water reservoir monitoring stations (Raymond 2008, 2009, 2010; Asarian et al. 2011), suggesting favorable habitat conditions in the reservoirs for this species.

Analysis of blue-green algae species present in the Klamath River from the Upper Klamath Lake to Turwar identified Iron Gate Reservoir as the principal source of *Microcystis aeruginosa* to the Klamath River downstream of Iron Gate Dam. Phytoplankton samples were collected either once or twice a month from April to December 2012 at fifteen sites along the Klamath River, including Copco No. 1 and Iron Gate reservoirs. The types of phytoplankton present were identified and genetic analysis (deoxyribonucleic acid [DNA] sequencing) was performed to identify genetic differences between the blue-green algae populations at the sample sites. Blue-green algae bloom populations at sites upstream of J.C. Boyle Dam were predominantly *Aphanizomenon flos-aquae* with some *Anabaena flos-aquae* (*Dolichospermum flos-aquae*) and a small amount of *Microcystis aeruginosa* present, but blue-green algae bloom populations in Copco No. 1 and Iron Gate reservoirs were primarily *Microcystis aeruginosa* and *Aphanizomenon flos-aquae*. *Microcystis aeruginosa* cells were present in low concentrations upstream of Copco No. 1 Reservoir, suggesting the majority of *Microcystis aeruginosa* cells in Copco No. 1 and Iron Gate reservoirs grew in the reservoirs and they were not transported into the reservoirs from upstream. Genetic analysis of the *Microcystis aeruginosa* populations showed Copco No. 1 Reservoir populations were dominated by one genetic type the entire year, but the *Microcystis aeruginosa* populations in Iron Gate Reservoir and immediately downstream of Iron Gate Dam had a simultaneous change in the dominant genetic type in late August. The genetic change was also detected in the *Microcystis aeruginosa* populations in the Klamath River downstream of Iron Gate Dam. The simultaneous timing of the genetic change in Iron Gate Reservoir and downstream *Microcystis aeruginosa* populations, but no corresponding genetic change in Copco No. 1 Reservoir, provides direct evidence that downstream river populations are originating in Iron Gate Reservoir rather than Copco No. 1 Reservoir or locations farther upstream (Otten et al. 2015).

Blooms of *Microcystis aeruginosa* are of particular concern since this species is known to produce the algal toxin microcystin, a hepatotoxin that affects liver function in animals and humans (State Water Board et al. 2010, updated 2016; OEHHA 2012). In humans, exposure to microcystin has been documented to cause abdominal pain, headache, sore throat, vomiting, nausea, dry cough, diarrhea, blistering around the mouth, pneumonia, muscle weakness, and acute liver failure (OEHHA 2012) (see also Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*). Studies suggest that the presence of toxin producing *Microcystis aeruginosa* blooms could result in acute (short-term) and chronic (long-term) effects on fish including increased mortality, reduced fertility, reduced feeding, and habitat avoidance (Interagency Ecological Program 2007; Fetcho 2008, 2009; CH2M Hill 2009; Teh et al. 2010; Kann et al. 2013) (see also Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Project*).

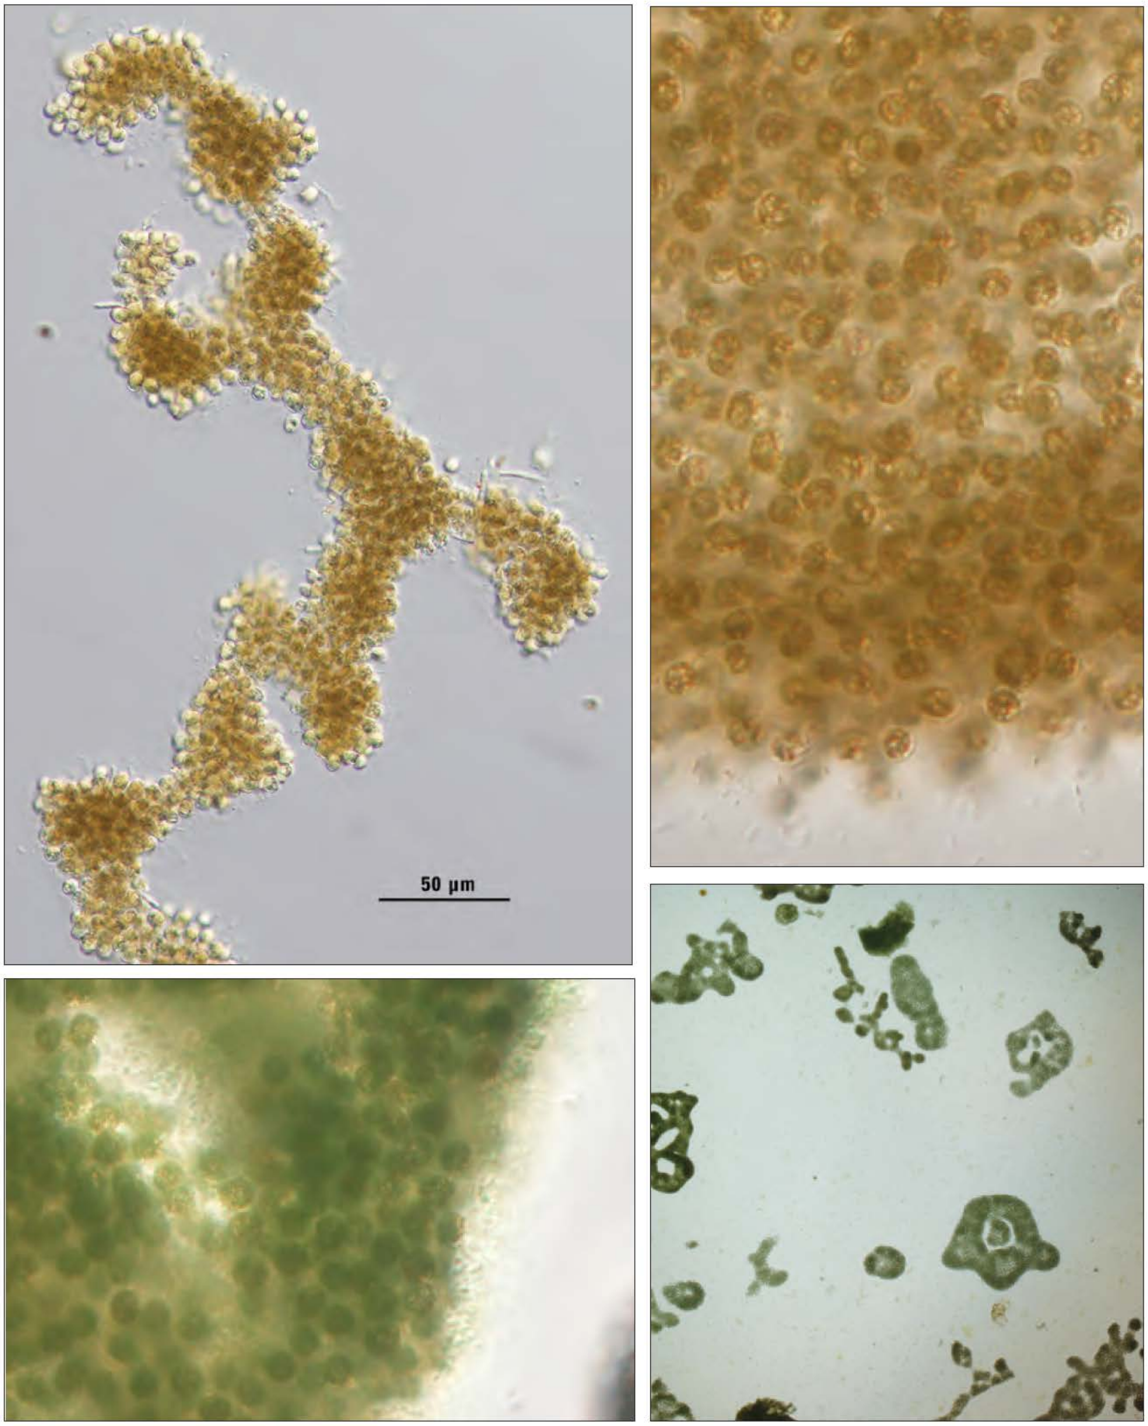

Figure 3.4-7. Microscopic views of *Microcystis aeruginosa*. Photographs: Barry H. Rosen. Source: Rosen and St. Amand 2015.

Figure 3.4-8. Blue-green algae *Microcystis aeruginosa* bloom. Photograph: Susan Corum. Source: Stillwater Sciences et al. 2013.

Algal blooms of nitrogen-fixing *Aphanizomenon flos-aquae* and *Anabaena flos-aquae* early in the year (spring) can supply a new nitrogen source to lakes or reservoirs, potentially promoting *Microcystis aeruginosa* growth later in the year (summer and fall) (FERC 2007; Eldrige et al. 2012; Otten et al. 2015). As blooms of *Aphanizomenon flos-aquae* and *Anabaena flos-aquae* die and decay, fixed nitrogen in their cells is released and becomes a source of nitrogen for *Microcystis aeruginosa*, which cannot fix nitrogen from the atmosphere. Studies of cyanobacteria [blue-green algae] dynamics in 2009 in the Upper Klamath Lake report a low initial *Microcystis aeruginosa* population followed by an increase after a major decline in an *Aphanizomenon flos-aquae* bloom. The *Microcystis aeruginosa* population continued to increase rapidly during a second *Aphanizomenon flos-aquae* bloom, suggesting that these two species can coexist (Eldridge et al. 2012).

Cyanobacteria [Blue-green Algae] Thresholds and Guidelines

Thresholds and guidelines for cyanobacteria [blue-green algae] densities (in cells/mL) and algal toxin concentrations (in µg/L) that are protective of human health have been established and are occasionally updated (see also Section 3.2.3.1 *Thresholds of Significance*). The World Health Organization (WHO) specifies for safe recreational water contact (not drinking water) a cell density of less than 20,000 cells/mL for cyanobacteria [blue-green algae] species and a microcystin concentration of less than 4 µg/L for a relatively low probability of adverse human health effects during recreational water contact (Falconer et al. 1999). The California Cyanobacteria and Harmful Algal Bloom (CCHAB) Network, composed of various entities with expertise, including the State Water Board, the California Department of Public Health (CDPH), the California Environmental Protection Agency Office of Environmental Health and Hazard Assessment (OEHHA), Native American tribes, and reservoir managers has established thresholds and guidance for the cyanobacteria [blue-green algae] cell densities and cyanotoxin [algal toxin] concentrations for the protection of human health in recreational waters. The 2010 CCHAB thresholds (also referred to as the SWRCB/OEHHA Public Health Thresholds or the California Health Thresholds) recommended posting a health advisory warning sign[105] if the *Microcystis aeruginosa* cell density was greater than or equal to 40,000 cells/mL, the potentially toxigenic[106] cyanobacteria [blue-green algae] species cell density was greater than or equal to 100,000 cells/mL, or the microcystin concentration was greater than or equal to 8 ug/L. The 2016 CCHAB thresholds revised the 2010 CCHAB thresholds and specified primary and secondary threshold triggers for posting health advisories for recreational water contact (Table 3.4-1). The 2016 CCHAB thresholds are 4,000 cells/mL for total potentially toxigenic cyanobacteria [blue-green algae] species cell density and 0.8 ug/L for microcystin concentration, which are approximately one to two orders of magnitude less than the 2010 CCHAB thresholds (State Water Board et al. 2010, updated 2016).

Table 3.4-1. 2016 California Cyanobacteria Harmful Algal Bloom (CCHAB) Trigger Levels for Human Health.

Trigger Level	Primary Triggers[1]			Secondary Triggers	
	Total Microcystins (ug/L)	Anatoxin-a (ug/L)	Cylindrospermopsin (ug/L)	Total Potentially Toxigenic Cyanobacteria [Blue-green Algae] Species (cells/mL)	Site Specific Indicators of Cyanobacteria [Blue-green Algae]
Caution Action	0.8	Detection[2]	1	4,000	Blooms, scums, mats, etc.
Warning TIER I	6	20	4	-	-
Danger TIER II	20	90	17	-	-

Source: (State Water Board et al. 2010, updated 2016)
[1] Primary triggers are met when ANY toxin exceeds criteria.
[2] Must use an analytical method that detects less than or equal to 1 ug/L anatoxin-a.

[105] The advisory signs communicate to the public the potential risk of exposure to algal toxins in the associated waterbody and contain information about how to avoid or minimize the risk. The advisory signs include: "Caution – Harmful algae may be present in this water"; "Warning – Toxins from algae in this water can harm people and kill animals"; "Danger – Toxins from algae in this water can harm people and kill animals" (California Water Quality Monitoring Council 2018).
[106] Potentially toxigenic cyanobacteria [blue-green algae] that have been detected in California include those of the genera *Anabaena*, *Microcystis*, *Aphanizomenon*, *Planktothrix*, and *Gloeotrichia*.

The Hoopa Valley Tribe surface-water objectives are less than 100,000 cells/mL for total potentially toxigenic cyanobacteria [blue-green algae] species for recreational waters, less than 5,000 cells/mL *Microcystis aeruginosa* for drinking water, less than 40,000 cells/mL *Microcystis aeruginosa* for recreational water, and no cyanobacterial [blue-green algae] scums (see also Table 3.2-6). The Hoopa Valley Tribe surface-water objectives for algal toxins specify total microcystins less than 1 ug/L for drinking water and total microcystins less than 8 ug/L for recreational water (HVTEPA 2008). Similarly, the Yurok Tribe guidelines include posting "caution" public health advisories[105] when toxigenic blue-green algae species, *Microcystis aeruginosa*, or microcystin is detected; "warning" public health advisories when toxigenic blue-green algae species are greater than or equal to 100,000 cells/mL, *Microcystis aeruginosa* is greater than or equal to 1,000 cells/mL, or microcystin is greater than or equal to 0.8 ug/L; and "danger" public health advisories when toxigenic blue-green algae species are greater than or equal to 500,000 cells/mL, *Microcystis aeruginosa* is greater than or equal to 5,000 cells/mL, or microcystin is greater than or equal to 4.0 ug/L (see also Table 3.2-10; YTEP 2016).

Frequent exceedances of the cyanobacteria [blue-green algae] density and/or algal toxin concentration thresholds and guidelines have occurred since 2004 in the Lower Klamath Project reservoirs (Kann 2006) and since 2007 in the Middle and Lower Klamath River and the Klamath River Estuary (Chorus and Bartram 1999; Fetcho 2006, 2007, 2008; Kann 2008; Kann and Corum 2009; YTEP 2014, 2015; Genzoli and Kann 2016, 2017; Gibson 2016). The Klamath River from the upstream end of Copco No. 1 Reservoir to the Klamath River's confluence with the Trinity River is included in the CWA Section 303(d) list as impaired for microcystin due to regular exceedances of the established microcystin thresholds and water quality objectives (see also Table 3.2-3, Section 3.2.2.7 *Chlorophyll-a and Algal Toxins,* Potential Impact 3.2-12*,* Appendix C – Section C.6 *Chlorophyll-a and Algal Toxins*). Detailed discussion of phytoplankton communities by reach is presented below in Section 3.4.2.3 *Hydroelectric Reach* through Section 3.4.2.6 *Pacific Ocean nearshore environment*.

3.4.2.2 Periphyton

Periphyton are generally dominated by diatoms and green algae. Cyanobacteria [blue-green algae] can also occur in the periphyton community, but they are typically a small component of the community and do not reach nuisance levels (Asarian et al. 2014, 2015). Like phytoplankton in lakes and reservoirs, periphyton are important components of the base of the food web in riverine systems. Periphyton can also play an important role in riverine water quality, affecting nutrient cycling and resulting in diel (24-hour cycle) fluctuations in dissolved oxygen and pH (Anderson and Carpenter 1998, Kuwabara 1992, Tanner and Anderson 1996). Excessive swings in dissolved oxygen and pH can be stressful to aquatic biota, such that too much periphyton can adversely affect designated beneficial uses related to fish and other aquatic organisms (State Water Board 2001; HVTEPA 2008; North Coast Regional Board 2011). Monitoring at multiple locations along the Middle and Lower Klamath River indicates that dissolved oxygen and pH patterns over a 24-hour period are driven primarily by photosynthesis and respiration of periphyton (Ward and Armstrong 2010, Asarian et al. 2015). The repeatable and consistent diel cycling of dissolved oxygen is characteristic of a stream metabolism that is dominated by periphyton photosynthesis and respiration (Odum 1956). However, free-floating algae transported through the system likely exert some influence on the dissolved oxygen signal in the Klamath River, as does the oxygen demand from decaying organic matter (e.g., bacteria, algae, plant litter) exported from upstream Klamath River reservoirs (PacifiCorp 2006; FERC 2007).

Documented algae species in the Klamath River periphyton community include nuisance filamentous (thread-like) green algae species such as *Cladophora* sp. (FERC 2007), which can form dense mats in some places in the Lower Klamath River. These mats tend to be patchy and occur in lower velocity areas. They are not a dominant feature of the Klamath River, but in some locations they are an important habitat for the polychaete worm (*Manayunkia speciose*) that is the intermediate host of the fish parasites *Ceratomyxa shasta* and *Parvicapsula minibicornis* (Figure 3.4-9). The factors influencing periphyton abundance and community composition are complex and include physical factors such as nutrients, substrate, flow velocity, shading, light availability, and water temperature (Biggs 2000), as well as ecological factors (such as macroinvertebrate grazing) that interact with the physical factors (Power et al. 2008). The Lower Klamath Project dams influence the abundance of periphyton by altering the nutrient availability, riverbed substrate, flow, light availability, and water temperature in the Klamath River (NMFS 2010; NMFS and USFWS 2013; Alexander et al. 2016; Gillett et al. 2016). Analysis and modeling of pre- and post-Klamath Irrigation Project hydrology indicates that operation of the Klamath Irrigation Project upstream of the Lower Klamath Project dams has altered Klamath River flows by increasing flows in October and November, decreasing flows in the late-spring and summer, and decreasing the peak flows (NMFS and USFWS 2013). As a result of upstream Klamath Irrigation Project operations, the Klamath River peak flows downstream of Iron Gate Dam are less frequent, resulting in less frequent high-velocity flows that would scour streambed sediments downstream of the dam. In addition to lower peak flows, the Lower Klamath Project dams trap sediment behind the dams and reduce the availability of fine sediments downstream that can be transported at lower flows, leading to streambed armoring and less frequent scouring events that disturb the streambed. Reduced scouring frequency along with higher fall water temperatures, promote dense growth of periphyton. Additionally, operation of the upstream Klamath Irrigation Project results in flow modifications downstream of the Lower Klamath Project dams that alters the light availability for periphyton on the streambed, with lower flows generally decreasing water depth and increasing light penetration to the streambed for periphyton photosynthesis. These conditions favor proliferation of polychaete worm habitat and subsequent infection of fish by parasites (NMFS 2010; NMFS and USFWS 2013; Alexander et al. 2016) (see also Figure 3.4-8 [parasite life cycle]). Overall, data regarding the distribution, community composition, and biomass of periphyton in the Area of Analysis for phytoplankton and periphyton are limited.

Figure 3.4-9. Lifecycle of *Ceratomyxa shasta*. Source: NMFS 2012.

3.4.2.3 Hydroelectric Reach

Phytoplankton

Phytoplankton dynamics in the Hydroelectric Reach can be influenced by upstream conditions, so the following briefly discusses phytoplankton conditions from the Upper Klamath Lake to the Hydroelectric Reach before detailing the conditions within the Hydroelectric Reach. In the Upper Klamath Lake, the mean total phytoplankton biomass annually increases from relatively low concentrations ranging from less than 5 mg/L wet weight to approximately 15 mg/L wet weight per data collected between 1990 and 1996 in winter and spring (January to May) to peak concentrations ranging from approximately 30 mg/L wet weight to 60 mg/L wet weight per data collected between 1990 and 1996 in summer to fall (June to October), before decreasing to relatively low concentrations again in late fall/early winter (November to December) (Kann 1997). In addition to the seasonal change in total phytoplankton biomass, the phytoplankton community also has an annual seasonal shift from diatom-dominated communities in spring (Kann 1997; ODEQ 2002; Sullivan et al. 2009) to blue-green algae-dominated communities in summer and fall (Eilers et al. 2004; FERC 2007; Eldridge et al 2012). Phytoplankton biovolume in summer and fall is dominated by blue-green algae blooms comprised primarily of *Aphanizomenon flos-aquae*, but also includes *Anabaena flos-aquae* and *Microcystis aeruginosa* (Eilers et al. 2004; FERC 2007; Eldridge et al. 2012). Data from 2009 indicate concentrations of *Microcystis aeruginosa* in the Upper Klamath Lake are typically low during the early part of the calendar year, but concentrations increase later in the year following the decline of large blue-green algae blooms dominated by *Aphanizomenon flos-aquae* (Eldridge et al. 2012). *Microcystis aeruginosa* is believed to be responsible for the production of microcystin in the Upper Klamath Lake, which has exceeded the WHO guidelines for drinking water (1 ug/L) and safe recreational water contact (4 ug/L) with annual peaks in 2007 to 2009 between 1.6 and 24.4 ug/L (VanderKooi et al. 2010; Eldridge et al. 2012).

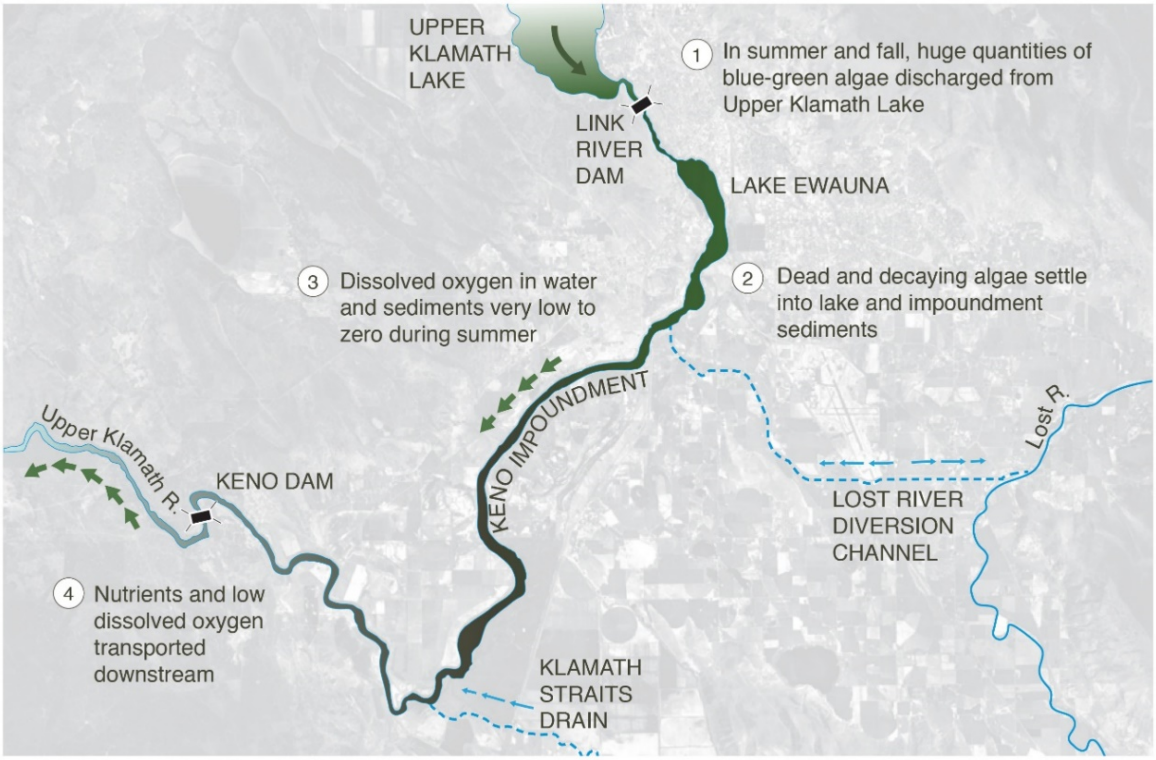

Figure 3.4-10. Blue-green algae transport from the Upper Klamath Lake into the Upper Klamath River. Blue-green algae do not completely die and settle out in the Keno Impoundment, with some blue-green algae exported into the Upper Klamath River downstream of Keno Dam. Source: Stillwater Sciences et al. 2013.

Phytoplankton patterns from the Link River downstream to Keno Dam are driven by blooms that originate in Upper Klamath Lake and are transported into this reach (Figure 3.4-10), with the phytoplankton community varying seasonally and reflecting the community present in the Upper Klamath Lake. In 2008, a total of 141 algae species were identified in the reach from Link River downstream to Keno Dam, with *Aphanizomenon flos-aquae* having the highest average density (61 percent) when present. In spring, 56 percent of the total phytoplankton biovolume was composed of diatoms, with blue-green algae making up only 24 percent the total phytoplankton biovolume. The remainder of the total phytoplankton biovolume was composed of other types of phytoplankton. In summer and fall, the phytoplankton community composition shifted to being primarily comprised of blue-green algae (76 to 80 percent of total phytoplankton biovolume), with diatoms (7 to 15 percent) and other phytoplankton (4 to 10 percent) making up the remainder of the total phytoplankton biovolume (Sullivan et al. 2009). Phytoplankton biovolume generally decreases in the Klamath River with distance downstream of Upper Klamath Lake, with the greatest median decrease in this reach occurring between the Upper Klamath Lake (at Pelican Marina/Fremont Street Bridge) and Link River (Figure 3.4-11; Raymond 2005; Kann and Asarian 2006; Sullivan et al. 2009). In Lake Ewauna and the Keno Impoundment, phytoplankton concentrations are observed to decrease, which is attributed to dead and decaying phytoplankton, especially blue-green algae, settling out of the water column and forming lake and impoundment sediments (Deas and Vaughn 2006; Stillwater Sciences et al. 2013; ODEQ 2017).

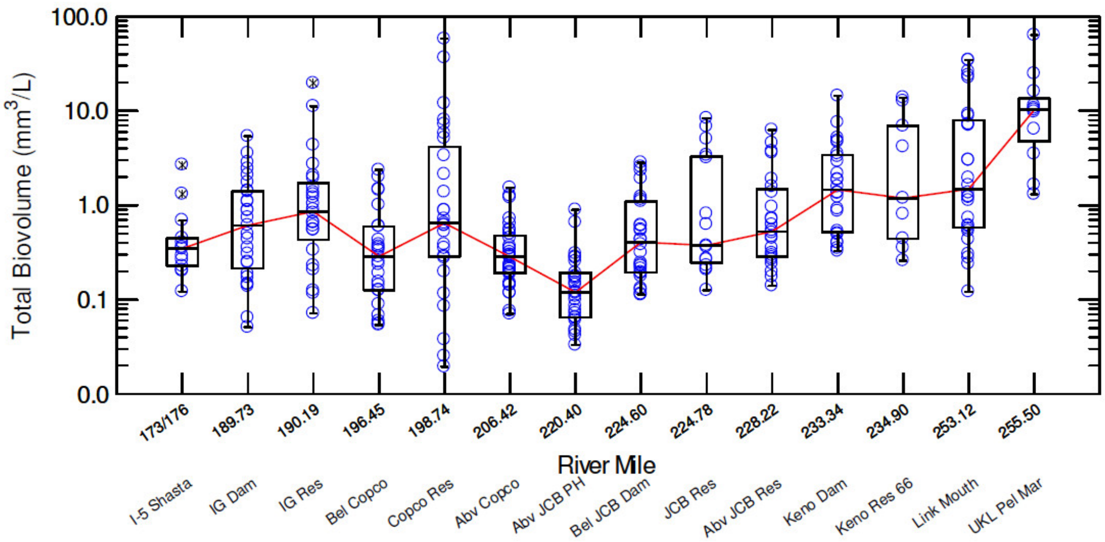

Figure 3.4-11. Total phytoplankton biovolume in mm^3/L from June 1 to September 30 for the years 2001 to 2004. River miles associated with Klamath River features are based on the river miles in 2006 and differ slightly from current river miles in this EIR. Station definitions: UKL Pel Mar = Upper Klamath River at Pelican Marina; Link Mouth = Link River at Mouth; Keno Res 66 = Klamath River at Hwy 66 Keno Bridge; Keno Dam = Keno Dam outflow; Abv JCB Res = Klamath River upstream of J.C. Boyle Reservoir; JCB Res = J.C. Boyle Reservoir at log boom; Bel JCB Dam = Klamath River downstream of J.C. Boyle Dam; Abv JCB PH = Klamath River upstream of the J.C. Boyle Powerhouse; Abv Copco = Klamath River upstream of Shovel Creek; Copco Res = Copco No. 1 Reservoir; Bel Copco = Klamath River downstream of Copco No. 2 Powerhouse; IG Res = Iron Gate Reservoir near dam; IG Dam = Klamath River downstream of Iron Gate Dam; I-5 Shasta = Klamath River at I-5 Rest Area and Klamath River upstream of Shasta River. Source: modified from Kann and Asarian 2006.

Phytoplankton abundance, including abundance of blue-green algae, generally decreases in the Klamath River with distance downstream of Keno Dam to upstream of Copco No. 1 Reservoir (Figure 3.4-11; Kann and Asarian 2006; Kann and Corum 2009; Asarian and Kann 2011; Watercourse Engineering, Inc. 2016). In this reach, turbulent mixing and higher water velocities that constitute unfavorable growing conditions and break apart phytoplankton cells, and cold groundwater-fed springs in the J.C. Boyle Bypass Reach that add flow and cool the river creating less favorable water temperatures for growth, result in decreasing phytoplankton concentrations and associated algal toxins (i.e., microcystin) between Keno Dam and the upstream end of Copco No. 1 Reservoir (see also Section 3.2.2.7 *Chlorophyll-a and Algal Toxins* and Appendix C – Section C.6.1 *Upper Klamath Basin*). Additionally, the proportion of the phytoplankton community composed of diatoms increases relative to blue-green algae between Keno Dam and the upstream end of Copco No. 1 Reservoir (Kann and Asarian 2006).

Measurements of *Microcystis aeruginosa* abundance (measured by biovolume) between 2001 and 2004 also show a decreasing trend from Upper Klamath Lake to upstream of Copco No. 1 Reservoir (Figure 3.4-12). Individual measurements for *Microcystis aeruginosa* taken during this period are represented by circles (o) in Figure 3.4-12, but the circles overlap and appear as a single circle when multiple measurements have the same value (e.g., multiple non-detect results for sites appear as a single circle at zero along the x-axis). Box and whisker features showing the statistical trends (e.g., 25 to 75 percent of measurements occur within the biovolume range encompassed by the box) are shown for most sites, but these box and whisker features cannot be seen for sites with primarily non-detect results for *Microcystis aeruginosa* (i.e., biovolume equal to zero) because they are compressed at the x-axis. While there were eight detections (44 percent of measurements) of *Microcystis aeruginosa* in the Keno Impoundment/Lake Ewauna, no *Microcystis aeruginosa* was detected in 24 samples collected between the Keno Dam outflow and the Klamath River site upstream of J.C. Boyle Reservoir. At sites from J.C. Boyle Reservoir to the Klamath River site upstream of Copco No. 1 Reservoir, there were one to two detections (5 to 15 percent of measurements) per site in the July to October period (Kann 2006).

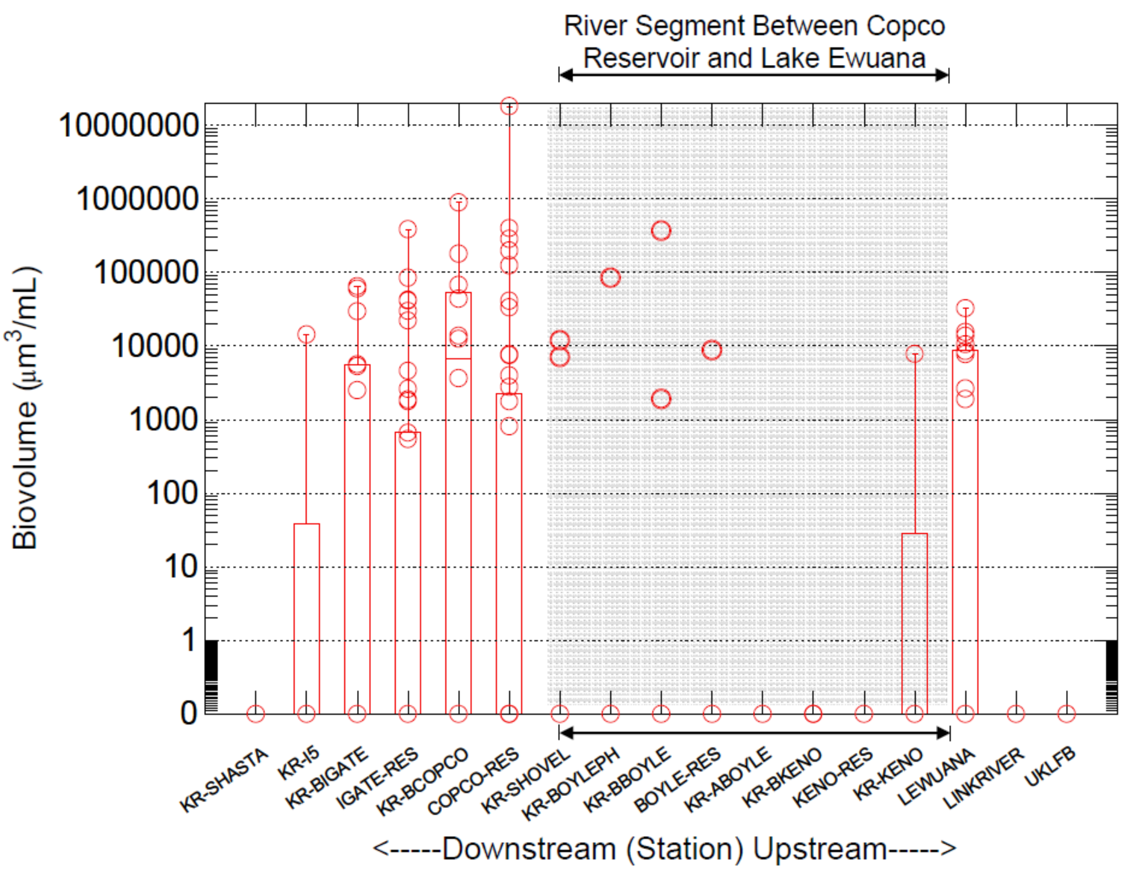

Figure 3.4-12. *Microcystis aeruginosa* biovolume in um^3/mL from July to October for the years 2001 to 2004. No *Microcystis aeruginosa* were detected before July or after October. Station definitions: UKLFB = Upper Klamath Lake at Fremont St. Bridge; LINKRIVER = Link River at mouth; LEWUANA = Lake Ewauna; KR-KENO = Klamath River upstream of Keno Reservoir; KENO-RES = Keno Reservoir; KR-BKENO = Klamath River downstream of Keno Reservoir; KR-ABOYLE = Klamath River upstream of J.C. Boyle Reservoir; BOYLE-RES = J.C. Boyle Reservoir; KR-BBOYLE = Klamath River downstream of J.C. Boyle; KR-BOYLEPH = Klamath River upstream of J.C. Boyle Powerhouse; KR-SHOVEL = Klamath River upstream of Shovel Creek; COPCO-RES = Copco No. 1 Reservoir; KR-BCOPCO = Klamath River downstream of Copco No. 2 Powerhouse; IGATE-RES = Iron Gate Reservoir; KR-BIGATE = Klamath River downstream of Iron Gate Dam; KR-I5 = Klamath River at I-5 Rest Area; KR-SHASTA = Klamath River upstream of Shasta River. Individual measurements are represented by circles (o), with overlapping circles appearing as a single circle when multiple measurements have the same value. Box and whisker features cannot be seen for sites with primarily non-detect results for *Microcystis aeruginosa* (i.e., biovolume equal to zero) because they are compressed at the x-axis. Source: Kann 2006.

The decreasing riverine trend with respect to algal cell concentration in the Hydroelectric Reach is interrupted by large summer and fall blooms of cyanobacteria [blue-green algae] in Copco No. 1 and Iron Gate reservoirs (Kann and Asarian 2006; Raymond 2008, 2009, 2010; Asarian et al. 2009; Asarian and Kann 2011; Otten et al. 2015; Watercourse Engineering, Inc. 2016; Otten and Dreher 2017). In these two reservoirs, a bloom of diatoms generally occurs in spring to early summer, followed by a period of low chlorophyll-*a* concentrations (FERC 2007; Raymond 2008, 2009, 2010; Asarian and Kann 2011) (see also Appendix C – Section C.6.1.1 *Hydroelectric Reach*). Large phytoplankton blooms occur in the reservoirs in mid-summer, dominated by *Aphanizomenon flos-aquae,* which are then followed by a late-summer or early-fall bloom of toxigenic *Microcystis aeruginosa* (Kann 2006; FERC 2007; Raymond 2008, 2009, 2010; Asarian and Kann 2011; Eldridge et al. 2012; Otten et al. 2015; Otten and Dreher 2017). During the late-season *Microcystis aeruginosa* bloom, this species typically constitutes a higher proportion of the overall algal biomass in Copco No. 1 and Iron Gate reservoirs than it does in blooms occurring in Upper Klamath Lake (Kann and Asarian 2006; Raymond 2008, 2009, 2010; Asarian and Kann 2011; Eldrige et al. 2012; Otten et al. 2015). Recent data from August and September 2012 using genetic analysis of the cyanobacteria [blue-green algae] community dynamics further confirms these trends in the Klamath River and its reservoirs. In Upper Klamath Lake in both August and September 2012, *Aphanizomenon flos-aquae* made up more than 75 percent of the blue-green algae population, while *Microcystis aeruginosa* was less than 1 percent. During that same time period, the cyanobacteria [blue-green algae] community composition shifted in Copco No. 1 and Iron Gate reservoirs from greater than approximately 90 percent *Aphanizomenon flos-aquae* and less than approximately 5 percent *Microcystis aeruginosa* (August 2012) to approximately 10 to 45 percent *Aphanizomenon flos-aquae* and approximately 50 to 90 percent *Microcystis aeruginosa* (September 2012). The remaining cyanobacteria [blue-green algae] community in Upper Klamath Lake, Copco No. 1 Reservoir, and Iron Gate Reservoir during this time was primarily comprised of *Anabaena flos-aquae* (*Dolichospermum flos-aquae*) (Otten et al. 2015).

Copco No. 1 and Iron Gate reservoirs provide ideal habitat conditions for the proliferation of large seasonal blooms of *Microcystis aeruginosa*, which subsequently become the source of *Microcystis aeruginosa* to the Middle and Lower Klamath River. This pattern is robust and repeatable in most years. Figure 3.4-2, modified from Kann and Asarian (2007), illustrates the pattern in 2005. At the Klamath River station, just upstream of Copco No. 1 Reservoir ("KRAC" in Figure 3.4-2), *Microcystis aeruginosa* was never detected during multiple summer samplings; however, nitrogen-fixing blue-green algae such as *Aphanizomenon flos-aquae* were detected at KRAC during that period (Kann and Asarian 2007). During the same period, blooms of *Microcystis aeruginosa* within the reservoirs (Copco No. 1 Reservoir stations CR02 and CR01 and Iron Gate Reservoir stations IR03 and IR01) were pronounced. Among all reservoir samplings in 2005, *Microcystis aeruginosa* comprised 20 to 60 percent of sample biovolume and during some periods it was 60 to 100 percent of sample biovolume, particularly in Iron Gate Reservoir. Significant export of the *Microcystis aeruginosa* bloom from Iron Gate Reservoir to downstream reaches of the Klamath River is evident by the relatively high biovolume observed at the river station downstream from Iron Gate Dam (KRBI). Nearly identical patterns were documented for other years, such as 2006 (Kann and Corum 2007), 2008 (Kann and Corum 2009), 2012 (Otten et al. 2015), and 2015 (Watercourse Engineering, Inc. 2016), as well as patterns aggregated over longer time periods such as 2001 to 2004 (Kann 2006), 2005 to 2011 (Asarian and Kann 2011) demonstrating the repeatable nature of this phenomenon.

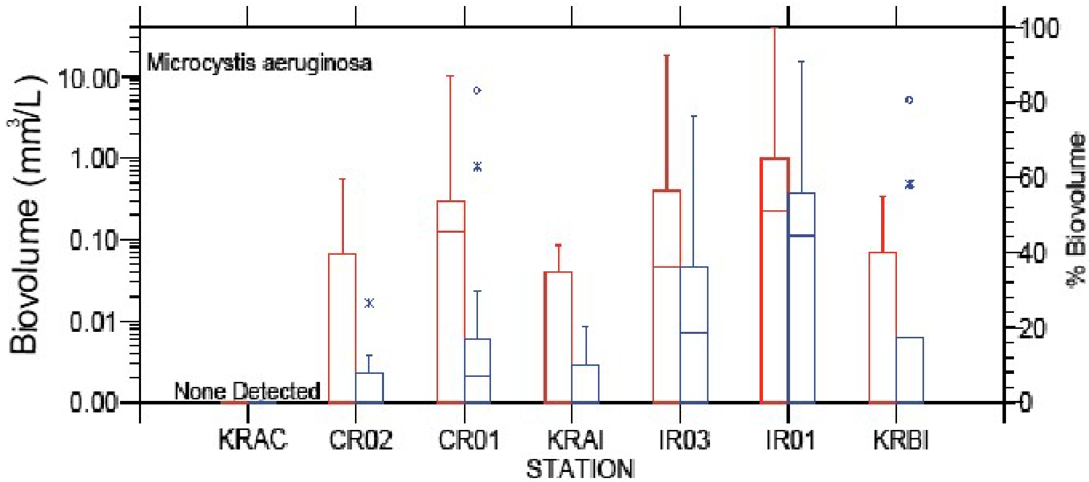

Figure 3.4-13. Biovolume (in red) and percent biovolume (in blue) of *Microcystis aeruginosa* above, within, and downstream from Copco No. 1 and Iron Gate reservoirs during 2005. Station definitions: KRAC = Klamath River upstream of Copco No. 1 Reservoir; CR01 = Copco No. 1 Reservoir Station 1; CR02 = Copco No. 1 Reservoir Station 2; KRAI = Klamath River upstream of Iron Gate Reservoir; IR03 = Iron Gate Reservoir Station 3; IR01 = Iron Gate Reservoir Station 1; KRBI = Klamath River downstream of Iron Gate Reservoir. Source: modified from Kann and Asarian (2007).

As previously noted in Section 3.4.2.1 *Phytoplankton*, genetic analysis of the *Microcystis aeruginosa* in Copco No. 1 Reservoir, Iron Gate Reservoir, and multiple Klamath River sites downstream of Iron Gate Dam also identified Iron Gate Reservoir as the principal source of *Microcystis aeruginosa* to the Klamath River downstream of Iron Gate Dam (Otten et al. 2015). In 2012, measured *Microcystis aeruginosa* at sites in the Klamath River and its reservoirs was comprised of two distinct genetic types (SNP 131-A and SNP 131-G) of *Microcystis aeruginosa.* These two genetic types were either not detected (Upper Klamath Lake) or infrequently detected upstream of Copco No. 1 Reservoir. In Copco No. 1 Reservoir, SNP 131-A was the dominant type (i.e., highest relative proportion) of *Microcystis aeruginosa* throughout the measurement period from June to December 2012. The dominant genetic type varied in Iron Gate Reservoir and downstream Klamath River sites, with a shift from SNP 131-A to SNP 131-G in July and August, followed by another change from SNP 131-G back to SNP 131-A in September (Figure 3.4-14). Both shifts in the dominant genetic type at Iron Gate Reservoir and downstream Klamath River sites occurred simultaneously without a corresponding genetic shift in Copco No. 1 Reservoir. This provides direct evidence that in 2012 downstream populations originated in Iron Gate Reservoir rather than Copco No. 1 Reservoir or further upstream (Otten et al. 2015).

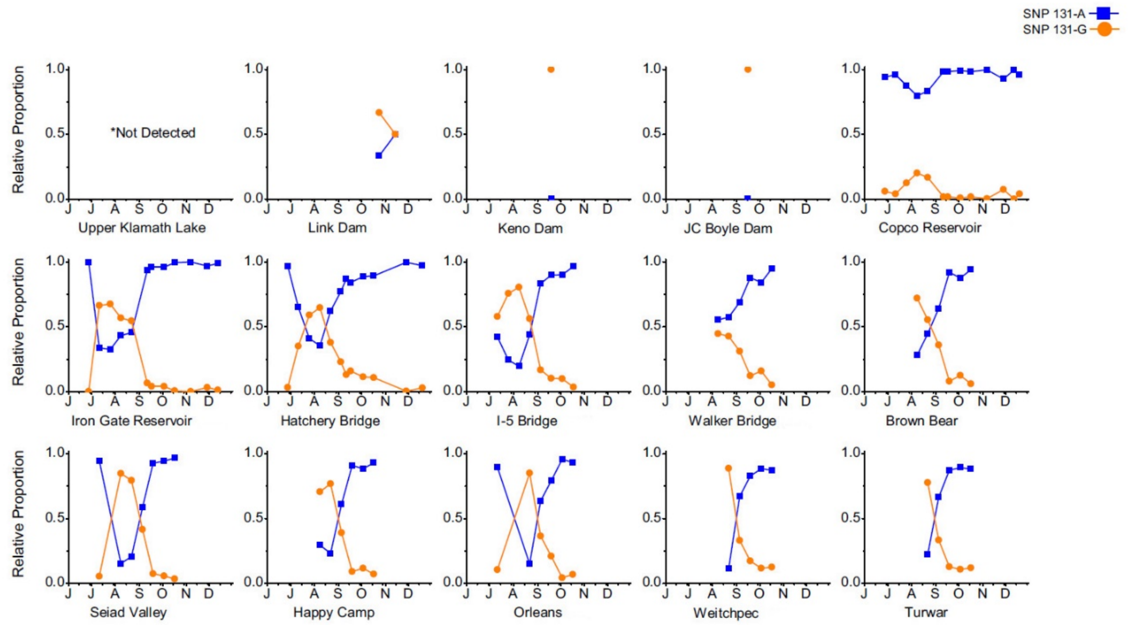

Figure 3.4-14. Relative proportion of the *Microcystis aeruginosa* population comprised of two *Microcystis aeruginosa* genetic types (SNP 131-A and SNP 131-G) at sites in the Klamath River and reservoirs. Relative proportion ranges from 1.0 (100 percent) to 0.0 (0 percent). The month is specified using the first letter of the month starting from June. Source: modified from Otten et al. 2015.

As illustrated Figure 3.4-12 and Figure 3.4-14, the main supply of *Microcystis aeruginosa* was not from sources upstream of Copco No. 1 Reservoir (i.e., Upper Klamath Lake), but instead most likely originated within Iron Gate Reservoir and continued downstream. Although some colonies of *Aphanizomenon flos-aquae* and *Microcystis aeruginosa* are transported into the Hydroelectric Reach from upstream sources, the low detection of *Aphanizomenon flos-aquae* and *Microcystis aeruginosa* at the monitoring sites upstream of Copco No. 1 Reservoir indicate that *Aphanizomenon flos-aquae* and *Microcystis aeruginosa* are primarily generated within Copco No. 1 and Iron Gate reservoirs (Asarian and Kann 2011; Otten et al. 2015). Additionally, the genetic and toxin analyses show that the *Microcystis aeruginosa* populations in Copco No. 1 and Iron Gate reservoirs are genetically distinct, providing evidence that blooms in Iron Gate Reservoir are internally derived and not due to transport of *Microcystis aeruginosa* populations from Copco No. 1 Reservoir or further upstream (Otten et al. 2015).

The documented presence of algal toxins in water and fish tissue in the Hydroelectric Reach corresponds with spatial and temporal patterns in the distribution of blue-green algae blooms within the reach. Recent data indicate that microcystin is undetectable or at very low levels in the Upper Klamath River at the upstream entrance to the Hydroelectric Reach, but microcystin increases through the reach as water is impounded in Copco No. 1 and Iron Gate reservoirs. The reservoirs create ideal growing conditions for toxigenic blue-green algae (calm, stable lacustrine conditions with bioavailable nutrients), regularly resulting in high microcystin concentrations from approximately July through October (Kann and Corum 2006, 2009; Asarian and Kann 2011; Otten et al. 2015; Watercourse Engineering, Inc. 2016; Otten and Dreher 2017). The CCHAB Network, consisting of the State Water Board, CDPH, OEHHA, Native American tribes, and reservoir managers, has primary and secondary cyanotoxin [algal toxin] trigger threshold levels that would result in posting public health advisories[105] for a water body (e.g., lake, reservoir, or river reach), if one or more of the algal toxin threshold levels is exceeded. While microcystin is the algal toxin typically measured in water bodies, the algal toxins anatoxin-a and cylindrospermopsin also have threshold levels which would trigger posting of the water body (see also Section 3.4.2.1 *Phytoplankton*).

Since 2005, high levels of microcystin have prompted the posting of public health advisories around Copco No. 1 and Iron Gate reservoirs, and during certain years along reaches of the Middle and Lower Klamath River downstream from Iron Gate Dam in the late summer months (see Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*, Appendix C – Section C.6.1.1 *Hydroelectric Reach* for more detail). In 2010, the Lower Klamath Project reservoirs and the entire Klamath River downstream from Iron Gate Dam (including the Klamath River Estuary) were posted to protect public health due to elevated blue-green algae cell counts (i.e., *Aphanizomenon flos-aquae, Anabaena flos-aquae,* and *Microcystis aeruginosa*) and algal toxin (i.e., microcystin) concentrations. Public health advisories for both Copco No. 1 and Iron Gate reservoirs were also posted in 2012 (North Coast Regional Board 2012), 2013 (North Coast Regional Board 2013), 2014 (North Coast Regional Board 2014), 2015 (Watercourse Engineering, Inc. 2016), and 2016 (North Coast Regional Board 2016). Measurement of elevated algal toxin (i.e., microcystin) concentrations also prompted a public health advisory in 2017 for Copco No. 1 and Iron Gate reservoirs and reaches of the Klamath River downstream of Iron Gate Dam (North Coast Regional Board 2017). Blue-green algae cell counts and microcystin concentrations greater than CCHAB thresholds for posting public health advisories were also measured in Copco No. 1 and Iron Gate during summer and fall 2018 (E&S Environmental Chemistry, Inc. 2018b). High cell counts and toxin concentrations in the water column can result in bioaccumulation of microcystin in muscle and/or liver tissues of resident (e.g., yellow perch) and anadromous fish (e.g., juvenile hatchery Chinook, adult Chinook salmon, steelhead) and in freshwater mussels (Kann 2008; Kann and Corum 2009; PacifiCorp 2010; Kann et al. 2011; Kann et al. 2013) (see also Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Project*).

Periphyton

Nuisance blooms of periphyton have not been documented in the riverine portions of the Hydroelectric Reach. In the J.C. Boyle Peaking Reach, it has been noted that periphyton tends to be absent from the margins of the river that are alternately dried and wetted during peaking operations (E. Asarian, pers. comm., 2011).

3.4.2.4 Middle and Lower Klamath River

Phytoplankton

Although both *Aphanizomenon flos-aquae* and *Microcystis aeruginosa* have been observed in the Klamath River just downstream from Iron Gate Dam, and as far downstream as the Klamath River Estuary, this reach of the river is more suitable for the growth of periphyton and does not provide optimal habitat for phytoplankton species that typically thrive in reservoir and lake environments. As discussed above, data collected in 2001 through 2010 suggest that the phytoplankton composition of Klamath River sites immediately downstream from Iron Gate Reservoir is dominated by cyanobacteria [blue-green algae] on a seasonal basis, when large blooms occurring in this reservoir are transported downstream (Kann and Asarian 2006; Asarian and Kann 2011). Additional monitoring from 2013 to 2018 further documents the seasonal abundance of cyanobacteria [blue-green algae] downstream of Iron Gate Dam (E&S Environmental Chemistry, Inc. 2013, 2014, 2015, 2016, 2018a, 2018b). Genetic analysis of *Microcystis aeruginosa* indicates genetic similarities of populations found in Iron Gate Reservoir and downstream river sites, providing further evidence that Iron Gate Reservoir is the source of *Microcystis aeruginosa* populations in the Klamath River downstream of Iron Gate Dam (see Section 3.4.2.3 above; Otten et al. 2015).

In general, turbulent mixing, increased velocity, and tributary dilution result in a gradual decrease in suspended algal materials from the Klamath River water column as the river travels downstream (Armstrong and Ward 2008; Ward and Armstrong 2010) (see also discussion in Appendix C – Section C.2.2.1 *Iron Gate Dam to Salmon River* and Section C.6.2.1 *Iron Gate Dam to Salmon River*). *Microcystis aeruginosa* transported downstream from Copco No. 1 and Iron Gate reservoirs can become trapped and accumulate in calm pools and eddies along the edges of the Middle and Lower Klamath River (Kann and Corum 2006) in some years (e.g., 2007) resulting in pockets of highly concentrated cyanobacteria [blue-green algae] along the river shoreline in greater concentrations than those measured immediately downstream from Iron Gate Dam (Fetcho 2008; Raymond 2008; Kann and Corum 2009; Kann et al. 2010). The spatially and temporally variable nature of blue-green algae blooms along the edges of the Middle and Lower Klamath River makes it difficult to fully assess the distribution and frequency of these events (Kann and Corum 2009). In measurements of the cyanobacteria [blue-green algae] cell density across one transect of the Klamath River, the cyanobacteria [blue-green algae] cell density was substantially higher near the shoreline where turbulent mixing and water velocities were lower (Figure 3.4-15; Kann et al. 2010; Genzoli and Kann 2016, 2017). The presence of blue-green algae along the shoreline is particularly important because the shoreline is where animals (e.g., pets) and humans are most likely come in contact with water and any blue-green algae or algal toxins present in the water, especially during recreational activities (see Section 3.20.2.2 *Klamath River-based Recreation*). At times, accumulations of cyanobacteria [blue-green algae], including *Microcystis aeruginosa,* along shorelines and in protected coves and backwaters in the Middle and Lower Klamath River can result in exceedances to the 2016 CCHAB secondary thresholds for the protection of human health (4,000 cells/mL of all toxin-producing cyanobacteria [blue-green algae] or site specific indicators of cyanobacteria [blue-green algae] like blooms, scums, or mats) and the WHO guidelines for *Microcystis aeruginosa* cell density (20,000 cells/mL for a relatively low probability of adverse human health effects) (Falconer et al. 1999; State Water Board et al. 2010, updated 2016). These thresholds and guidelines have been set for safe recreational water contact (not drinking water) (see also Section 3.4.2.1 *Phytoplankton*)

Despite these localized accumulations of blue-green algae along shorelines and in backwaters, data collected in June through November during 2005 to 2015 indicate that the measured *Microcystis aeruginosa* cell density at river sites in the Middle and Lower Klamath River was usually less than the vast majority of measured *Microcystis aeruginosa* cell densities in Copco No. 1 and Iron Gate reservoir sites (Appendix C, Figure C-49; see also Kann et al. 2010; Kann and Bowman 2012; Genzoli and Kann 2017). While the majority of *Microcystis aeruginosa* cell density measurements at river sites in the Middle and Lower Klamath River were less than the 2010 CCHAB (SWRCB/OEHHA Public Health) threshold of 40,000 cells/mL, the measured *Microcystis aeruginosa* cell densities at river sites frequently exceeded the 2016 CCHAB threshold of 4,000 cells/mL (Genzoli and Kann 2017). The measured *Microcystis aeruginosa* cell density at river sites in the Middle and Lower Klamath River in June through November during 2005 to 2015 was typically less than the higher WHO guidelines (20,000 cells/mL), but measurements of *Microcystis aeruginosa* cell density from the Klamath River I-5 Rest Area (RM 181.8) to Orleans (RM 58.9) reached 20,024 to 35,784 cells/mL in late July/early August 2015, with the maximum occurring at Seiad Valley (RM 132.7) (Watercourse Engineering, Inc. 2016).

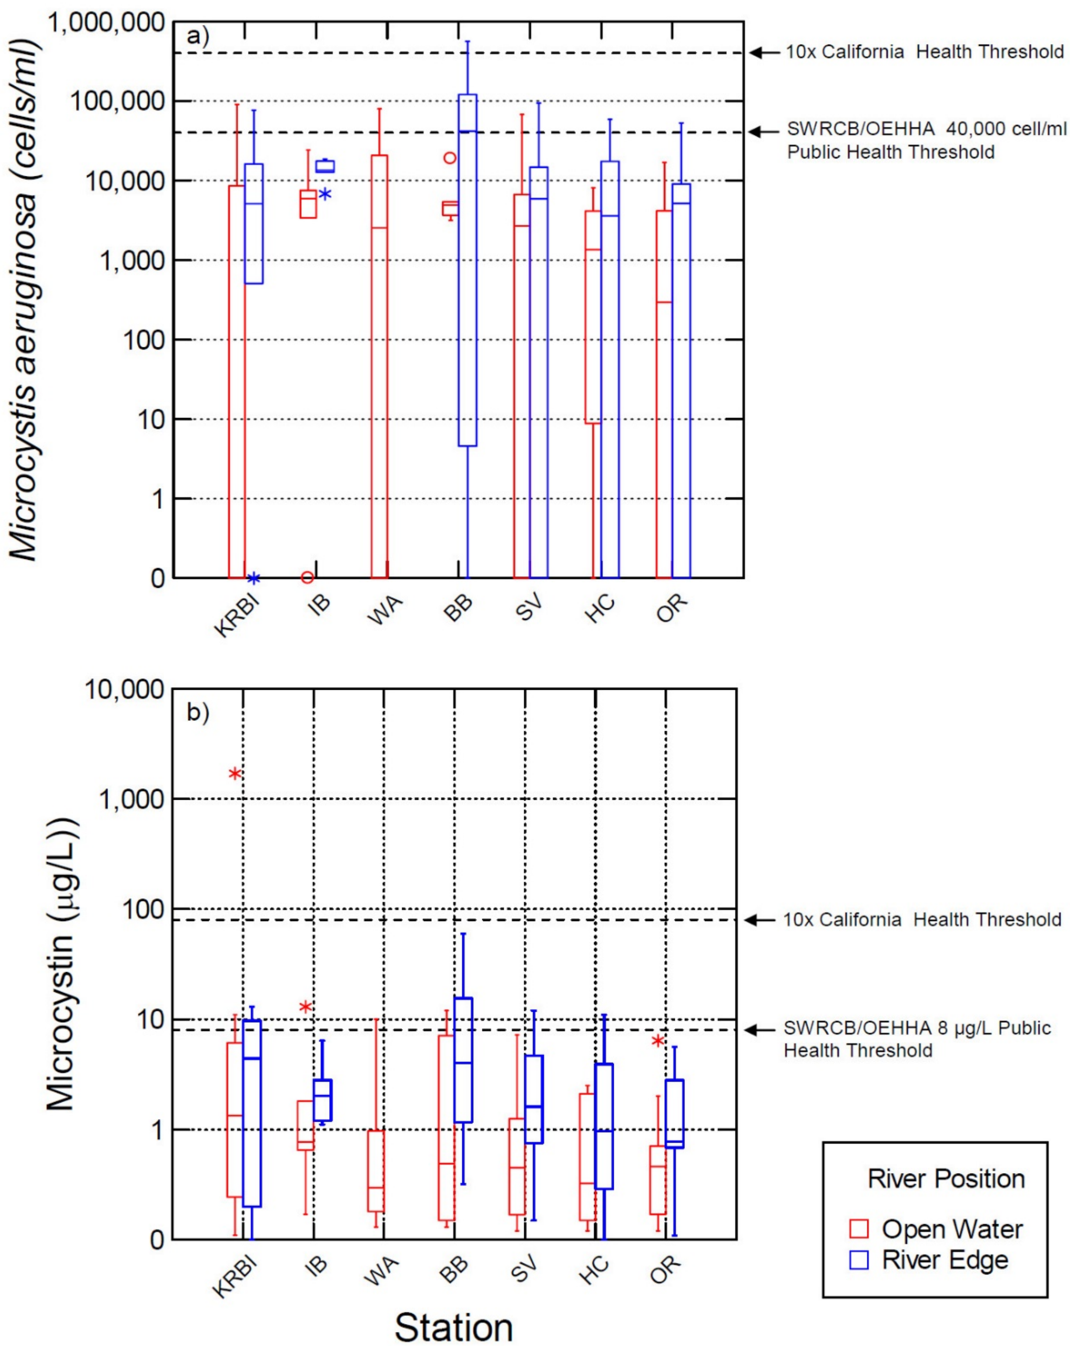

Figure 3.4-15. *Microcystis aeruginosa* density and microcystin concentration variations between open water and along the river edge in the Klamath River. Station locations on the Klamath River: KRBI = Klamath River downstream of Iron Gate Dam; IB = I-5 Bridge; WA = Walker Bridge; BB = Brown Bear River Access just east of Horse Creek; SV = Seiad Valley; HC = Happy Camp; and OR = Orleans. Thresholds listed are those that were applicable when study was published and do not reflect current thresholds. Current threshold is 0.8 ug/l as discussed in Section 3.4.2.1 *Phytoplankton*. Source: Kann et al. 2010.

Algal toxins (e.g., microcystin, anatoxin-a) are a critical concern in the Klamath River downstream from Iron Gate Dam, because they can remain viable along the low-velocity margins of the river where little mixing occurs (Kann and Corum 2009; Genzoli and Kann 2016, 2017). During cyanobacteria [blue-green algae] growth, most toxins are contained within the cells of the cyanobacteria [blue-green algae]. However, once cyanobacteria [blue-green algae] die and decay, its cells break apart (lyse) and toxins are released (Falconer et al. 1999). Microcystin is the primary algal toxin concern in the Klamath River downstream of Iron Gate Dam, because microcystin is extremely stable and resists common chemical breakdown such as hydrolysis, oxidation, or photolysis (i.e., photochemical degradation by sunlight) under conditions found in most natural water bodies. The time it takes for half of the microcystin to break down (i.e., half-life) under typical ambient conditions is 10 weeks (OEHHA 2009), so microcystin concentrations can continue to increase over multiple weeks in the areas of the Klamath River with limited mixing as blue-green algae continue to die, decay, and release microcystin. Even after boiling, microcystin can persist in water, indicating that cooking is not sufficient to destroy microcystin (Chorus and Bartram 1999; OEHHA 2009). Anatoxin-a, the other blue-green algae toxin that has been detected in the Klamath River downstream of Iron Gate Dam (see Appendix C – Section C.6.2 *Mid- and Lower Klamath Basin*), is much less stable than microcystin, with a half-life of 1 to 10 hours in natural light under typical ambient conditions. Anatoxin-a has been found to persist up to 21 days at low pH (4 s.u.) or up to several months in the absence of sunlight (USEPA 2015).

Concentrations of microcystin in the Klamath River downstream from Iron Gate Dam are typically 1 to 3 orders of magnitude lower than observed in Copco No. 1 and Iron Gate reservoirs (Appendix C, Figure C-49; see also Raymond 2008; Kann et al. 2010; Kann and Bowman 2012). However, the lowest 2016 CCHAB threshold (0.8 ug/L), the 2010 CCHAB (SWRCB/OEHHA Public Health) threshold (8 ug/L), the WHO guideline (4 ug/L), the Hoopa Valley Tribe recreational water objective (8 ug/L), and the lowest Yurok Tribe guideline (detection) for exposure to microcystin have each been exceeded downstream from Iron Gate Dam on numerous occasions (Kann 2004; Kann and Corum 2009; Kann et al. 2010; Fetcho 2011; Kann and Bowman 2012; Watercourse Engineering, Inc. 2012, 2013, 2014, 2015, 2016; KTWQC 2016), including late-summer/early-fall *Microcystis aeruginosa* blooms in September 2007, 2009, 2010, 2011, 2012, 2013, and 2016 from Iron Gate Dam (RM 193.1) to the mouth of the Klamath River (RM 0.5). Overall, the data indicate that while Middle and Lower Klamath River microcystin exceedances do occur, they are far less in number than exceedances in Copco No. 1 and Iron Gate reservoirs (Appendix C, Figure C-49; see also Raymond 2008; Kann et al. 2010; Kann and Bowman 2012). Data from 2007 also indicate that microcystin can bioaccumulate in juvenile salmonids reared in Iron Gate Hatchery (see Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project* for more details; Kann 2008), potentially resulting in earlier hatching; disruption of development, growth, immune status, and cardiac function; damage to the liver, kidney, and gills; and death (OEHHA 2009).

Overall, the literature and studies to date overwhelmingly support the conclusion that blue-green algae blooms in Iron Gate Reservoir are the primary source of *Microcystis aeruginosa* detected seasonally in the Klamath River downstream from the Hydroelectric Reach. Additionally, Copco No. 1 Reservoir may also contribute to *Microcystis aeruginosa* populations in these reaches. Measured data along with the persistence of microcystin in the environment indicate that microcystin concentrations downstream of J.C. Boyle are typically below detectable concentrations with only infrequent measurements, so blue-green algae blooms in both Copco No. 1 and Iron Gate reservoirs provide the primary source of the seasonally detected microcystin in the Klamath River downstream from the Hydroelectric Reach rather than transport of microcystin from upstream of Copco No. 1 through the reservoirs and into the Middle or Lower Klamath River. The relatively high turbulence and velocity of the Middle and Lower Klamath River makes it poor habitat for blue-green algae species to thrive in most reaches, although colonies of *Microcystis aeruginosa* can be transported into the river from Iron Gate Reservoir and potentially Copco No. 1 Reservoir and accumulate, and in some cases, may persist in the localized pools and edges of the river. That Copco No. 1 and Iron Gate reservoirs receive excessive nutrients and potentially a small amount of viable blue-green algae cells transported from upstream of the Hydroelectric Reach, while well documented, does not diminish the fundamental role of Copco No. 1 Reservoir and especially Iron Gate Reservoir, in fostering excessive growth of *Microcystis aeruginosa,* the production of high concentrations of microcystin, and the downstream transport of both, to the Middle and Lower Klamath River.

Periphyton

Periphyton sampling in the Klamath River downstream from Iron Gate Dam reveals distinct longitudinal and seasonal patterns in species composition. In a single survey undertaken downstream of Iron Gate Dam between September 1 and 2, 2004, Eilers (2005) documented relatively high periphyton coverage (near 80 percent) on stream rocks and periphyton chlorophyll-*a* content (near 50 micrograms per square centimeter [ug/cm^2]) immediately downstream from Iron Gate Dam ([RM 193.1]). Several miles downstream, near the Collier Rest Area at the I-5 bridge (RM 182.1), periphyton coverage (near 10 percent) on stream rocks was relatively low. Downstream from the Collier Rest Area, both periphyton coverage and chlorophyll-*a* content increased gradually to peak levels near the confluence with the Salmon River (RM 66). While periphyton biomass was generally found to be low to moderate during the survey (with the exception of the site immediately downstream from Iron Gate Dam), it is believed that increased discharge (i.e., a doubling of flow from approximately 600 cfs around August 15 to approximately 1,200 cfs near the end of August, and decreasing to approximately 800 cfs by September 1, the start of the survey) may have dislodged filamentous algae that had proliferated under the previous lower flow regime (Eilers 2005; FERC 2007).

Analysis of periphyton data collected between 2004 and 2013 indicates that attached diatoms represent the highest percentage of total periphyton biomass in the Middle and Lower Klamath River, but variations in the periphyton community occur in specific reaches and time periods (Asarian et al. 2014, 2015). During June through October, periphyton communities[107] occurring from Iron Gate Dam (RM 193.1) to RM 160 tend to exhibit the highest percentage of species tolerant of degraded dissolved oxygen conditions, bacteria capable of obtaining energy from organic nitrogen-containing compounds as well as from photosynthesis, and free-floating, un-attached algae species, including cyanobacteria [blue-green algae] *Aphanizomenon flos-aquae* and *Microcystis aeruginosa* that are part of the periphyton assemblage (Asarian et al. 2014). The periphyton community established between Seiad Valley (RM 132.7) and Happy

[107] A periphyton community is comprised of all the species of algae found when sampling a section of the streambed, including both attached periphyton species and free-floating, un-attached algae species that may be associated with the attached periphyton species.

Camp (RM 108.3), shows strong seasonal trends, with a high diatom, low cyanobacteria [blue-green algae] community dominant until June, followed by a community that is more tolerant of low dissolved oxygen concentrations and exhibits higher cyanobacteria [blue-green algae] biomass during August through October (Asarian et al. 2014). Nitrogen-fixing species are not present directly downstream from Iron Gate Dam, but begin to appear by Seiad Valley and then make up an increasing percentage of periphyton biomass at sites farther downstream (Asarian et al. 2010; E. Asarian, pers. comm. 2011; Asarian et al. 2014, 2015). There is also seasonal variation evident in the periphyton community from Happy Camp (RM 108.3) to the Klamath River Estuary (RM 2), with the majority of periphyton falling into the high diatom, low blue-green algae community in May and June, then transitioning in July to a periphyton community comprised primarily of nitrogen-fixing diatom and blue-green algae species (i.e., species that can use nitrogen from the atmosphere). The three main nitrogen-fixing diatoms in the periphyton community beginning in July and continuing through October are *Epithemia sorex*, *Epithemia turgida*, and *Rhopalodia gibba,* which all contain cells of cyanobacteria [blue-green algae] that live inside the diatom cells to help the diatoms fix nitrogen. The main nitrogen-fixing cyanobacteria [blue-green algae] species in the periphyton community from July to October is *Calothrix* sp., a species of cyanobacteria [blue-green algae] that grows as pronounced tapering filaments (i.e., threads) attached to the streambed and rocks (Asarian et al. 2014, 2015). The nitrogen-fixing diatom and blue-green algae periphyton community dominates in the Lower Klamath River between August and October, which coincides with very low levels of inorganic nitrogen (ammonia and nitrate) concentrations in water samples (Asarian et al. 2010, 2014, 2015).

Variations in periphyton communities in the Middle and Lower Klamath River are influenced by both nutrient concentrations and flow conditions. The overall longitudinal pattern in periphyton communities described above is driven by changes in nutrient concentrations in the Middle and Lower Klamath River. Nutrient concentrations tend to decrease in a downstream direction due to nutrient retention dynamics (e.g., nutrients being used and retained in biomass) along the Middle and Lower Klamath River and dilution, as tributaries with lower nutrient concentrations flow into the Klamath River (Asarian and Kann 2013). As nutrient concentrations decrease and less nutrients are available in the water for periphyton growth, the percentage of nitrogen-fixing periphyton in the periphyton community increases, because those species are able to overcome the nitrogen limitations in the Middle and Lower Klamath River waters by using nitrogen from the atmosphere. While nutrient concentrations decrease from upstream to downstream, the overall periphyton biomass tends to increase due to these nitrogen-fixing periphyton species (Asarian et al. 2015; Gillet et al. 2016). Variations in the periphyton community during the year correspond to changes in flow in the Klamath River, with higher flow associated with a lower abundance of nitrogen-fixing periphyton. These variations are most pronounced in late summer (after July) and at locations in the Lower Klamath River (Gillet et al. 2016). As an example, the percent of the periphyton community comprised of nitrogen-fixing periphyton at the Turwar Klamath River site decreased from approximately 80 percent at flows less than approximately 3,000 cfs, to approximately 20 percent at flows greater than 10,000 cfs (Gillet et al. 2016).

Cladophora sp. have been noted to dominate the periphyton community at a Shasta River (tributary) site, where this species made up 50 percent of the periphyton community by biovolume; however, *Cladophora* sp. were not documented at any of the other tributary or mainstem Klamath River sites surveyed between September 1 and 2, 2004 (Eilers 2005). The abundance of *Cladophora* sp. in the Klamath River found in

Eilers (2005) was likely influenced by a release from Iron Gate Dam that increased the flow in the Klamath River one week prior to the study from approximately 700 cfs to 1,100 cfs for several days before decreasing to approximately 900 cfs. The increased flow may have dislodged *Cladophora* sp. and other periphyton, resulting in lower abundances than would have occurred before that release. As discussed previously (Section 3.4.2.2 *Periphyton*), *Cladophora* sp. provide suitable habitat for the polychaete worm that is the intermediate host for fish parasites. However, data regarding *Cladophora* biomass are limited, making it difficult to determine the primary factors that control the biomass and distribution of these species (E. Asarian, pers. comm., 2011). While periphyton has been studied in the Klamath River and *Cladophora* sp. has been detected in those studies, the methods used for the sampling was not designed to adequately characterize filamentous algae like *Cladophora* sp. (Asarian et al. 2014, 2015).

3.4.2.5 Klamath River Estuary

The algal community in the Klamath River Estuary is dominated by phytoplankton, although it does exhibit relatively greater amounts of periphyton in the upper portion of the estuary where conditions are more riverine. The presence of brackish water influences the types of phytoplankton and periphyton present in different areas of the estuary. Similar to the Lower Klamath River, the Klamath River Estuary phytoplankton community is composed primarily of diatoms and blue-green algae (Fetcho 2007, 2008, 2009). Phytoplankton densities are more frequently lower in the estuary than those measured concurrently in the Lower Klamath River, but phytoplankton cell densities are occasionally higher in the estuary than measured upstream. Between 2010 and 2015 when *Microcystis aeruginosa* was concurrently detected at the Klamath River Estuary and Turwar (i.e., the Lower Klamath River site upstream of the estuary), *Microcystis aeruginosa* was lower in the estuary than at the upstream site in 57 percent (12 of 21) of measurements. However, *Microcystis aeruginosa* was higher in the estuary than upstream in 43 percent (9 of 21) of measurements, so there is not always a decreasing trend in *Microcystis aeruginosa* cell densities between the Lower Klamath River and the Klamath River Estuary (Gibson 2016).

Phytoplankton sampling of the lower estuary surface by the Yurok Tribe since 2005 has indicated that blue-green algae concentrations peak annually between August and October (Fetcho 2006, 2007, 2008, 2009, 2011; Sinnott 2011, 2012; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014; Gibson 2016). Concentrations of *Microcystis aeruginosa* measured between 2010 and 2015 further support that trend, with annual peaks occurring primarily between August and October (Figure 3.4-16; Gibson 2016).

Blue-green algae concentrations, especially *Microcystis aeruginosa*, in the Klamath River Estuary have exceeded 2010 CCHAB, 2016 CCHAB, WHO, and Yurok Tribe blue-green algae thresholds and guidelines multiple times since 2005 (Fetcho 2006, 2007, 2008, 2009, 2011; Sinnott 2011, 2012; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014; Gibson 2016). On one occasion in September 2005, blue-green algae cell density exceeded the WHO guidelines for low risk recreational use (20,000 cells/mL), with instances of elevated levels of *Microcystis aeruginosa* corresponding to elevated levels measured at upstream locations in the Lower Klamath River (Fetcho 2006, 2008). In September 2007, estuary *Microcystis aeruginosa* cell density twice exceeded the then-current Yurok Tribe posting action level

(40,000 cells/mL). Yurok Tribe posting guidelines have been revised since 2007 and a caution posting currently occurs after detection of *Microcystis aeruginosa* cells (see Section 3.2.3.1 *Thresholds of Significance* and 3.4.2.1 *Phytoplankton*). In 2010 to 2014, *Microcystis aeruginosa* was detected every year, with *Microcystis aeruginosa* cell densities greater than the 2016 CCHAB threshold of 4,000 cells/mL total potentially toxigenic cyanobacteria [blue-green algae] at least once every year (Figure 3.4-16). However, *Microcystis aeruginosa* was not detected in surface samples of the Klamath River Estuary during 2015, even though it was detected upstream in the Lower Klamath River (Gibson 2016).

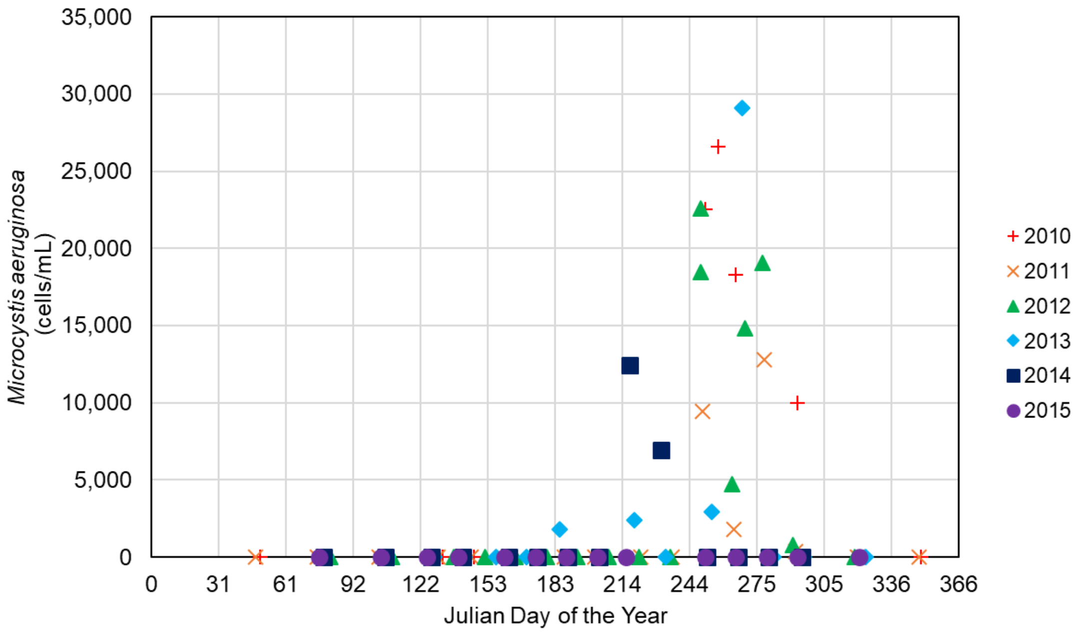

Figure 3.4-16. *Microcystis aeruginosa* cell density in the Klamath River Estuary between 2010 and 2015. Source: adapted from Gibson 2016.

Although periphyton data for the estuary are unavailable, in part due to the difficulty of sampling in deeper areas, abundant periphyton cover has been documented in the south slough (Hiner 2006).

3.4.2.6 Pacific Ocean Nearshore Environment

The algal community of the nearshore Pacific Ocean is dominated by marine algae, including attached red and brown seaweeds, as well as many marine planktonic species. The freshwater algae discussed in Section 3.4.2 *Phytoplankton* are not expected to thrive in the turbulent, saline marine environment, but they may be carried into the ocean with the current and survive for limited periods. Toxins can also be washed into the ocean, but they are expected to be rapidly diluted. There have been no reports of problems relating to freshwater algal toxins in the Pacific Ocean near the mouth of the Klamath River. However, microcystin has been reported as the cause for numerous deaths of sea otters, a federally-listed species, in the vicinity of Monterey Bay, California. Miller et al. (2010) presented evidence that microcystin produced by *Microcystis aeruginosa* in freshwater streams and lakes flowed out into the Pacific Ocean nearshore environment in Monterey Bay, California, and bioaccumulated in marine invertebrates (e.g., clams) that are a sea otter food source. Sea otter deaths due to microcystin exposure were attributed to consumption of microcystin contaminated marine invertebrates, rather than direct exposure to microcystin in freshwater, because most sea otters that died from microcystin were recovered near embayments, harbors, or river mouths. Further, sea otters do not venture into rivers to feed (Miller et al. 2010).

3.4.3 Significance Criteria

For purposes of this EIR, impacts of the Proposed Project related to phytoplankton and/or periphyton would be significant if they were to result in the following:

- An increase in the spatial extent, temporal duration, toxicity, or concentration of nuisance and/or noxious phytoplankton blooms. The nuisance and/or noxious phytoplankton blooms in the Area of Analysis are comprised of the blue-green algae species *Aphanizomenon flos-aquae*, *Anabaena flos-aquae*, and *Microcystis aeruginosa*.
- An increase in the spatial extent, temporal duration, or biomass of nuisance periphyton species that results in new or further impairment of designated beneficial uses (Table 3.2-2). The nuisance periphyton species in the Area of Analysis is *Cladophora* sp.

For this EIR's phytoplankton and periphyton analysis, short-term is defined as the period during pre-dam removal activities, reservoir drawdown, dam removal, and associated sediment flushing events that could transport sediment-associated nutrients, which could influence phytoplankton or periphyton growth. This period corresponds to pre-dam removal years 1 and 2, dam removal year 1, dam removal year 2, and post-dam removal year 1 (Table 2.7-1). Long-term is defined as occurring after post-dam removal year 1 (i.e., greater than three years after dam removal begins).

3.4.4 Impact Analysis Approach

Existing information regarding blue-green algae blooms in the Area of Analysis for phytoplankton and periphyton suggests that several critical factors affect the frequency and toxicity of blue-green algae blooms in the Lower Klamath Project reservoirs: water temperature, light levels (FERC 2007), flow rates (Kann 2006; Asarian and Kann 2013), nutrient availability/ratios (Chorus and Bartram 1999; Fetcho 2008; Moisander et al. 2009, Asarian and Kann 2011), and wind-induced turbulence and mixing.

The assessment of the effects of the Proposed Project on phytoplankton and periphyton, especially toxic blue-green algae blooms, in the Klamath River reaches in the Area of Analysis is based on the expected effects of dam removal on water temperature, light availability, hydrodynamic conditions (water movement), nutrient availability, streambed scour conditions, and transport of blue-green algae cells in the reservoirs downstream of the dams. Existing model output and empirical data describing the expected effects of dam removal on water quality (see Section 3.2.4 *Impact Analysis Approach*) provide the basis for the anticipated effects on water temperature, suspended sediment concentrations, and nutrients. In combination with existing literature regarding the biology and ecology of blue-green algae species, the water temperature and nutrient information is used to determine whether the Proposed Project would alter the spatial extent of optimal habitat in the Area of Analysis for blue-green algae or periphyton.

Suspended sediment concentrations were used to evaluate the relative magnitude and timing of potential sediment-associated nutrients available in the river during transport of reservoir sediment deposits under the Proposed Project. Light availability that would alter photosynthesis and growth for phytoplankton and periphyton also was qualitatively assessed from expected suspended sediment concentrations, with light availability, photosynthesis, and growth potential decreasing as suspended sediment concentrations increase.

The following specific metrics are evaluated:

- The extent to which monthly mean and maximum water temperatures would be within the range of 64 to 77°F or exceed 82°F;
- Total suspended sediment and nutrient concentrations; and,
- The presence or absence of lacustrine (i.e., lake- or reservoir-like) conditions.

The water temperature range of 64 to 77ºF has been selected because the algal toxin content in cyanobacteria [blue-green algae] cells is the highest within this range and the algal toxin content decreases at water temperatures greater than 82ºF (Van Der Westhuizen and Eloff 1985; Chorus and Bartram 1999; State Water Board et al. 2010, updated 2016). Suspended sediment and nutrient concentration data are based on output from the SRH-1D model and the California Klamath River TMDLs model, respectively (see Section 3.2.4 *Impact Analysis Approach* and Appendix D for descriptions of these numeric models).

The potential effects of the Proposed Project on periphyton growth were evaluated using information about nutrients in the Klamath River presented in Asarian et al. (2010), which quantified nutrient loads and nutrient retention (seasonal removal and/or release) rates in reaches of the Klamath River. Asarian et al. (2010) estimated daily nutrient concentrations from measurements occurring monthly or more frequently using five different methods, including two constant flow-weighted-mean concentration methods, a linear interpolation method, and two regression methods. Nutrient loads (metric tons/day) for each surface inflow and outflow of individual reaches of the Klamath River and its tributaries were then estimated using the daily estimated nutrient concentrations (mg/L) and the daily mean flows (cfs). See Asarian et al. (2010) for further explanation of the method details, including equations. Table 3.4-2 presents five nutrient load estimates for each reach based on the five different methods of estimating the daily nutrient concentrations and highlights how the mean daily nutrient load estimate is similar regardless of the method used to estimate the daily nutrient concentration. A nutrient mass balance on individual reaches of the Klamath River assumes mass is never destroyed (i.e., conserved) and the nutrient mass that stays in a river reach (e.g., via uptake by periphyton, aquatic plants, or bacteria, burial in streambed sediments, sediment sorption) is equal to the nutrient mass that enters a river reach (e.g., nutrient mass from the mainstem Klamath River plus any nutrients from an incoming tributary in that reach) minus the nutrient mass exiting a river reach (e.g., transported to downstream reaches, lost to atmosphere) (Asarian et al. 2010).

[a] Constant flow-weighted-mean concentration (flow-weighted average of concentration from sampled days multiplied by the mean flow over the entire period).
[b] Constant flow-weighted-mean concentration within low and high-flow strata (above and below the mean flow for the entire period).
[c] Linear interpolation of concentrations between sampling dates (used in Asarian and Kann [2006]).
[d] Regression without residual (observed minus predicted values) interpolation.
[e] Regression with residual interpolation to incorporate relationships between concentration, flow and season, as well as adjacent sample points.

Anticipated changes in water quality (i.e., water temperature, suspended sediment concentrations, and nutrients) between conditions under the Proposed Project and existing conditions during the growth season (i.e., summer and early fall) in the reaches where the Lower Klamath Project reservoirs are located and at various in-river locations within the phytoplankton and periphyton Area of Analysis are also used to evaluate Proposed Project-induced changes on other phytoplankton (e.g., diatoms) and periphyton.

This analysis will then inform comparison of phytoplankton and periphyton conditions under the Proposed Project with the existing condition described above. To the extent that there is an increase in the periphyton as defined in the significance criteria, the analysis will consider whether these changes would affect a new or further impairment of designated beneficial uses.

3.4.5 Potential Impacts and Mitigation

3.4.5.1 Phytoplankton

Potential Impact 3.4-1 Short-term increase in growth of nuisance and/or noxious phytoplankton blooms due to increases in sediment-associated nutrients from release of sediments currently trapped behind the Lower Klamath Project dams.
Under the Proposed Project, J.C. Boyle Reservoir would be removed in Oregon and Iron Gate, Copco No. 1, and Copco No. 2 reservoirs would be removed in California, and sediment accumulated behind each dam would be released and transported downstream through the Klamath River and into the Pacific Ocean (see Section 3.2.5.2 *Suspended Sediments* and Potential Impacts 3.11-5 and 3.11-6). By calendar year 2020, the total amount of sediment expected to have been deposited behind J.C. Boyle, Copco No. 1, Copco No. 2, and Iron Gate dams is approximately 15.1 million cubic yards (Table 2.7-10), with modeling indicating that reservoir drawdown would erode and transport between 36 and 57 percent of the reservoir sediment (between 5.4 and 8.6 million cubic yards) downstream through the Klamath River (Table 2.7-11). Large quantities of sediment would remain in place after dam removal, primarily on areas above the active channel of the Klamath River and these remaining reservoir sediments would dry out, decrease in thickness, and stabilize within the historical reservoir footprints (see Section 2.7.3 *Reservoir Sediment Deposits and Erosion During Drawdown* for more details). Reservoir sediments consist primarily of fine and sand sediments (see Table 2.7-9) with the fine sediments mostly an accumulation of silt-size particles of organic material from dead and decaying algae and silt-size inorganic particles of rock (USBR 2012). Sediment-associated nutrients that have accumulated in the sediment deposits are primarily from dead algae and are typically bound to the fine sediments (Deas 2008, Downs et al. 2010, USBR 2012).

Short-term increases in sediment-associated nutrients could occur in the Hydroelectric Reach, Middle and Lower Klamath River, and the Klamath River Estuary due to the release of sediments currently trapped behind the dams (see Potential Impact 3.2-7). While there would be a short-term increase in sediment-associated nutrients, minimal deposition of fine suspended sediments, including the associated nutrients, would occur in the river channel and the estuary (Stillwater Sciences 2008; USBR 2012). Thus, the short-term increase in nutrients would be limited to the time period when sediment deposits are being transported through the Klamath River. The reservoir drawdown and release of these nutrients would occur during winter months when the rates of phytoplankton growth and reproduction, which require nutrients, are relatively low. As a result, the ability of phytoplankton to use sediment-associated nutrients mobilized during reservoir drawdown would be low and the Proposed Project would not be likely to stimulate an increase in phytoplankton growth or reproduction. Sediment released during reservoir drawdown under the Proposed Project also would increase suspended sediment concentrations and water turbidity (Potential Impact 3.2-3), limiting light availability for phytoplankton photosynthesis and further reducing the potential for additional phytoplankton growth and reproduction.

Further, by mid- to late-spring when phytoplankton would have begun to bloom in the calm Lower Klamath Project reservoir habitat, reservoir drawdown would be complete and the riverine concentration of suspended sediments (see Potential Impact 3.2-3) and the additional sediment-associated nutrients (see Potential Impact 3.2-7) would be low. The minimal deposition of fine suspended sediments, including associated nutrients, in the river channel and the estuary (Stillwater Sciences 2008; USBR 2012) could provide nutrients for phytoplankton growth. However, because higher velocity river conditions would replace the slower-moving reservoir habitat in the Hydroelectric Reach after drawdown, there would be limited suitable habitat for phytoplankton growth and reproduction, regardless of any sediment-associated nutrients that may be deposited in the river channel or the estuary during drawdown. Phytoplankton, especially cyanobacteria [blue-green algae], growth is highest in stable water column conditions (Konopka and Brock 1978; Kann 2006; Asarian and Kann 2011) and the abundance of cyanobacteria [blue-green algae] decreases compared to other phytoplankton (e.g., diatoms and green algae) when mixing in a water body increases (McDonald and Lehman 2013; Visser et al. 2016). The lack of suitable habitat in the Hydroelectric Reach in mid- to late-spring would limit phytoplankton growth and reproduction, even with any sediment-associated nutrients that may be present. Furthermore, the reaches of the Hydroelectric Reach where the reservoirs are located would no longer transport high concentrations of nuisance and/or noxious phytoplankton species from phytoplankton blooms in the reservoirs into the Middle and Lower Klamath River and the Klamath River Estuary under the Proposed Project (Potential Impact 3.4-2), so phytoplankton growth and reproduction also would be limited in these reaches, even with any sediment-associated nutrients.

Additional movement of reservoir sediment deposits not mobilized during drawdown in dam removal year 2 may occur during winter high flows in post-dam removal year 1, resulting in additional transport of sediment-associated nutrients. However, nuisance and/or noxious phytoplankton blooms would not be stimulated by these nutrients, since they would occur during winter months when growth, reproduction, and nutrient transformation rates would be low, suspended sediment during transport of sediment-associated nutrients would limit light availability for phytoplankton growth, and calm, slow-moving habitat for phytoplankton would be limited. Winter high flows during post-dam removal year 1 would be likely to transport some sediments from remaining reservoir sediment deposits, although this would be limited due to revegetation of the reservoir footprints (Potential Impact 3.2-3) and the reasons identified above (e.g., limited light and faster-moving water) that would generally limit potential phytoplankton growth during winter flows. Thus, there would be minimal deposition of fine sediments and associated nutrients in the river channel and the estuary and negligible stimulation of phytoplankton growth later in post-dam removal year 1 in associated with sediment export related to the Proposed Project.

For the reasons stated above, phytoplankton growth and reproduction would not be increased by mobilization of sediment-associated nutrients during dam removal year 2 (i.e., reservoir drawdown) and post-dam removal year 1. Accordingly, the Proposed Project would not increase the spatial extent, temporal duration, toxicity, or concentration of nuisance and/or noxious phytoplankton blooms in the Hydroelectric Reach, Middle and Lower Klamath River, or the Klamath River Estuary, and there would be no short-term impact.

Significance

No significant impact

Potential Impact 3.4-2 Alterations in the spatial extent, temporal duration, transport, or concentration of nuisance and/or noxious phytoplankton blooms and concentrations of algal toxins due to dam removal and elimination of reservoir habitat.

Hydroelectric Reach

The removal of the Lower Klamath Project dams and reservoirs, particularly the larger Copco No. 1 and Iron Gate reservoirs, would decrease or eliminate support for excessive growth of blue-green algae (i.e., blooms) over the long term by eliminating large areas of quiescent habitat where these phytoplankton species currently thrive. In the nutrient-rich Klamath River system, the elevated water temperatures and increased light levels that occur during the summer and early fall result in seasonal blue-green algae blooms in the phytoplankton and periphyton Area of Analysis, and especially the Hydroelectric Reach (Section 3.4.2.3 *Hydroelectric Reach*). In addition to Copco No. 1 and Iron Gate reservoirs, riverine reaches downstream of the reservoirs generally experience high abundance of *Microcystis aeruginosa*, with the highest cell densities and microcystin toxin concentrations occurring directly downstream of Iron Gate Reservoir (see Section 3.2.2.7 *Chlorophyll-a and Algal Toxins*, Section 3.4.2.4 *Middle and Lower Klamath River*, and Appendix C – C.6.2 *Mid- and Lower Klamath Basin*). Available data strongly indicate that the reservoirs provide ideal conditions for blue-green algae blooms and serve as a source of blue-green algae cells and their toxins (e.g., microcystin) to downstream areas. While cyanobacteria [blue-green algae] can occur in riverine and estuarine environments (Christian et al. 1986, Lehman et al. 2005, Lehman et al. 2008), the rate of turbulent mixing in the water column relative to the flotation velocity of cyanobacteria [blue-green algae] is a critical factor controlling the size of cyanobacteria [blue-green algae] blooms (Huisman et al. 2004). Numerous studies in water bodies around the world have documented how blue-green algae tend to dominate the phytoplankton community in environments with low turbulent mixing (e.g., lakes, reservoirs). However blue-green algae abundance compared to other phytoplankton (e.g., diatoms and green algae) decreases as water column mixing increases because the net growth rate of blue-green algae decreases as they are mixed into the deeper water column where there is greater light variation and less overall light availability for photosynthesis. In addition to less overall light availability, Mitrovic et al. (2003) reports that the variation in light availability cyanobacteria [blue-green algae] would experience in a turbulent river mixing environment would reduce *Microcystis aeruginosa* and *Anabaena* growth compared to other phytoplankton species (e.g., diatoms and green algae). Under turbulent mixing conditions, cyanobacteria [blue-green algae] also face more competition from other phytoplankton that can remain suspended in the water column, compete for available light, and increase their net growth rate relative to cyanobacteria [blue-green algae] (Visser et al. 2016).

The Proposed Project would dramatically decrease the amount of optimal (i.e., calm, slow-moving reservoir) habitat available for the growth of nuisance and/or noxious phytoplankton species in the Hydroelectric Reach, resulting in a corresponding decrease in phytoplankton blooms compared to under existing conditions. After reservoir drawdown finishes, the calm, slow-moving reservoir habitat would be replaced by higher velocity riverine conditions, with limited suitable habitat for phytoplankton growth and reproduction. Higher mixing conditions would especially decrease blue-green algae abundance, since the increases in mixing would decrease the overall light availability for growth and reproduction compared to calm conditions where these organisms can remain exclusively near the water surface. Diatoms and green algae tend to grow better in turbulent river conditions than calm lake conditions, so blue-green algae also would be out-competed by these other phytoplankton. The lack of suitable habitat would substantially reduce seasonal phytoplankton bloom occurrence, especially blue-green algae blooms, and the associated production of algal toxins that are potentially harmful to animals and humans and impair designated beneficial uses. While the nutrients currently entering the Hydroelectric Reach may continue to be available to organisms in the Klamath River following dam removal, phytoplankton, especially blue-green algae, would be limited in their ability to use those nutrients for growth and reproduction without calm reservoir habitat. Cyanobacteria [blue-green algae] do not dominate under the current nutrient conditions in the turbulently mixing Klamath River downstream of J.C. Boyle Reservoir and upstream of Copco No. 1 Reservoir (Kann and Asarian 2006), so blue-green algae also would not be expected to dominate in the new turbulently mixed river reaches formed when Copco No. 1 and Iron Gate dams are removed. Under the Proposed Project, reductions in nuisance and/or noxious phytoplankton blooms, due to the elimination of the reservoirs in the Hydroelectric Reach, would be beneficial.

Drawdown of the reservoirs would begin in winter and would be largely complete by March/April (i.e., the beginning of the growth season) of dam removal year 2, so complete elimination of the reservoir environment would occur by the end of dam removal year 2 under the Proposed Project. Thus, the reductions in nuisance and/or noxious phytoplankton blooms would also occur by the end of dam removal year 2 in the Hydroelectric Reach and this would be a short-term benefit as well as a long-term benefit.

Middle and Lower Klamath River

Under the Proposed Project, nuisance and/or noxious phytoplankton blooms and concentrations of algal toxins would be expected to decrease in the Middle and Lower Klamath River, because the removal of Copco No. 1 and Iron Gate reservoirs would eliminate the primary source of Microcystis aeruginosa in the Middle and Lower Klamath River downstream of Iron Gate Dam. Existing data indicate blue-green algae (e.g., Microcystis aeruginosa) and associated algal toxins (e.g., microcystin) in the Middle and Lower Klamath River downstream of Iron Gate Dam do not result from transport of blue-green algae or algal toxins from upstream sources (i.e., Upper Klamath Lake), but originate from large seasonal blue-green algae blooms in Iron Gate and potentially Copco No. 1 reservoirs (see Section 3.4.2.3 *Hydroelectric Reach*, Section 3.4.2.4 *Middle and Lower Klamath River*, and Appendix C – *Section* C.6 *Chlorophyll-a and Algal Toxins*). Large seasonal blue-green algae blooms occurring upstream of the Area of Analysis are removed from the Upper Klamath River by upstream processes (e.g., settling in Keno Reservoir, microbial degradation) as well as dilution from tributaries in the Hydroelectric Reach and natural groundwater springs occurring in the J.C. Boyle Bypass Reach (see Section 3.2.2.3 *Suspended Sediments* and Appendix C – Section C.2.1.1 *Hydroelectric Reach*). *Microcystis aeruginosa* are typically not detected immediately upstream of Copco No. 1, but measurements of *Microcystis aeruginosa* taken at sampling locations in Copco No. 1 and Iron Gate reservoirs on the same day as the upstream measurements did occasionally detect large blooms of *Microcystis aeruginosa*, supporting the conclusion *Microcystis aeruginosa* blooms are primarily originating in those reservoirs. *Microcystis aeruginosa* was detected in only 2 of 17 measurements at the Klamath River station just upstream of Copco No. 1 Reservoir near the confluence with Shovel Creek ("KRAC" monitoring location in Figure 3.4-2) from 2001 to 2004 (Kann and Asarian 2006) and no detections were reported in data from 2005 (Kann and Asarian 2007), 2006 (Kann and Corum 2007), 2007 (Kann 2007), and 2008 (Kann and Corum 2009). However, three detections of *Microcystis aeruginosa* (in

79 measurements) were reported upstream of Copco No. 1 Reservoir near the confluence with Shovel Creek in a compilation of data from 2005 to 2010, with two measurements in 2007 and one measurement in 2008 (Asarian and Kann 2011). Those three measurements of *Microcystis aeruginosa* occurred in October or November after *Microcystis aeruginosa* had peaked in Copco No. 1 and Iron Gate reservoirs. Furthermore, genetic analysis of cyanobacteria [blue-green algae] populations in Copco No. 1 and Iron Gate reservoirs indicate the cyanobacteria [blue-green algae] found in the Middle and Lower Klamath River are similar to those found in Iron Gate Reservoir and not due to transport of cyanobacteria [blue-green algae] populations from Copco No. 1 Reservoir or farther upstream (Otten et al. 2015).

Microcystin trends in the Hydroelectric Reach and Middle and Lower Klamath River (see Appendix C, Figures C-52 and C-53 for details) also support the conclusion that microcystin detected downstream of Iron Gate Dam is not the result of transport from upstream sources (i.e., Upper Klamath Lake), but originates from large seasonal blue-green algae blooms in Iron Gate and potentially Copco No. 1 reservoirs. Microcystin toxin rarely persists in the Upper Klamath River under current conditions due to upstream removal mechanisms. Adsorption onto both suspended and streambed sediments (e.g., clay particles), breakdown by sunlight (i.e., photodegradation), and microbial degradation are several key microcystin removal mechanisms in natural freshwater and marine environments (Schmidt et al. 2014). Measured microcystin concentrations within Copco No. 1 and Iron Gate reservoirs have annually exceeded the CCHAB threshold 0.8 ug/L total microcystin between 2009 and 2018, with peak concentrations often exceeding 10 ug/L total microcystin multiple times per year and exceeding 100 ug/L total microcystin in both reservoirs between 2014 and 2017 (Watercourse Engineering Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; E&S Environmental Chemistry, Inc. 2013, 2014, 2015, 2016, 2018a, 2018b). While microcystin was greater than the 2016 CCHAB threshold in Copco No. 1 and Iron Gate reservoirs, in the Klamath River upstream of Copco No. 1 microcystin was typically below detectable concentrations with infrequent measurements above the 2016 CCHAB threshold of 0.8 ug/L total microcystin (see also Figure 3.4-13; Kann and Asarian 2006, 2007; Kann 2007; Kann and Corum 2007, 2009; Watercourse Engineering Inc. 2011a, 2011b, 2012, 2013, 2014, 2015, 2016; Otten et al. 2015). The frequency of higher microcystin measured in Copco No. 1 and Iron Gate reservoirs than upstream of Copco No. 1 Reservoir strongly supports data that *Microcystis aeruginosa* blooms within the reservoirs are the source of microcystin in the two reservoirs and in the Klamath River downstream of Iron Gate Dam rather than microcystin being transported into the reservoirs from upstream.

Under the Proposed Project, turbulence and higher velocities would occur in the Hydroelectric Reach where the calm, slow-moving waters of Copco No. 1 and Iron Gate reservoirs currently exist, and these conditions would potentially provide additional removal of *Microcystis aeruginosa* from upstream sources, which would also reduce associated microcystin concentrations. The calm, slow-moving reservoir habitat that supports seasonal nuisance and/or noxious phytoplankton blooms in the Hydroelectric Reach would be eliminated and the available data suggests that large blooms of *Microcystis aeruginosa* from upstream would not be transported through the Hydroelectric Reach into the Middle Klamath River and further downstream reaches. Therefore, the overall occurrence of nuisance and/or noxious phytoplankton blooms and associated toxins in the Middle and Lower Klamath River would be substantially reduced or eliminated. Drawdown of the reservoirs would begin in winter and would be largely complete by March/April (i.e., the beginning of the growth season) of dam removal year 2, so complete elimination of the reservoir environment would occur by the end of dam removal year 2 under the Proposed Project. Thus, the reductions in nuisance and/or noxious phytoplankton blooms transported downstream from the reservoirs would also occur by the end of dam removal year 2 and this would be a short-term benefit as well as a long-term benefit.

Long-term increases in annual total nutrient levels would occur in the Middle and Lower Klamath River due to the lack of continued interception of nutrients by the Lower Klamath Project dams (Potential Impact 3.2-8). However, possible summer and fall increases in nutrient concentrations following Lower Klamath Project dam removal (see Section 3.2.5.3 *Nutrients*), particularly directly downstream from Iron Gate Dam, would not substantially contribute to blue-green algae blooms downstream from the dam, due to the lack of the suitable habitat conditions required for extensive phytoplankton growth in the Klamath River (see discussion above under the Hydroelectric Reach). Some phytoplankton growth may still occur after dam removal in calm, slow-moving habitats along shorelines and protected coves and backwaters during low-flow periods in the Middle and Lower Klamath River, but these habitats already support growth of blue-green algae, including *Microcystis aeruginosa*, that results in occasional exceedances of 2016 CCHAB secondary thresholds and WHO guidelines (Falconer et al. 1999; Kann et al. 2010; State Water Board et al. 2010, updated 2016; Genzoli and Kann 2016, 2017). While total nutrient transport into the Middle and Lower Klamath River after dam removal would slightly increase under the Proposed Project, *Microcystis aeruginosa* cell density and microcystin concentrations in Middle and Lower Klamath River after dam removal are expected to decrease due to reduced transport of *Microcystis aeruginosa* and microcystin from the Hydroelectric Reach into the Middle and Lower Klamath River. Therefore, the slight increase in nutrient availability is not expected to support nuisance phytoplankton growth or blooms that exceed current levels.

This analysis suggests that the Proposed Project would have a positive effect on aquatic resources in the Klamath River downstream from Iron Gate Dam in the long term based on reductions in downstream transport and concentrations of phytoplankton and microcystin toxins to this area. Overall, under the Proposed Project, long-term reductions in nuisance and/or noxious phytoplankton blooms in the reservoirs in the Hydroelectric Reach would reduce or eliminate the transport of nuisance and/or noxious phytoplankton species, blooms of these phytoplankton species, and concentrations of algal toxins (e.g., microcystin) into the Middle and Lower Klamath River and would be beneficial.

Klamath River Estuary

Information relating current conditions of phytoplankton biomass, population dynamics, and nutrient limitation to phytoplankton growth in the Klamath River Estuary is limited even though blue-green algae cell concentrations are monitored monthly to bi-weekly during much of the year (Fetcho 2006, 2007, 2008, 2011; Sinnott 2011, 2012; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014; Gibson 2016). Consequently, it is difficult to determine the potential long-term effects that the Proposed Project would have on phytoplankton in the Klamath River Estuary. Existing information indicates that instances of elevated levels of *Microcystis aeruginosa* in the Klamath River Estuary correspond with elevated levels measured at upstream locations in the Lower Klamath River (see Section 3.4.2.5 *Klamath River Estuary*). Removal of the Lower Klamath Project would reduce or eliminate elevated

Microcystis aeruginosa levels in the Lower Klamath River (see discussion in the prior section), so levels in the Klamath River Estuary are also likely to be reduced or potentially eliminated. Klamath River tributaries may influence Klamath River Estuary cyanobacteria [blue-green algae] conditions; however, infrequent detections of low cyanobacteria [blue-green algae] concentrations and associated algal toxins at the mouth of major Klamath River tributaries downstream of Iron Gate Dam (e.g., Scott River) suggest that tributaries are a lesser influence on cyanobacteria [blue-green algae] concentrations in the Klamath River Estuary compared with the mainstem Klamath River (Kann et al. 2010).

As detailed for the Middle and Lower Klamath River, small increases in nutrient transport from the upper watershed could occur over the long term because of dam removal (Potential Impact 3.2-8). The potential nutrient increase to the Klamath River Estuary would be smaller than in the Middle and Lower Klamath River, with the Yurok Tribe analysis modeling an increase of approximately 0.15 mg/L or less total nitrogen and an increase of approximately 0.01 mg/L or less total phosphorus (see Figure 3.2-19). The Yurok Tribe analysis' estimate of nutrient increases conservatively includes assumptions that would tend to over-estimate the potential change, since it does not take into account other possible factors that may decrease nutrients upstream of Copco No. 1 Reservoir under the Proposed Project, such as TMDL implementation or elimination of peaking flows from hydropower operations. If reductions in nutrients do occur upstream of Copco No. 1 Reservoir, then there would be an even smaller long-term increase in nutrients to the Klamath River Estuary (Asarian et al. 2010).

Estimated long-term increases in nutrients to the Klamath River Estuary are less than or within current annual and inter-annual variations in nutrients, suggesting the additional nutrients would not stimulate an increase in phytoplankton growth beyond current conditions in the Klamath River Estuary. In the Klamath River Estuary between 2010 and 2014, the annual variation between maximum and minimum total nitrogen ranged from 0.28 to 0.55 mg/L, with a 0.13 to 0.18 mg/L variation in peak total nitrogen between years. The annual variation between maximum and minimum total phosphorus ranged from 0.03 to 0.15 mg/L, with a 0.01 to 0.12 mg/L variation in peak total phosphorus between years from 2010 to 2014 (Sinnott 2011b, 2012b; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014).

Some additional growth of nuisance and/or noxious phytoplankton species could occur in the Klamath River Estuary during summer and fall low-flow periods due to the previously mentioned small increase in nutrients. The relative increase in phosphorus would be particularly small such that the prevalence of nitrogen-fixing blue green algae species (i.e., *Aphanizomenon flos-aquae* and *Anabaena flos-aquae*) would be unlikely to change relative to existing conditions. Nitrogen availability in the water is relatively more important for *Microcystis aeruginosa* because it does not fix nitrogen from the air (Eldridge et al. 2012). Although nitrogen would also increase in the estuary water, *Microcystis aeruginosa* cell density and microcystin concentrations are likely to be the same or less than current conditions due to the lack of downstream transport of seasonal blooms of this species from Copco No. 1 and Iron Gate reservoirs. Under the Proposed Project, long-term reductions in nuisance and/or noxious phytoplankton blooms in the Hydroelectric Reach and the reduction or elimination of transport of phytoplankton cells and their associated toxins into the estuary would be beneficial for the Klamath River Estuary.

Pacific Ocean nearshore environment
The Pacific Ocean nearshore environment is not a suitable habitat for the freshwater phytoplankton species of concern (i.e., *Aphanizomenon flos-aquae*, *Anabaena flos-aquae*, *Microcystis aeruginosa*) therefore the Proposed Project would have no impact on these species. Further, nutrient increases in the Pacific Ocean nearshore environment due to the lack of continued interception by the Lower Klamath Project dams would be considerably less than the background supply of nutrients from coastal upwelling (Bruland et al. 2001; Bograd et al. 2009), so the nutrient increase is not expected to affect marine phytoplankton blooms.

Significance
Beneficial for the Hydroelectric Reach, Middle and Lower Klamath River, and Klamath River Estuary in the short term and long term

No significant impact for the Pacific Ocean nearshore environment in the short term and long term

3.4.5.2 Periphyton

Potential Impact 3.4-3 Short-term increase in growth of nuisance periphyton species due to increases in sediment-associated nutrients from release of sediments currently trapped behind the Lower Klamath Project dams.
Under the Proposed Project J.C. Boyle Reservoir would be removed in Oregon and Iron Gate, Copco No. 1, and Copco No. 2 reservoirs would be removed in California, releasing sediment accumulated behind each dam and transporting the sediment downstream through the Klamath River and into the Pacific Ocean (see 3.2.5.2 *Suspended Sediments* and 3.11.4 *Impact Analysis Approach).* Modeling indicates reservoir drawdown eroding and transporting between 5.4 and 8.6 million cubic yards of reservoir sediment downstream through the Klamath River (Table 2.7-11). Large quantities of sediment would remain in place after dam removal, primarily on areas above the active channel of the Klamath River and these remaining reservoir sediments would dry out, decrease in thickness, and stabilize in place within the historical reservoir footprints (see Section 2.7.3 *Reservoir Sediment Deposits and Erosion During Drawdown* for more details). Reservoir sediments consist primarily of fine and sand sediments (see Table 2.7-9) with the fine sediments mostly an accumulation of silt-size particles of organic material from dead and decaying algae and silt-size inorganic particles of rock (USBR 2012). Sediment-associated nutrients that have accumulated in the sediment deposits are primarily from dead algae and typically bound to the fine sediments (Deas 2008; Downs et al. 2010; USBR 2012).

In the short term, through winter and early to mid-spring of dam removal year 2 (Table 2.7-1), periphyton growth would be unlikely to be stimulated by sediment-associated nutrients or conversion of the reservoir areas to free-flowing streams and elimination of hydropower peaking operations. Short-term increases in sediment-associated nutrients would occur in the Hydroelectric Reach, Middle and Lower Klamath River, and the Klamath River Estuary due to the release of sediments currently trapped behind the dams (see Potential Impact 3.2-7). However, reservoir drawdown would occur during winter months when rates of periphyton growth and reproduction, which require nutrients, are relatively low due to less light availability for photosynthesis and lower water temperatures. As a result, the ability of periphyton to use sediment-associated nutrients would be limited and there would not be an increase in periphyton growth or reproduction during this period, even though additional nutrients would be available due to the release of sediments trapped behind the Lower Klamath Project dams. Light limitation from high concentrations of suspended sediments in the water (Potential Impact 3.2-3) would also reduce any potential for nuisance levels of periphyton growth during reservoir drawdown.

Additionally, high river flows during the winter drawdown period and late spring storm events would result in greater sediment movement and scouring under the Proposed Project (Potential Impacts 3.11-5 and 3.11-6), which would greatly limit, if not eliminate, the area of the streambed that periphyton can thrive during this period. At individual monitoring sites in the Klamath River, higher flow consistently corresponds to lower total periphyton biovolume, especially at sites with a larger variation in flows. After natural high flows due to storms, periphyton is reduced to a thin layer of scour-resistant diatoms, since some diatom species are well suited to withstand higher flows (Asarian et al. 2015). Three studies analyzed the flows required to mobilize the streambed downstream of Iron Gate Dam from the Klamath River confluence with Bogus Creek (RM 192.6) to either its confluence with the Shasta River (RM 179.5) or Blue Creek (RM 16.2) (dependent on study). An analysis of those studies indicates that under current conditions, flows between 5,000 to 8,700 cfs would move surface fine sediments on 20 to 30 percent of the streambed (i.e., surface flushing), flows between 8,700 and 11,250 cfs would move in-filled fine sediment between streambed cobbles (i.e., deep flushing), and flows between 11,250 to 15,000 cfs would move individual cobbles (i.e., armor disturbance) (Hillemeier et al. 2017). Modeling indicates that during drawdown flow downstream of Iron Gate Dam would exceed the minimum surface flushing flows for approximately one week to over one month between January and April under wet, above normal, and normal water year types, while flow would exceed the minimum armor disturbance flows for approximately one day to one week between January and February under wet and above normal water year types. Mobilization of the streambed during drawdown flows would also be expected to scour periphyton attached to the streambed sediments. This effect is particularly important for periphyton during winter because high drawdown or natural flows that move larger sediments like gravels and cobbles would limit and potentially eliminate short-term establishment of periphyton along the streambed and other underwater surfaces. This reduction in the area periphyton can establish and grow due to these high flows in winter and spring would result in decreases in the overall periphyton abundance in the river, further inhibiting uptake of sediment-associated nutrients by periphyton for growth as those nutrients are transported through the Klamath River.

Additional movement of reservoir sediment deposits not removed during drawdown in dam removal year 2 may occur during winter high flows in post-dam removal year 1 resulting in more transport of sediment-associated nutrients. However, growth of nuisance periphyton species would not be stimulated by these nutrients since they would be transported through the Klamath River during winter months when growth, reproduction, and nutrient transformation rates would be low, high flows may scour the streambed and reduce periphyton abundance, and suspended sediment during transport of sediment-associated nutrients would limit light availability for periphyton growth. Similar to conditions during reservoir drawdown, winter high flows that transport suspended sediments would result in minimal deposition of fine sediments, so minimal sediment-associated nutrients would deposit and be available to stimulate periphyton growth later in the year.

As the periphyton growth would be unaffected by mobilization of sediment-associated nutrients during dam removal year 2 (reservoir drawdown) and post-dam removal year 1, the Proposed Project would not increase the spatial extent, temporal duration, or biomass of nuisance periphyton species to the degree that new or further impairment of designated beneficial uses would occur in the Hydroelectric Reach, Middle and Lower Klamath River, or the Klamath River Estuary due to transport of sediment-associated nutrients from release of reservoir sediment deposits from behind the Lower Klamath Project dams, and there would be no short-term impact.

Significance

No significant impact

Potential Impact 3.4-4 Alterations in growth of nuisance periphyton species in the Hydroelectric Reach due to increased nutrients and available low-gradient channel margin habitat formed by conversion of the reservoir areas to a free-flowing river and the elimination of hydropower peaking operations.

Periphyton growth in low-gradient channel margin areas in the Hydroelectric Reach could increase on a seasonal basis following dam removal because removal of the reservoirs and elimination of hydropower operations in the J.C. Boyle Peaking Reach would provide additional low-gradient habitat suitable for periphyton assemblages. Dam removal, construction, and restoration activities in dam removal year 2 and sediment transport and scour during winter post-dam removal year 1 may reduce periphyton abundance and growth, but, overall, periphyton would be expected to begin colonizing the newly created suitable habitat within the short term and this colonization and growth of periphyton would continue in the long term.

The particular periphyton species that could occupy these areas are unknown (E. Asarian, pers. comm., 2011), but analysis of periphyton species downstream of Iron Gate Dam indicates the types of periphyton assemblages that could occur in the free-flowing Hydroelectric Reach under the Proposed Project (Asarian et al. 2015). The exact periphyton assemblage would be dependent primarily on nutrient availability and seasonal flow variations (Gillet et al. 2016).

Under the Proposed Project, there would be less artificial diel temperature variation during summer and early fall in the J.C. Boyle Peaking Reach from the Oregon-California state line to Copco No. 1 Reservoir (see also Potential Impact 3.2-1). While J.C. Boyle retains relatively little nutrients under existing conditions (see Appendix C, Section C.3.1.1 *Hydroelectric Reach*), nutrients could increase slightly if J.C. Boyle Dam is removed. However, less diel temperature variations and a slight decrease in the maximum water temperature in this reach are not anticipated to affect periphyton colonization. Additionally, the generally high gradient and velocity in the J.C. Boyle Peaking Reach does not currently support excessive periphyton mats and it is not anticipated that this reach would support excessive periphyton mats if J.C. Boyle Dam were to be removed and hydropower peaking flows were to cease. In the short term and long term, increases in periphyton biomass from elimination of peaking flows along with the change in water temperatures are expected to be limited in the Hydroelectric Reach from the Oregon-California state line to Copco No. 1 Reservoir and any potential increase in periphyton would not result in new or further impairment of designated beneficial uses. Thus, there would be a less than significant impact of the Proposed Project on periphyton colonization in this reach.

Further downstream, in the lower-gradient portions of the Hydroelectric Reach, from Copco No. 1 Reservoir to Iron Gate Dam, long-term heavy colonization of periphyton mats in the Hydroelectric Reach is unlikely as potential increases in periphyton growth could be disrupted by increased flow variability during storm flow under the Proposed Project (see also Potential Impact 3.6-3) and more frequent river bed sediment movement (see also Potential Impact 3.11-5). Removal of the Lower Klamath Project dams and reservoirs, particularly Copco No. 1 and Iron Gate reservoirs, would produce slightly higher peak flows and more flow variations because modeling indicates the Lower Klamath Project provides a slight attenuation (1.1 to 6.9 percent) of peak flood flows (USBR 2012) and storm flow variations from tributaries entering the Hydroelectric Reach are dampened by the reservoirs. Additionally, upstream fine and sand sediments currently trapped by the Lower Klamath Project reservoirs, particularly Copco No. 1 and Iron Gate reservoirs, would be transported and deposited along the Hydroelectric Reach streambed, so the flow necessary to mobilize the streambed in the existing riverine sections of the Hydroelectric Reach would be less than existing conditions. Together these processes (i.e., higher peak flows, more flow variations, and lower flow needed to move sediments) would result in more frequent sediment transport in the Hydroelectric Reach, which may result in increased scouring of periphyton during winter and spring storm events compared to existing conditions and a lower overall biomass later in the growth season (FERC 2007; North Coast Regional Board 2010, Appendix 2).

However, the overall effect of the Proposed Project would likely be to increase periphyton in the margins of low gradient portions of Copco No. 1 and Iron Gate reservoir footprints due to the creation of new, previously uncolonized low gradient river channels. While there is considerable uncertainty, there is the potential under the Proposed Project that nuisance periphyton species could be part of the periphyton assemblages that grow in the margins of these new low gradient river channels. The nuisance periphyton species would potentially provide habitat for the polychaete worm (*Manayunkia speciose*) that is the intermediate host of the fish parasites *Ceratomyxa shasta* and *Parvicapsula minibicornis,* so the short-term and the long-term increase in growth of nuisance periphyton species due to increases in available habitat along channel margin areas of the Hydroelectric Reach within the Copco No. 1 and Iron Gate reservoir footprints also would potentially result in a new or further impairment of designated beneficial uses, and would therefore be a significant impact.

The above analysis represents a conservative assessment of the effects of the Proposed Project on short-term and long-term growth of nuisance periphyton species. The response of periphyton in the Klamath River is subject to many competing processes that could either accelerate or hinder periphyton growth and potential increases in nuisance periphyton species (i.e., *Cladophora* sp.) extent, duration, and biomass. In the long term, improvements (i.e., reductions in periphyton biomass) are expected from several processes such as scour, and in-stream nutrient retention processes, but periphyton biomass reductions could be diminished by processes such as reduced nutrient retention from the loss of the reservoirs or climate change. While the growth of nuisance periphyton species along channel margin areas is not expected to contribute algal toxins that would impair water quality, the degree to which designated beneficial uses would be impaired due to an increase in nuisance periphyton species (i.e., *Cladophora* sp.) in the newly formed low-gradient channel margin areas of the Hydroelectric Reach is not fully understood. The implications of potential changes in periphyton biomass and community composition on dissolved oxygen and the spread of fish disease are described in Section 3.2.5.4 *Dissolved Oxygen* and Section 3.3.5.5 *Fish Disease and Parasites*, respectively.

Periphyton are a natural component of river ecology and they are an important element of aquatic food webs. The establishment and growth of periphyton, including nuisance periphyton species, along the margins of the newly created low gradient river channel is a natural process. While processes that influence periphyton establishment and growth have been identified (e.g., light availability, nutrient availability, water temperature, seasonal flow variations, sediment transport), variations in these processes within the Hydroelectric Reach of the Klamath River after dam removal would not completely prevent the potential for growth of nuisance periphyton species along the margins of the newly created low gradient river channels. In the reservoir areas of the Hydroelectric Reach that would become the newly created low gradient habitat, there is no periphyton since it is not suitable habitat. No mitigation measure would completely eliminate the potential for establishment and growth of periphyton or specifically nuisance periphyton within these areas. As such, there are no mitigation measures that can be proposed to significantly avoid or minimize this impact and reduce the impact to less than significant.

Significance

No significant impact for the Hydroelectric Reach from the Oregon-California state line to Copco No. 1 Reservoir in the long term

Significant and unavoidable for the Hydroelectric Reach from Copco No. 1 Reservoir to Iron Gate Dam in the long term

Potential Impact 3.4-5 Alterations in biomass of nuisance periphyton species due to increased nutrients from upstream dam removal and conversion of the reservoir areas to a free-flowing river.

Middle and Lower Klamath River

As described in Section 3.4.2.4 *Middle and Lower Klamath River*, seasonal periphyton growth under existing conditions is relatively high in the Middle and Lower Klamath river (Eilers 2005). Under the Proposed Project, the Lower Klamath Project dams would no longer trap and store annual upstream nutrient inputs nor create the conditions where nutrients stored in reservoir sediments would be seasonally released downstream resulting in an anticipated overall less-than-significant long-term increase in absolute nutrient concentrations (see Section 3.2.5.3 *Nutrients*, Potential Impact 3.2-8 for more details).

The long-term increase in Total Nitrogen (TN) and Total Phosphorus (TP) are not expected to result in a significant biostimulatory effect on periphyton growth because nutrients do not appear to be limiting periphyton growth in the Klamath River from Iron Gate Dam (RM 193.1) to approximately Seiad Valley (RM 132.7) (and potentially farther downstream), N-fixing periphyton are abundant in the Lower Klamath River, and the increase in TP is minimal. While existing data regarding TN:TP ratios in the Klamath River suggest the potential for N-limitation (TN:TP <10), with some periods of co-limitation by N and P (see also Section 3.2.2.4 *Nutrients* and Appendix C – Section C.3.2 *Mid- and Lower Klamath Basin*), concentrations of both nutrients are high enough in the river from Iron Gate Dam to approximately Seiad Valley (and potentially further downstream) that periphyton growth is currently nutrient saturated. Nutrients are not likely to be limiting periphyton growth in this portion of the Klamath River (FERC 2007;

HVTEPA 2008; Asarian et al. 2010, 2014, 2015; Gillet et al. 2016) and additional upstream nutrients would not alter periphyton conditions in this reach. While there would be long-term increases in nutrients due to dam removal, seasonal (i.e., fall) downstream releases of nutrients stored in reservoir sediments would also be eliminated by removing the reservoirs and the overall magnitude of the long-term increases in nutrients available to stimulate periphyton growth downstream of the reservoirs would be less during fall. In the lower reaches of the Klamath River (i.e., downstream of approximately Seiad Valley), where inorganic nitrogen concentrations are low, N-fixing periphyton species currently dominate the periphyton communities (Asarian et al. 2010, 2014, 2015; Gillet et al. 2016). Since N-fixing species can fix their own nitrogen from the atmosphere, increases in TN due to dam removal may alter the composition of the periphyton community and shift the location where N-fixing species begin to dominate farther downstream in the Lower Klamath River (Asarian et al. 2010). However, the Proposed Project would be accompanied by only relatively minor increases in TP, so it is not expected to significantly increase periphyton biomass in these reaches.

In addition to the effects of changes in nutrient concentrations, periphyton community composition and biomass may be affected by light levels and substrate stability. As discussed for the Hydroelectric Reach (Potential Impact 3.4-4), potential increases in periphyton growth could be counteracted by increased flow variability during storm flow (see also Potential Impact 3.6-3) and by more frequent river sediment movement (Potential Impact 3.11-5). Removal of the Lower Klamath Project dams and reservoirs would produce more flow variations because modeling indicates the Lower Klamath Project dams provide a slight attenuation (1.1 to 6.9 percent) of peak flood flows (USBR 2012) and storm flow variations from tributaries entering the Hydroelectric Reach are dampened by the reservoirs. Additionally, upstream fine and sand sediments currently trapped by the Lower Klamath Project reservoirs would be transported and deposited downstream, so the flow necessary to mobilize the streambed would be less than under existing conditions. Together these processes would potentially increase scour of periphyton during winter and spring storm events following dam removal compared to existing conditions (FERC 2007; North Coast Regional Board 2010, Appendix 2). The magnitude of the effect of bed turnover and scouring on periphyton would decrease with distance downstream, with increased scour occurring from Iron Gate Dam to approximately the Shasta River (RM 179.5). TMDL model results suggest that increased scouring may somewhat limit long-term periphyton biomass following dam removal (North Coast Regional Board 2010, Appendix 2). Overall, these processes would reduce periphyton growth downstream from Iron Gate Dam.

Because of these many competing factors, some that may favor enhanced periphyton growth downstream from Iron Gate Dam (i.e., increasing nutrient transport and recycling), and some that counteract this response (i.e., increasing uptake and retention of nutrients by periphyton in the Hydroelectric Reach, increasing frequency and intensity of scouring events, eliminating seasonal nutrient releases from reservoir sediments), it is likely that long-term increases in periphyton growth in the Middle and Lower Klamath River, should they occur, would not be sufficient to result in an overall increase in the growth, extent, duration, or biomass of nuisance periphyton species, and would therefore be less than significant.

Klamath River Estuary

As discussed for the Middle and Lower Klamath River, periphyton growth in the Klamath River Estuary could be affected by increased nutrient availability following dam removal.

Long-term increases in nutrients in the Klamath River Estuary would be relatively small due to tributary dilution and nutrient retention in the 190 river miles between Iron Gate Dam and the Klamath River Estuary, with the Yurok Tribe analysis modeling reporting a potential increase of approximately 0.15 mg/L or less total nitrogen and approximately 0.01 mg/L or less total phosphorus in the Klamath River Estuary (see Figure 3.2-19; Asarian et al. 2010). The Yurok Tribe analysis' estimate of nutrient increases conservatively includes assumptions that would tend to over-estimate the potential change since it does not consider other possible factors that may decrease nutrients under the Proposed Project, such as full TMDL implementation or elimination of peaking flows from hydropower operations upstream of Copco No. 1 Reservoir. There would be an even smaller long-term increase in nutrients to the Klamath River Estuary, if these other factors occur (Asarian et al. 2010).

Estimated long-term increases in nutrients to the Klamath River Estuary are less than or within current annual and inter-annual variations in nutrients, suggesting the long-term increases in nutrients would not result in an increase in periphyton growth beyond the range occurring under existing conditions. In the Klamath River Estuary between 2010 and 2014, the annual variation between maximum and minimum total nitrogen ranged from 0.28 to 0.55 mg/L, with a 0.13 to 0.18 mg/L variation in peak total nitrogen between years. The annual variation between maximum and minimum total phosphorus ranged from 0.03 to 0.15 mg/L, with a 0.01 to 0.12 mg/L variation in peak total phosphorus between years from 2010 to 2014 (Sinnott 2011b, 2012b; Hanington and Torso 2013; Hanington and Stawasz 2014; Hanington and Cooper-Carouseli 2014). These annual variations are less than the estimated long-term increases in total nitrogen (i.e., 0.15 mg/L or less) and total phosphorus (i.e., 0.01 mg/L or less) and the inter-annual variations in peak nutrient concentrations are within the estimated long-term increases in nutrient concentrations. Variations in the growth of periphyton that rely on nitrogen in the water for growth (i.e., non-nitrogen fixing species like *Cladophora* sp.) would be expected to be within the range of existing conditions since the estimated long-term increase in nitrogen is within the range of total nitrogen variations under existing conditions. Additionally, nitrogen-fixing species that can fix their own nitrogen from the atmosphere dominate the periphyton communities in the lower reaches of the Klamath River where inorganic nitrogen concentrations are low (Asarian et al. 2010, 2014, 2015; Gillet et al. 2016) and these species also likely dominate the periphyton community in the estuary. Increases in total nitrogen due to dam removal are not likely to significantly increase periphyton biomass of these species in the Klamath River Estuary, since additional nitrogen could be obtained from the atmosphere by these periphyton, regardless of nutrient inputs. Some variation in periphyton growth could occur in the Klamath River Estuary due to the long-term increase in phosphorus. However, the estimated long-term increase in phosphorus is on the low end of natural variations in phosphorus in the Klamath River Estuary, so the growth and abundance of periphyton species, including nuisance periphyton species, in the estuary would likely remain within the current annual variation in periphyton growth.

Overall, the biological significance of potential increases in periphyton biomass in the Klamath River Estuary and its influence on designated beneficial uses is unknown due to uncertainty regarding the magnitude of increase in biomass required to generate a significant reduction in habitat quality for aquatic resources (North Coast Regional Board 2010, Appendix 2). Nonetheless, for the reasons described above, under the Proposed Project long-term increases in the growth of nuisance periphyton species in the Klamath

Estuary would be a less-than-significant impact since they would be within the range of existing conditions.

Significance

No significant impact for the Middle and Lower Klamath River and the Klamath River Estuary

3.5 Terrestrial Resources

This section describes existing conditions of terrestrial resources in the Area of Analysis and analyzes potential impacts that the Proposed Project would have on these resources. Terrestrial resources include existing terrestrial vegetation and rare natural communities[108] and their value as habitat for wildlife; terrestrial special-status[109] wildlife and plant species; use and dependence of terrestrial species on riparian, wetland, and aquatic reservoir habitat; and terrestrial wildlife corridors.

A moderate number of comments were received during the NOP public scoping process relating to terrestrial resources (see Appendix A). The majority of commenters stated that the existing reservoirs provide breeding and resting habitats for many wildlife species, and these species should be considered and studied to assess impacts from dam removal. For example, one commenter recommended that the best available science be used to inform dam removal and riparian restoration planning and that robust regional avian science and conservation objectives be integrated into planning and evaluation. Comments associated with aquatic wildlife (e.g., whales and sea lions) are addressed in Section 3.3 *Aquatic Resources*. A summary of the terrestrial resource comments received during the NOP public scoping process, as well as the individual comments themselves, are presented in Appendix A.

3.5.1 Area of Analysis

The Area of Analysis for terrestrial resources (Figure 3.5-1) is the California portion of the Klamath Basin that may be influenced by the Proposed Project and focuses on terrestrial resources downstream from the dams proposed for removal, within the reservoir footprints, and upstream of and surrounding the reservoirs in areas that may be impacted by construction activities.

For this EIR, the Area of Analysis for terrestrial resources is subdivided into two areas, the Primary Area of Analysis and the Secondary Area of Analysis (Figure 3.5-1). The Primary Area of Analysis includes areas associated with proposed dam removal activities and reaches of the Klamath River that have the potential to be affected by dam removal, whereas the Secondary Area of Analysis accounts for potential future actions during the transfer of Parcel B lands to the respective states (i.e., California or Oregon), or to a designated third-party transferee following dam removal (see also Section 2.7.10 *Land Disposition and Transfer*. The analysis for this EIR focuses mainly on the Primary Area of Analysis. For the Secondary Area of Analysis, the EIR briefly reviews potential

[108] Rare natural communities are defined as those natural community types with a state ranking of S1 (critically imperiled), S2 (imperiled), or S3 (vulnerable).

[109] Special-status species are defined as those species listed, proposed, or under review as endangered or threatened under the federal Endangered Species Act (ESA) or the California Endangered Species Act (CESA); and those designated by the USDA Forest Service as sensitive or watch list species. Additional listings for plants include those listed as rare under the California Native Plant Protection Act and/or included on CDFW's most recent *Special Vascular Plants, Bryophytes, and Lichens List* with a California Rare Plant Rank (CRPR) of 1, 2, 3, or 4 (CDFW 2017a). Additional listings for wildlife include those designated as a Species of Special Concern by CDFW; designated as Fully Protected under the California Fish and Game Code (Sections 3511, 4700, 5050, and 5515); and/or protected under the federal Bald and Golden Eagle Protection Act.

future actions on Parcel B lands following dam removal. However, because of uncertainty regarding what activities, their extent, and their precise location, this analysis is necessarily less detailed.

The Primary Area of Analysis is defined as the Limits of Work plus a 0.25-mile buffer, which includes the Proposed Project construction locations in California (e.g., Proposed Project facilities, staging and disposal areas, recreation locations, transmission lines), the Klamath River reaches from the Oregon-California state line to the Pacific Ocean, and the three California Lower Klamath Project reservoirs (Copco No. 1 Reservoir, Copco No. 2 Reservoir, and Iron Gate Reservoir) (Figure 3.5-1). The 0.25-mile buffer was included to account for terrestrial wildlife species that may occur adjacent to the Limits of Work and may be potentially affected by the Proposed Project activities. For northern spotted owl, the Primary Area of Analysis includes a 0.25-mile, 0.-5 mile, or up to a 1-mile buffer around the Limits of Work to address the potential for noise impacts due to blasting and revegetation activities from helicopters or use of heavy equipment (e.g., disking) as part of the Proposed Project. The northern spotted owl buffer is based on a disturbance distance, which is defined as the distance at which an owl, if present, could be distracted from its normal activity (USFWS 2008). Specifically, the Primary Area of Analysis for the northern spotted owl is a 1-mile buffer around Copco No. 1, Copco No. 2, and Iron Gate dams to account for the loudest noise disturbance distance associated with blasting, a 0.5-mile buffer around the reservoirs to account for the loudest noise disturbance distance associated with helicopter use, and a 0.25-mile buffer around all other areas within the Limits of Work to account for noise disturbance associated with heavy equipment (Figure 3.5-1). The Secondary Area of Analysis includes Parcel B lands (Figure 3.5-1).

Proposed Project activities have the potential to affect terrestrial resources at the following locations (a complete list of Proposed Project activities are provided in Section 2.7 *Proposed Project*):

- Copco No. 1—upgrading haul routes/bridges; establishing a disposal site; and removing four 69-kV transmission lines, recreation structures (i.e., Mallard Cove and Copco Cove), dam, penstocks, spillway gates, decks, piers, powerhouse intake structure, gate houses on right abutment, diversion control structure, powerhouse, switchyard, warehouse, and operator residence (see also Table 2.7-3 and Figure 2.7-2).
- Copco No. 2—upgrading haul routes/bridges; establishing a disposal site (same as Copco No. 1); and removing the 69-kV transmission lines, dam, power penstock intake structure, wooden-stave penstock, spillway, concrete pipe cradles, steel penstock, supports, anchors, powerhouse, and tailrace (see also Table 2.7-4 and Figure 2.7-2).
- Iron Gate—upgrading haul routes/bridges; establishing a disposal site; and removing the dam, unused transmission lines and diversion tunnel control gate and tunnel portals, penstock, fish facilities on dam, powerhouse, switchyard, recreation structures (i.e., Fall Creek recreation, Jenny Creek recreation, Wanaka Springs recreation, Camp Creek recreation, Juniper Point recreation, Mirror Cove recreation, Overlook Point recreation, Long Gulch recreation, Iron Gate Hatchery Public Use Area recreation), and water supply pipes (see also Table 2.7-5 and Figure 2.7-4).
- Improvements to the City of Yreka water supply pipeline.

- Modifications to the Fall Creek and Iron Gate hatcheries.

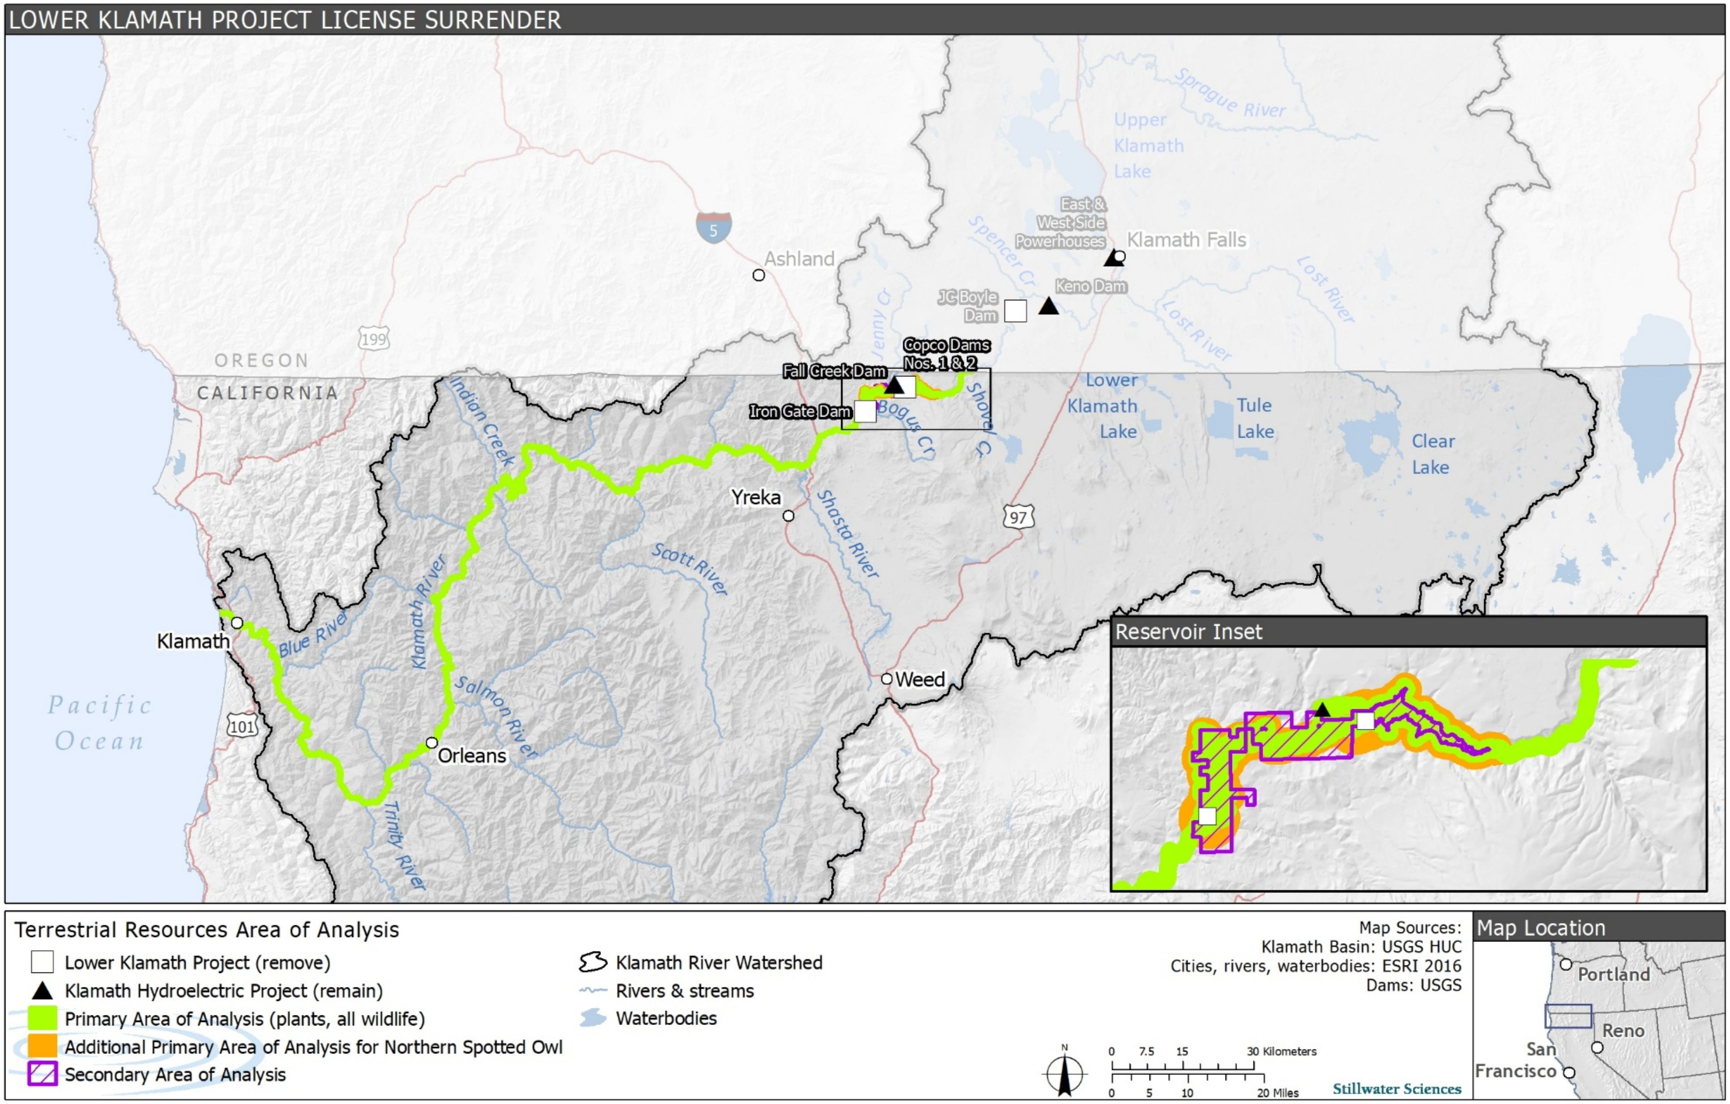

Figure 3.5-1. Area of Analysis for Terrestrial Resources.

3.5.2 Environmental Setting

This section provides a description of the environmental setting for terrestrial resources in the Primary Area of Analysis, including vegetation communities (current and historic), invasive plant species, culturally significant plant species, non-special-status wildlife, and special-status species (plants and wildlife).

The Primary Area of Analysis for terrestrial resources includes diverse habitats ranging from wetland surfaces just below sea level in the Klamath River Estuary (-0.16 ft elevation) to the slopes above the Upper Klamath River near the California-Oregon state line (3,428 ft elevation). The Primary Area of Analysis for terrestrial resources is within the California-Florisic Province and includes the High Cascade Subregion of the Cascade Region and the North Coast, North Coast Ranges, and Klamath Range Subregions of the Northwest Region as defined in The Jepson manual (Baldwin et al. 2012). The High Cascade Subregion is characterized by ponderosa pine (*Pinus ponderosa*), montane fir/pine, and lodgepole pine (*Pinus contorta* subsp. *murrayana*) forests. The North Coast Subregion supports coastal vegetation including coastal prairie, coastal marsh, coastal scrub, closed-cone pine/cypress forest and grand fir (*Abies grandis*)/Sitka spruce (*Picea sitchensis*) forest. The Outer North Coast Ranges District is characterized by very heavy rainfall and supports redwood (*Sequoia sempervirens*), mixed-evergreen and mixed-hardwood forests (Baldwin et al. 2012). The Klamath Range subregion is also characterized by heavy rainfall and is geologically old and serpentine-rich. The Klamath-Siskiyou mountain ranges are recognized for their biological diversity, supporting more than 3,000 plant species including 30 temperate conifer tree species including Douglas-fir (*Pseudotsuga menziesii* var. *menziesii*), ponderosa pine, and sugar pine (*Pinus lambertiana*) (CDFG 2006, Baldwin et al. 2012).

3.5.2.1 Vegetation Communities

Current Vegetation

Information in this section was obtained primarily from the PacifiCorp Final Technical Report on terrestrial resources prepared for the Klamath Hydroelectric Project (PacifiCorp 2004a,b) in combination with the Classification and Assessment with Landsat of Visible Ecological Groupings (CALVEG) datasets available through the California Land Cover Mapping and Monitoring Program (United States Department of Agriculture Forest Service [USDA] Forest Service 2017a) and data from USFWS (2017); additional information was obtained from the CDM Smith's 2018 surveys (CDM Smith 2018a) that covered a portion of the Primary Area of Analysis for terrestrial resources. Table 3.5-1 summarizes the vegetation cover types documented in the Primary Area of Analysis for terrestrial resources based on the California Wildlife Habitat Relationships (CWHR) System (California Department of Wildlife [CDFW] 2014a), and Figures 1 through 66 of Appendix G display the mapped vegetation. Additional habitat types mapped but not included in Table 3.5-1 include a total of 794 acres of agricultural lands (Cropland, Deciduous Orchard, and Pasture), 2,554 acres of developed areas, 1,286 acres of unvegetated habitat (barren, exposed rock and rock talus) and 10,938 acres of aquatic habitat (Riverine, Lacustrine and Marine; USDA Forest Service 2017a). Below is a general description of each CWHR vegetation type within California including specific information regarding the location and acreage of each type within the Primary Area of Analysis. Vegetation types with one acre or less in the Primary Area of Analysis for terrestrial resources are not included in this discussion.

Table 3.5-1. Vegetation Types Documented in the Primary Area of Analysis for Terrestrial Resources.[1]

CHWR Vegetation Cover Types (USDA-FS2017a, USFWS 2017a)	Reaches[2]				Total ac (Percent of total[3])

1 All vegetation types with a total of one acre or less documented in the Primary Area of Analysis for terrestrial resources are not included in this table.
2 Defined in Figure 2.4-3.
3 Percent of total for vegetation types within the terrestrial resources Primary Area of Analysis; excludes other habitat types (e.g., agricultural lands).
4 Not a CWHR type; based on the Cowardin classification for wetlands and deepwater habits (Cowardin et al. 1979.
5 Totals listed are based on numbers that were not rounded to the nearest acre so may vary slightly from the total derived from adding the acreages per vegetation type as they appear in the table.

Appendix H lists the rare natural communities[110] documented in the Proposed Project vicinity (i.e., the USGS 7.5-minute quadrangles in which the Primary Area of Analysis for terrestrial resources is located and the adjacent quadrangles) in CDFW's California

[110]Rare natural communities are defined as vegetation types with a ranking of S1 (critically imperiled), S2 (imperiled), or S3 (vulnerable) by CDFW.

Natural Diversity Database (CNDDB) (CDFW 2017a) and notes which of those rare natural communities have the potential to be present in the Primary Area of Analysis for terrestrial resources. CDM Smith's 2018 surveys (CDM Smith 2018a) classified vegetation to the alliance level[111] according to the online edition of *A Manual of California Vegetation* (CNPS 2018). Alliances documented during these surveys, including those that are considered rare natural communities, are noted below in the corresponding CWHR type with the exception of the stand of *Hesperocyparis bakeri* Woodland Alliance, a rare natural community, that was documented at Iron Gate Reservoir; it is not included in descriptions below as the corresponding CWHR type (Closed-cone Pine-cypress) has not been documented in the Primary Area of Analysis.

Upland Habitats

Annual Grassland

In California, Annual Grassland occurs throughout the state, mostly on flat plains to gently rolling foothills and on a variety of soil types (CDFW California Interagency Wildlife Task Group 2014a). Annual Grassland accounts for approximately nine percent (5,223 acres) of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Hydroelectric Reach and the Middle Klamath River where it occurs in scattered patches that are most concentrated toward the northern end of the Hydroelectric Reach (Appendix G).

Annual Grassland is dominated by non-native, annual plant species. Common grasses include wild oats (*Avena* spp.), soft chess (*Bromus hordeaceus*), ripgut brome (*Bromus diandrus*), red brome (*Bromus madritensis*), and wild barley (*Hordeum* spp.). Common forbs include filaree (*Erodium* spp.), turkey mullein (*Ereomocarpus setigerus*), true clover (*Trifolium* spp.), bur clover (*Medicago* spp.), and popcorn flower (*Plagiobothrys* spp.) (CDFW California Interagency Wildlife Task Group 2014aCDFW California Interagency Wildlife Task Group 2014a). During 2018 surveys the following alliances (based on the online edition of *A Manual of California Vegetation* [CNPS 2018]) were documented that fall within the Annual Grassland CWHR type: *Bromus tectorum - Taeniatherum caput-medusae* Herbaceous Semi-Natural Alliance (Iron Gate, Copco No. 1, and Copco No. 2 reservoirs); and *Bromus* (*diandrus, hordaceus*) – *Brachypodium distachyon* Herbaceous Semi-Natural Alliance (Copco No. 1 and Copco No. 2 reservoirs; CDM Smith 2018a).

Coastal Oak Woodland

In California, Coastal Oak Woodland occurs in the coastal foothills and valleys from Trinity County to northern Baja California. Soils and parent material are extremely variable (CDFW California Interagency Wildlife Task Group 2014a). Coastal Oak Woodland accounts for approximately three percent (1,398 acres) of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Lower Klamath River toward the eastern end of the reach. There are also a few scattered patches in the Middle Klamath River (Appendix G).

Coastal Oak Woodland is often dominated by Coast live oak (*Quercus agrifolia*). Other overstory species may include: Oregon oak (*Quercus garryana*), California black oak (*Quercus kelloggii*), canyon live oak (*Quercus chrysolepis*), Pacific madrone (*Arbutus menziesii*) and interior live oak (*Quercus wislizeni*); however, where these species

[111] A category of vegetation classification defined in A Manual of California Vegetation (CNPS 2018) describing repeating patterns of plants across a landscape with consistent plant species composition (CNPS 2018).

dominate, the habitat is considered Montane Hardwood. Typical Coastal Oak Woodland understory shrubs include: California blackberry (*Rubus ursinus*), creeping snowberry (*Symphoricarpos mollis*), and toyon (*Heteromeles arbutifolia*). The herbaceous layer includes natives such as western bracken fern (*Pteridium aquilinum*), California polypody (*Polypodium californica*), and miner's lettuce (*Claytonia perfoliata*), as well as a high percentage of non-native, annual grasses (e.g., bromes and oats) (CDFW California Interagency Wildlife Task Group 2014a). During 2018 surveys, the following alliances were documented that fall within the Coastal Oak Woodland CWHR type: *Quercus garryana* (tree) Woodland Alliance (a rare natural community; Iron Gate, Copco No. 1, and Copco No. 2 reservoirs) and *Quercus kelloggii* Forest Alliance (Copco No. 1 and Copco No. 2 reservoirs; CDM Smith 2018a).

<u>Coastal Scrub</u>

Coastal Scrub occurs discontinuously in a narrow band along the Pacific Coast on steep, south-facing slopes and on sandy, mudstone, or shale soils. It usually occurs within 20 miles of the ocean at elevations ranging from sea level to 3,000 feet (CDFW California Interagency Wildlife Task Group 2014a). Coastal Scrub accounts for less than one percent (91 acres) of the Primary Area of Analysis for terrestrial resources and occurs towards the southern end of the Lower Klamath River, and in larger patches closer to the Klamath River Estuary (Appendix G).

In exposed areas very close to the ocean, Coastal Scrub includes yellow bush lupine (*Lupinus arboreus*), which is naturalized to the area (Jepson Herbarium 2017) and many-colored lupine (*Lupinus variicolor*). Farther inland, and in more protected areas, the habitat type is dominated by coyote bush, blue blossom ceanothus, coffeeberry, bush monkey flower (*Mimulus aurantiacus*), blackberry (*Rubus spp.*), poison oak, and salal. Bracken fern, swordfern (*Polystichum californicum*), cow parsnip (*Heracleum lanatum*), several species of Indian paint brush (*Castilleja spp.*), yerba buena *(Satureja douglasii*), and California oatgrass *(Danthonia californica)* are common ground cover species (CDFW California Interagency Wildlife Task Group 2014a).

<u>Douglas Fir</u>

Douglas Fir occurs in the north Coast Range of California, from Sonoma County north to the Oregon border at elevations ranging from 500 to 2,000 feet and in the Klamath Mountains of California and Oregon at elevations from 1,000 to 4,000 feet (CDFW California Interagency Wildlife Task Group 2014a). Relative to the Redwood CWHR habitat type, Douglas Fir occurs on drier sites with poorer soils; soil types include sedimentary granitic and ultramafics (gabbro, peridotite, and serpentine) (CDFW California Interagency Wildlife Task Group 2014a). Douglas Fir accounts for approximately 23 percent (12,902 acres) of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Middle Klamath River; large, dense patches are also concentrated along the Lower and Middle Klamath River reaches (Appendix G). Though it has not been documented, the rare natural community type, Upland Douglas Fir Forest, may be present within the areas classified as Douglas Fir in the Primary Area of Analysis for terrestrial resources (Holland 1986; Appendix H).

The Douglas Fir habitat type is composed of a canopy of at least 50 percent Douglas-fir and a sub-canopy level of broad-leaved evergreen trees. Plant species composition varies with soil parent material, moisture, topography, and disturbance history. Sub-dominant tree species on less rocky, dry soils include canyon live oak, tanoak (*Notholithocarpus densiflorus*), Pacific madrone, and California black oak. A wide range of understory shrubs may be present, varying primarily by soil type and along a moisture gradient, and include the following: Oregon grape (*Berberis aquifolium*), California blackberry, dwarf rose (*Rosa gymnocarpa*), poison oak (*Toxicodendron diversilobum*), vine maple (*Acer circinatum*), California hazel (*Corylus cornuta*), salal (*Gaultheria shallon*), California rhododendron (*Rhododendron macrophyllum*), California laurel (*Umbellularia californica*), California buckthorn (*Rhamnus californica*), and white oak (CDFW California Interagency Wildlife Task Group 2014a).

<u>Jeffrey Pine</u>
Jeffrey Pine occurs in the Klamath Mountains, North Coast Range, Cascade Range, Modoc Plateau, Sierra Nevada, Transverse Range, and the Peninsular Range in California at elevations ranging from 500 to 9,500 feet. Jeffrey Pine habitat is associated with Douglas-fir at its lower elevations and subalpine conifer at its higher elevations in the Klamath Mountains (CDFW California Interagency Wildlife Task Group 2014a). Jeffrey Pine accounts for less than 1 percent (62 acres) of the Primary Area of Analysis for terrestrial resources; a few scattered patches occur in the Middle Klamath River (Appendix G).

Jeffrey Pine habitat is characterized by stands of Jeffrey pine (*Pinus jeffreyi*) as it is the dominant and typically the only species in the canopy layer. Jeffrey pines are generally 98 to 164 feet tall at maturity. Common species include other pines such as ponderosa, Coulter (*Pinus coulteril)*, sugar, and lodgepole pines, as well as red fir (*Abies magnifica*), white fir (*Abies concolor*), incense cedar (*Calocedrus decurrens*), and black cottonwood (*Populus trichocarpa*). The secondary tree layer (i.e., a layer of trees below the canopy layer) is typically composed of aspen (*Populus tremuloides*) on moist sites, California black oak on mesic sites, and pinyon pine (*Pinus monophylla*) and western juniper (*Juniperus occidentalis*) on drier sites. Huckleberry (*Vaccinium spp.),* oak (*Quercus* spp.), manzanita (*Arctostaphylos* spp.), Fremont silktassel (*Garrya fremontii*), and coffeeberry (*Frangula* spp.) dominate the shrub layer (CDFW California Interagency Wildlife Task Group 2014a).

<u>Juniper</u>
In California, Juniper occurs in the Modoc Plateau, portions of the Cascades, higher elevations of the Sierra Nevada, a number of the smaller interior coast ranges, and parts of the Mojave Desert (CNPS 2018), at elevations ranging from 330 to 10,170 feet. Juniper accounts for approximately one percent (643 acres) of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Middle Klamath River, with a few, scattered patches occurring in the Hydroelectric Reach (Appendix G).

Juniper habitat type is characterized by an open to dense overstory of juniper (*Juniperus* spp.) with grass and shrub understories. Junipers are generally 15 to 30 feet tall at maturity. Common species include white fir and Jeffery and ponderosa pines, as well as curl leaf mountain-mahogany (*Cercocarpus ledifolius*), antelope bitterbrush (*Purshia tridentata*), and big sagebrush (*Artemisia tridentata* subsp. *tridentata*) (CDFW California Interagency Wildlife Task Group 2014a, CNPS 2018). During 2018 surveys, *Juniperus occidentalis* Woodland Alliance was documented at Iron Gate Reservoir (CDM Smith 2018a).

<u>Klamath Mixed Conifer</u>
Klamath Mixed Conifer is found in the Klamath Region of northern California and southern Oregon. The region covers a complex of small mountain ranges, including the

Trinity Alps, which are characterized by glacially influenced topography of rugged steep slopes and deeply scoured terrain. Klamath Mixed Conifer is generally found between 4,500 and 6,900 feet (CDFW California Interagency Wildlife Task Group 2014a). Klamath Mixed Conifer accounts for less than one percent (72 acres) of the Primary Area of Analysis for terrestrial resources, with only a few scattered patches in the Middle Klamath River (Appendix G).

Klamath Mixed Conifer generally forms a dense overstory with a mixture of conifers and the occasional broad-leaved species. The understory is often a rich shrub layer, including small individuals of the overstory species, with a well-developed herbaceous layer. The dominant conifer species include white fir, Douglas-fir, ponderosa pine, incense cedar, and sugar pine. Shrub and herbaceous species include Sierra laurel (*Leucothoe davisiae*), Sadler oak (*Quercus sadleriana*), dwarf rose (*Rosa bridgesii*), thimbleberry (*Rubus parviflorus*), twinberry (*Lonicera involucrate*), rattlesnake plantain (*Goodyera oblongifolia*), and prince's pine (*Chimaphila* spp.) (CDFW California Interagency Wildlife Task Group 2014a).

<u>Mixed Chaparral</u>

Mixed Chaparral is an evergreen sclerophyllous shrubland type that occurs in the foothills and mid to upper mountain sides of the coast ranges as well as the Sierra Nevada, at elevations below 5,000 feet (Barbour et al. 2007). Mixed Chaparral can occur on all slope aspects and is most common on north-facing slopes at lower elevations. In these areas, shrubs adapted to dry conditions and soils with low nutrients are able to out-compete trees (CDFW California Interagency Wildlife Task Group 2014a). Mixed Chaparral accounts for approximately nine percent (4,694 acres) of the total acreage of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Middle Klamath River, with dense patches occurring on the northern end of the Middle Klamath River (Appendix G).

Mixed Chaparral forms dense stands on thin soils found on steep, north-facing slopes and varies north-to-south and depending upon precipitation regime, aspect, and soil type. Common shrub species include chamise (*Adenostoma fasciculatum)*, toyon, California yerba-santa (*Eriodictyon californicum*), and silk-tassel (*Garrya* spp.) (CDFW California Interagency Wildlife Task Group 2014a). During 2018 surveys, the following alliances were documented that fall within the Mixed Chaparral CWHR type: *Ceanothus cuneatus* Shrubland Alliance (Iron Gate and Copco Nos. 1 and 2 reservoirs); *Rhus trilobata - Crataegus rivularis - Forestiera pubescens* Shrubland Alliance (a rare natural community; Iron Gate Reservoir); and *Cercocarpus montanus* Shrubland Alliance (Copco No. 1 and Copco No. 2 reservoirs; CDM Smith 2018a).

<u>Montane Chaparral</u>

In California, Montane Chaparral occurs in mountainous areas of mid-to high-elevation (3,000 to 10,000 ft) in the North Coast Ranges, Klamath and Cascades mountains, and in the Transverse Range in the south (CDFW California Interagency Wildlife Task Group 2014a). Montane Chaparral accounts for approximately one percent (450 acres) of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Middle Klamath River in small patches immediately adjacent to the river (Appendix G).

Montane Chaparral, though markedly variable throughout California, is generally characterized by thick, dense stands of chaparral with little to no understory. In disturbed coniferous habitats, chaparral proliferates easily and may exclude other vegetation. Common species include whitethorn ceanothus (*Ceanothus cordulatus*), snowbrush ceanothus (*Ceanothus velutinus*), greenleaf manzanita (*Arctostaphylos patulal)*, pinemat manzanita (*Arctostaphylos nevadensis)*, hoary manzanita (*Arctostaphlos canescens*), and bitter cherry (*Prunus emarginata*). Conifer and oak trees may occur in sparse stands or as scattered individuals within the chaparral type (CDFW California Interagency Wildlife Task Group 2014a).

<u>Montane Hardwood</u>
In California, Montane Hardwood occurs broadly west of the Cascade-Sierra Nevada crest and is often found on steep, rocky, south-facing slopes within the Sierra Nevada (CDFW California Interagency Wildlife Task Group 2014a). Montane Hardwood accounts for approximately 13 percent (7,350 acres) of the Primary Area of Analysis for terrestrial resources. It is most prevalent in the Middle Klamath River where it is most densely clustered towards the northern half (Appendix G).

Montane Hardwood forms a dense forest with a thick layer of leaf litter and sparse cover of herbaceous species. The dominant species in the tree canopy is canyon live oak except at higher elevations where it is replaced by huckleberry oak (*Quercus vacciniifolia)*. In the North Coast Range, species vary by elevation and may include Douglas-fir, tanoak, Pacific madrone, California laurel, California black oak, knobcone pine (*Pinus attenuata*), foothill pine, coast live oak, California white fir, and Jeffrey pine. Understory vegetation includes manzanita, mountain mahogany, poison oak, and a few forbs (CDFW California Interagency Wildlife Task Group 2014a).

<u>Montane Hardwood-Conifer</u>
In California, Montane Hardwood-Conifer occurs broadly and covers a continuous band along the Sierra Nevada (CDFW California Interagency Wildlife Task Group 2014a). Montane Hardwood-Conifer is the most common habitat type in the Primary Area of Analysis for terrestrial resources, accounting for approximately 25 percent (13,899 acres) of the Primary Area of Analysis, and is most prevalent in the Lower and Middle Klamath River (Appendix G).

Like Montane Hardwood, Montane Hardwood-Conifer forms a dense forest with a thick layer of leaf litter and sparse cover of herbaceous species. Dominant species in the tree canopy include tanoak and California black oak. Common species include ponderosa pine, Douglas-fir, incense-cedar, California black oak, tanoak, Pacific madrone, and Oregon white oak (CDFW California Interagency Wildlife Task Group 2014a). Within the Primary Area of Analysis for terrestrial resources, juniper is also an associate.

<u>Perennial Grassland</u>
Perennial Grassland occurs along the California coast from Monterey County northward and as relic stands within annual grassland habitat patches, generally below 3,280 feet (CDFW California Interagency Wildlife Task Group 2014a). Perennial Grassland accounts for less than one percent (253 acres) of the Primary Area of Analysis for terrestrial resources, and is most prevalent in the Middle Klamath River (Appendix G).

Perennial Grassland is dominated by perennial grass species such as California oatgrass and needlegrass species (*Stipa* spp.). Common species include a variety of native and non-native grasses and forbs including redtop (*Agrostis stolonifera*), soft chess, orchardgrass (*Dactylis glomerata*), Idaho fescue (*Festuca idahoensis*), Douglas iris (*Iris douglasiana*), and western bracken fern (CDFW California Interagency Wildlife

Task Group 2014a). During 2018 surveys, *Festuca idahoensis* Herbaceous Alliance was documented at Copco No. 1 and Copco No. 2 reservoirs (CDM Smith 2018a).

Ponderosa Pine

In California, Ponderosa Pine occurs broadly and covers extensive areas within the Sierra Nevada at elevations between 800 and 5,000 feet (CDFW California Interagency Wildlife Task Group 2014a). Ponderosa Pine accounts for approximately two percent (998 acres) of the Primary Area of Analysis for terrestrial resources, with several scattered patches in the northern half of the Middle Klamath River (Appendix G).

Ponderosa Pine forms an open forest of relatively small-diameter trees. Associated species vary depending on location and site conditions and may include white fir, incense-cedar, Jeffrey pine, sugar pine, Douglas-fir, canyon live oak, California black oak, Oregon white oak, Pacific madrone, tanoak, manzanita, ceanothus, and poison oak (CDFW California Interagency Wildlife Task Group 2014a). During 2018 surveys, *Pinus ponderosa* Forest Alliance was documented at Copco No. 1 and Copco No. 2 reservoirs (CDM Smith 2018a).

Redwood

Redwood habitat is generally present within two to 10 miles of the coast (CDFW California Interagency Wildlife Task Group 2014a) in areas of consistent fog, high summer humidity, cool temperatures, and well-developed soils (Shuford and Timossi 1989) and can be found in elevations ranging from sea level to 3,000 feet (CDFW California Interagency Wildlife Task Group 2014a). Forests of pure coast redwood transition to redwood/Douglas-fir forests farther inland (CDFW California Interagency Wildlife Task Group 2014a) along a gradient of increased evapotranspiration and inadequate soil moisture (Mahony and Stuart 2000, Van Wagtendonk et al. 2018). Coast redwood trees tend to taper out approximately 31 miles inland from the coast (CDFW California Interagency Wildlife Task Group 2014a). Redwood accounts for approximately two percent (966 acres) of the Primary Area of Analysis for terrestrial resources and is most prevalent in the Lower Klamath River, with dense patches closer to the coast and clustered patches in the center of the reach (Appendix G).

Redwood and Douglas-fir trees often co-occur in areas classified as the Redwood habitat type, with Douglas-fir occupying up to half of the canopy cover. The associated species mix varies both north-to-south, as well as inland from the coast. Common associated tree species include Douglas-fir, tanoak, and Pacific madrone, with the following species potentially contributing: Bishop pine, grand fir, golden chinquapin (*Chrysolepis chrysophylla*), western hemlock, red alder (*Alnus rubra*), bigleaf maple (*Acer macrophyllum*), California laurel, and nutmeg (*Torreya californica*). Shrub species include blue blossom (*Ceanothus thyrsiflora*), coyote brush (*Baccharis pilularis*), manzanita, and California huckleberry (CDFW California Interagency Wildlife Task Group 2014a).

Sierran Mixed Conifer

In California, Sierran Mixed Conifer dominates the middle elevations of the western slope of the northern Sierra Nevada, at elevations ranging from 2,500 to 4,000 feet (CDFW California Interagency Wildlife Task Group 2014a). Sierran Mixed Conifer accounts for approximately four percent (2,197 acres) of the Primary Area of Analysis for terrestrial resources and is concentrated in dense patches towards the northern end of the Middle Klamath River (Appendix G).

Sierran Mixed Conifer forms a dense forest, with tree crowns often touching. Various conifers co-dominate, including white fir, Douglas-fir, ponderosa pine, sugar pine, and incense-cedar; California black oak is also present. Common understory species include ceanothus, manzanita, tanoak, bitter cherry, mountain whitethorn, gooseberry (*Ribes* spp.), and rose (*Rosa* spp.) (CDFW California Interagency Wildlife Task Group 2014a).

Wet Habitats

Estuarine

Estuarine habitat occurs along coastal California at the mouth of perennial rivers (CDFW California Interagency Wildlife Task Group 2014a). Estuarine habitat accounts for approximately one percent (398 acres) of the Primary Area of Analysis for terrestrial resources and is located in the Klamath River Estuary (Appendix G).

Estuarine habitat includes areas that are periodically or permanently inundated, including open water portions of semi-enclosed coastal waters where tidal seawater is diluted by freshwater. California estuaries do not often conform to the classic description of an estuary due to a restricted coastal plain and stream flow regimes characterized by summer drought. Estuarine habitat contains a high density of a few species that are able to withstand an estuary’s many physiological stressors, such as varying salinity. Suspended organisms, such as phytoplankton, occur in the open water of estuaries and are densest near the surface and in low-salinity areas in summer. Other associated species include algae (green and red) and eelgrass (*Zostera* spp.), which grow in dense stands in many subtidal estuarine habitats (CDFW California Interagency Wildlife Task Group 2014a).

Montane Riparian

Montane Riparian forest occurs in narrow bands along streams below 8,000 feet (CDFW California Interagency Wildlife Task Group 2014a). Montane Riparian habitat accounts for approximately four percent (2,034 acres) of the Primary Area of Analysis for terrestrial resources. It occurs along the river and reservoir shorelines in scattered patches throughout the Primary Area of Analysis for terrestrial resources but is most prevalent in the Lower and Middle Klamath River. A portion of the Middle Klamath River, from Iron Gate Dam to the Shasta River confluence, contains the highest percentage (approximately 41 percent) of Montane Riparian habitat in the Primary Area of Analysis for terrestrial resources (Appendix G).

Within the Klamath Range, Montane Riparian tends to be dominated by black cottonwood (*Populus balsamifera* subsp. *trichocarpa*) and may be codominant with bigleaf maple; dogwood (*Cornus* spp.), and boxelder (*Acer negundo*) are also present. At high elevations, quaking aspen and white alder (*Alnus rhombifolia*) may also be present. Oregon ash (*Fraxinus latifolia*), willow, and a high diversity of forbs are common associates (CDFW California Interagency Wildlife Task Group 2014a). Within the Primary Area of Analysis for terrestrial resources, the species composition of Montane Riparian varies by reach and includes the following subcategories as defined in PacifiCorp (2004a, b):

- riparian grassland: characterized by a dense herbaceous cover;
- riparian scrub: dominated by coyote willow and arroyo willow with Oregon ash saplings prevalent;

- riparian deciduous: characterized by a moderate canopy cover including coyote willow and shining willow and/or alder (white or red, depending on location), with moderate shrub and herb layers; and
- riparian mixed deciduous-coniferous: characterized by a dense tree layer that includes both deciduous riparian tree species and upland conifer tree species, moderate density shrub layer, and open herbaceous layer that includes reed canarygrass and devil's beggarstick (*Bidens frondosa*).

In the Lower Klamath River and Klamath River Estuary, red alder is dominant. The Middle Klamath River is typically populated with coyote willow, shining willow, Oregon ash, and Oregon oak. In the Hydroelectric Reach along the Copco No. 2 Bypass Reach, white alder is dominant and dense enough to prohibit establishment of coyote willow and reed canarygrass (PacifiCorp 2004a,b). During 2018 surveys, the following alliances were documented that fall within Montane Riparian CWHR type: *Fraxinus latifolia* Forest Alliance (Iron Gate, Copco No. 1, and Copco No. 2 reservoirs) and *Acer macrophyllum* Forest Alliance (Copco No. 1 and Copco No. 2 reservoirs; CDM Smith 2018a). These are both rare natural community types.

<u>Palustrine</u>
Palustrine is a habitat type defined in *Classification of Wetlands and Deepwater Habitats of the United States* (Cowardin et al. 1979) that includes all non-tidal wetlands as well as wetlands in tidal areas where ocean-derived salinity is below 0.5 percent. They are by definition less than 20 acres in size, lack active wave-formed or bedrock shoreline features, and are less than 6 feet deep at low water. Palustrine habitat occurs throughout California on the perimeters of lakes, river channels, and estuaries, as well as in river floodplains, isolated catchments, and depressions on slopes. Palustrine habitat accounts for approximately two percent (1,357 acres) of the Primary Area of Analysis for terrestrial resources. It occurs to varying degrees along the Lower Klamath Project reservoirs and river reaches, primarily limited to small patches in protected locations and near reservoir inlets and tributary mouths. Palustrine habitat occurs throughout the Lower and Middle Klamath River reaches and is most densely clustered in the Klamath River Estuary and the northern end of the Middle Klamath River (Appendix G).

Palustrine habitat can be broken into the following categories: Palustrine Emergent Wetland, Palustrine Scrub-shrub Wetland, Palustrine Forested Wetland, and Palustrine Aquatic Bed. Palustrine Emergent Wetland is dominated by a dense herbaceous layer, commonly including cattails (*Typha* spp.), bulrushes, sedges, reed (*Phragmites australis*), manna grasses (*Glyceria* spp.), purple loosestrife (*Lythrum salicaria*), dock (*Rumex* spp.), and many species of smartweeds (*Polygonum* spp.) (Cowardin et al. 1979). Within the Primary Area of Analysis for terrestrial resources, emergent vegetation along the reservoirs includes sedge, rush, bentgrass, bulrush, and cattail. Palustrine Scrub-shrub Wetland is characterized by an open canopy with a moderate shrub layer. Within the Primary Area of Analysis for terrestrial resources, species such as coyote willow (*Salix exigua*) and arroyo willow (*Salix lasiolepis*) are prevalent and coyote willow dominates at the reservoirs. Palustrine Forested Wetland is characterized by a dense tree cover that includes hydrophilic tree species such as coyote willow and shining willow (*Salix lasiandra*), brown dogwood (*Cornus glabrata*), and arroyo willow. Finally, Palustrine Aquatic Bed is dominated by pondweeds (*Potamogeton* spp.) and coontail (*Ceratophyllum demersum*) (PacifiCorp 2004a,b). During 2018 surveys, the following alliances were documented that fall within the Palustrine habitat type: *Typha (angustifolia, domingensis, latifolia)* Herbaceous Alliance (Iron Gate Reservoir); *Salix exigua* Shrubland Alliance (Iron Gate Reservoir); and *Schoenoplectus acutus* Herbaceous Alliance (Iron Gate, Copco No. 1, and Copco No. 2 reservoirs; CDM Smith 2018a).

Wet Meadow

Wet Meadow occurs along streams, areas with concave topography, and/or where springs or seeps provide abundant available water (Ratliff 1985). The habitat type usually occurs above 3,940 feet in the north of the Tahoe Basin and above 5,900 feet to the south of the Basin (CDFW California Interagency Wildlife Task Group 2014a). Wet meadows account for less than one percent (15 acres) of the Primary Area of Analysis for terrestrial resources, with the highest concentration (10 acres) in the Middle Klamath River (Appendix G).

The Wet Meadow habitat type is characteristically defined by its hydrology: seasonality and reliability of yearly water inflows and outflows largely determine the stability of this habitat type. It tends to succeed bog communities and in turn is succeeded by mesic meadows and dry meadows or forests. The Wet Meadow habitat type is variable throughout California, but generally supports graminoids, including a variety of sedges (e.g., Nebraska sedge [*Carex nebrascensis*] and beaked sedge [*Carex utriculata*]), reed grasses (*Calamagrostis* spp.) and bent grass (*Agrostis* spp.), and a variety of rushes (*Juncus* spp.), and a lower percentage cover of forbs such as Anderson aster (*Aster alpigenus*), primrose monkey flower (*Mimulus primuloides*), cow's clover (*Trifolium wormskioldii*), and small white violet (*Viola macloskeyi*). Shrub cover is present along the margins (CDFW California Interagency Wildlife Task Group 2014a). During 2018 surveys, *Poa pratensis* Herbaceous Semi-Natural Alliance was documented at Copco No. 1 and Copco No. 2 reservoirs (CDM Smith 2018a).

Historical Vegetation

The area where Copco No. 1 and Copco No. 2 reservoirs are currently located historically consisted of a wide floodplain confined by steep slopes and the distribution of Montane Riparian and Palustrine habitats were situated along several river bends (Figure 3.5-2); there were a total of 66.2 acres of Montane Riparian and 23.7 acres of Palustrine habitat (Table 3.5-2; EDAW 2000). Wet habitats were more limited at Iron Gate Reservoir and was confined to long, thin bands running along the Klamath River channel (Figure 3.5-3); there were 30.1 acres of Montane Riparian and 2.6 acres of Palustrine habitat (Table 3.5-2; EDAW 2000).

When the reservoirs were built, topography limited the establishment of Montane Riparian habitat but in many places the creation of the reservoir created a flat bench that facilitated Palustrine habitat establishment (PacifiCorp 2004a). Currently, there are 11.1 acres of Montane Riparian and 25.2 acres of Palustrine habitat within 300 feet of the reservoir footprint of Copco No. 1 and Copco No. 2 reservoirs and 4.7 acres of Montane Riparian and 27.1 acres of Palustrine habitat within 300 feet of the reservoir footprint of Iron Gate Reservoir (Table 3.5-2; Figures 3.5-4 and 3.5-5; PacifiCorp 2005).

Table 3.5-2. Comparison of Historical (EDAW 2000) and Current (PacifiCorp 2005) Wet Habitat Types at Copco Nos. 1 and 2 and Iron Gate Reservoirs.

CHWR Vegetation Cover Types	Copco Nos. 1 and 2 (ac)	Iron Gate Reservoir (ac)	Total ac
Historical (reservoir footprint) [1]			
Montane Riparian (MRI)	66.2	30.1	**96.3**
Palustrine (PAL)[2]	23.7	2.6	**26.3**
Current (within 300 feet of the reservoir footprint)			
Montane Riparian (MRI)	11.1	4.7	**15.8**
Palustrine (PAL)[2]	25.2	27.1	**52.3**

[1] No historical data is available outside of the reservoir footprint.
[2] Not a CWHR type; based on the Cowardin classification for wetlands and deepwater habits (Cowardin et al. 1979.

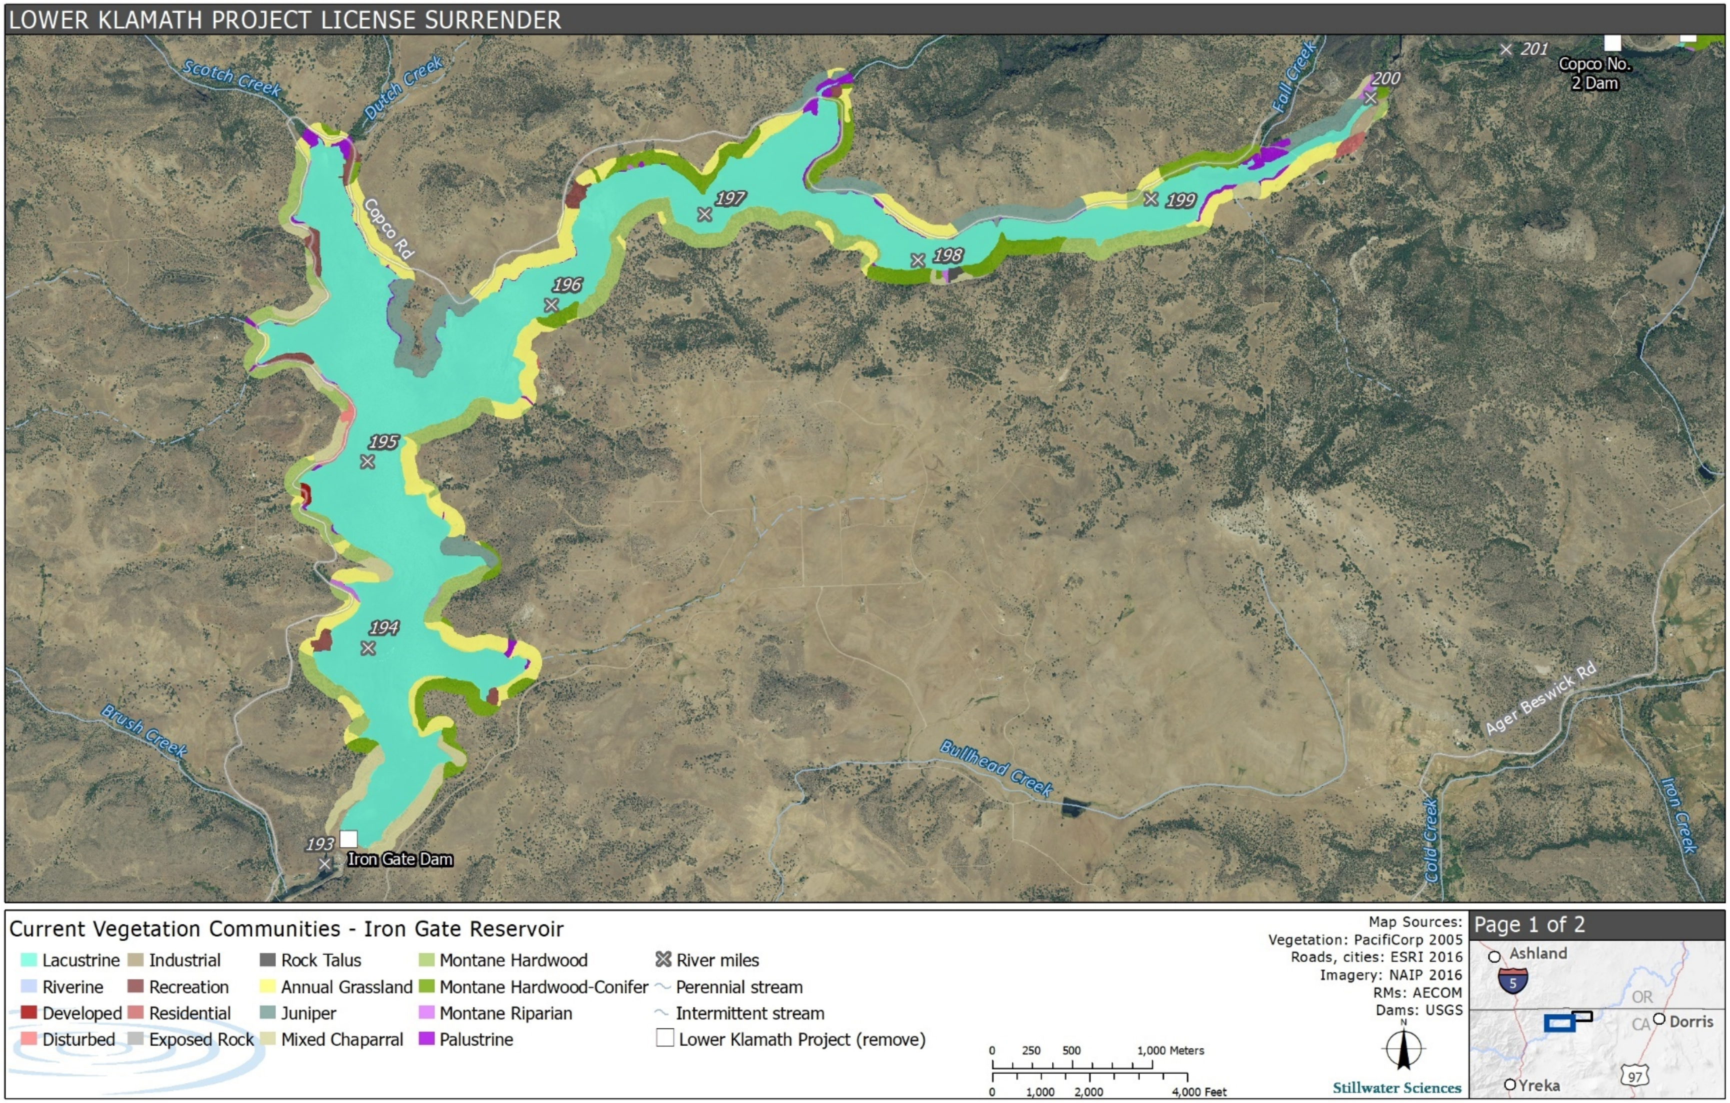

Figure 3.5-5. Current Vegetation Types within a 300-foot Buffer of Iron Gate Reservoir.

3.5.2.2 Invasive Plant Species

Multiple surveys for invasive plant species have been conducted in the Primary Area of Analysis for terrestrial resources. PacifiCorp conducted biological surveys in 2002, 2003, and 2004 (PacifiCorp 2004a,b) in the vicinity of the Primary Area of Analysis (PacifiCorp's study area overlaps but is not an exact match to the Primary Area of Analysis for terrestrial resources); vegetation surveys were conducted around the perimeter of Copco No. 1 and Iron Gate reservoirs in November 2009 and July 2010 (USBR 2011); and reconnaissance surveys were conducted in 2017 within the proposed Limits of Work and areas surrounding the reservoirs (Appendix B: *Definite Plan - Appendix J*). Twenty-two species of invasive plants have been documented within the vicinity of Primary Area of Analysis for terrestrial resources; based on available data, nine of the twenty-two species have been documented within the Primary Area of Analysis for terrestrial resources (Table 3.5-3).

Table 3.5-3. Invasive Plants Documented Within and in the Vicinity of the Primary Area of Analysis for Terrestrial Resources.

Scientific Name	Common Name	Data Source
Acroptilon repens	Russian knapweed	PacifiCorp (2004a,b)
Bromus tectorum	cheat grass	PacifiCorp (2004a,b)
Centaurea diffusa	diffuse knapweed	PacifiCorp (2004a,b)
Centaurea solstitialis[1]	yellow starthistle	PacifiCorp (2004a,b); USBR (2011); Bureau of Land Management (BLM) (2002); Appendix B: *Definite Plan – Appendix J*
Cirsium arvense	Canada thistle	PacifiCorp (2004a,b)
Cirsium vulgare	bull thistle	PacifiCorp (2004a,b)
Conium maculatum[1]	poison hemlock	Larson (2011); BLM (2002)
Cytisus scoparius	Scotch broom	PacifiCorp (2004a,b)
Elymus caput-medusae[1]	Medusahead	PacifiCorp (2004a,b); USBR (2011); Appendix B: *Definite Plan – Appendix J*
Fallopia japonica	Japanese knotweed	Hamilton (2011)
Hypericum perforatum[1]	St. John's wort	PacifiCorp (2004a,b); BLM (2002)
Isatis tinctoria[1]	Dyer's woad	PacifiCorp (2004a,b); EDAW (2004)
Lepidium draba[1]	hoary cress	PacifiCorp (2004a,b); EDAW (2004)
Lepidium latifolium	perennial pepperweed	PacifiCorp (2004a,b)
Linaria dalmatica subsp. *dalmatica*	Dalmatian toadflax	PacifiCorp (2004a,b)
Onopordum acanthium subsp. *acanthium*	Scotch thistle	PacifiCorp (2004a,b)
Persicaria wallichii	Himalayan knotweed	Hamilton (2011)
Phalaris canariensis	reed canary grass	Hamilton (2011)
Rubus armeniacus[1]	Himalayan blackberry	Hamilton (2011); BLM (2002); Appendix B: *Definite Plan – Appendix J*
Salvia aethiopis	Mediterranean sage	PacifiCorp (2004a,b)
Tribulus terrestris[1]	puncture vine	PacifiCorp (2004a,b); BLM (2002); EDAW (2004)
Xanthium spinosum[1]	spiny cocklebur	PacifiCorp (2004a,b); EDAW (2004)

[1] Species documented within the Primary Area of Analysis.

During the PacifiCorp biological surveys conducted in 2002, 2003, and 2004 (PacifiCorp 2004a,b), cheat grass (*Bromus tectorum*), yellow starthistle (*Centaurea solstitialis*), and medusahead (*Elymus caput-medusae*) were the most widespread invasive plants within the study area, and bull thistle (*Cirsium vulgare*) and Canada thistle (*Cirsium arvense*) were also pervasive (PacifiCorp 2004a,b). Many of the surveyed invasive plant species were found in uplands or near the riparian/upland interface and were abundant in areas where ground disturbance was evident (e.g., maintenance areas associated with power plants, transmission lines, flowlines, recreation sites, and roads). Along the Klamath River in high flow reaches, reed canarygrass was a commonly observed riparian plant species (PacifiCorp 2004a).

3.5.2.3 Culturally Significant Plant Species

Many plants in the Primary Area of Analysis for terrestrial resources were used by Native American Tribes in the Klamath River region as food sources (see also Section 3.12.2.1 *Cultural Chronology and Ethnography*); examples include seeds of wocus (yellow pond lily, *Nuphar lutea* subsp*olysepala*) and rootstocks of broad-leaved cattail (*Typha latifolia*) and bur reed (*Sparganium emersum*). Other plants such as hardstem bulrush (*Schoenoplectus acutus* var. *occidentalis*), cattails, and willows (*Salix* spp.) were used for basketry, clothing, and shelter (Larson and Brush 2010). Many of these plants are still culturally important today. Culturally significant plants used for food sources by the Yurok Tribe include acorns, seaweed, salal, wild grape (*Vitis californica*), various roots and berries including salmonberry (*Rubus spectabilis*), huckleberry and gooseberry and currants (O'Rourke 2017, 2016). Culturally significant plants used for food sources by the Shasta people include buckeye (*Aesculus californica*), pine nuts, manzanita berries, and a variety of other plants; acorns were a staple of the Shasta people's diet (Dixon 1907, Silver 1978).

Culturally significant plants used for basketry by the Yurok and/or Karuk tribes include alder (*Alnus* spp.), bear grass (*Xerophyllum tenax*), black maidenhair fern (*Adiantum capillus-veneris*), chain fern (*Woodwardia fimbriata*), chitum bark (*Frangula purshiana*), cottonwood (*Populus* spp.), hazel sticks (*Corylus cornuta*), mosses, sugar pine , redwood, spruce (*Picea* spp.), tobacco (*Nicotiana*), wild grape, Oregon grape and willow sticks and roots (O'Rourke 2017, 2016 and Hillman 2017, 2016) Many of these same plants are important medicinal plants used in healing and ceremony (Yurok Tribe Environmental Program 2009).

Culturally significant plants used as materials for fabrics and utensils by the Yurok include tanoak acorns, hazelnuts, pepperwood nuts (*Umbelleria californica*), berries, grasses, and bushes. Tall redwood trees are considered culturally significant by the Yurok as they used as part of the constitution and blessing and for the construction of canoes. Finally, culturally significant plants used as trade items by the Yurok include sugar pine nuts, tobacco seed, and juniper beads (O'Rourke 2017, 2016).

3.5.2.4 Non-special-status Wildlife

Information regarding non-special-status wildlife was compiled from surveys conducted by KRRC in 2018 and PacifiCorp in 2002 and 2003. The 2018 general wildlife surveys consisted of walking-transect surveys within a buffer of 0.25 mile of the proposed Limits of Work and via a boat along reservoir shorelines and open water (Appendix B: *Definite Plan*). The 2018 surveys focused on special-status species; however, some California non-special-status species of birds were also documented. PacifiCorp conducted terrestrial wildlife surveys in a variety of habitats in 2002 and 2003 and detected (or documented from other sources, such as BLM surveys from 2000 and 2001) numerous wildlife species (PacifiCorp 2004a). Targeted species surveys were conducted within areas that supported aquatic, wetland, and riparian habitats for amphibian breeding and refuge; upland and aquatic habitats for reptiles (e.g., snakes and turtles), and habitats for birds such as talus and mixed riparian habitats, sagebrush, aquatic, wetlands, pastures, and buildings. PacifiCorp also monitored mammal habitat surrounding Project facilities using track surveys, photographic bait stations, and structure monitoring for bat use. Incidental observations of species were also documented. Although the 2002 and 2003 PacifiCorp surveys are more than 15 years old, the wildlife previously documented have a reasonable potential of occurring in California under existing conditions as habitat conditions have not substantively changed since the surveys were conducted (e.g., reservoirs are still present).

Below is a summary of the numerous non-special status amphibians, reptiles, birds, and mammals documented, in or near the Primary Area of Analysis for terrestrial resources in California by KRRC, PacifiCorp, and BLM (PacifiCorp 2004a, CDM Smith 2018c). Species documented only in the J.C. Boyle Peaking Reach (by PacifiCorp or BLM) are noted in parenthesis when it was not clear if the species was observed in California or Oregon. Regardless, due to the proximity of the J.C. Boyle Peaking Reach to the state line, it is reasonable to assume that these species have the potential to occur in California.

- Non-special-status amphibians–Pacific giant salamander, western toad, Pacific treefrog, and non-native bullfrog;
- Non-special-status reptiles—southern alligator lizard, western fence lizard, striped whipsnake, California mountain kingsnake, California kingsnake, gopher snake, common kingsnake, common garter snake, and western rattlesnake (species documented only in J.C. Boyle Peaking Reach included western yellow-bellied racer, western terrestrial garter snake, ringneck snake, rubber boa, western skink);
- Non-special-status-birds—mountain quail, double-crested cormorant, herons (great blue, black-crowned night), great egret, bufflehead, osprey, hawks (sharp-shinned, Cooper's), great-horned owl, terns (Forster's, Caspian), woodpeckers (acorn, pileated, Lewis'), black phoebe, black-capped chickadee, pygmy nuthatch, blue-gray gnatcatcher, western bluebird, and Swainson's thrush, (species documented only in J.C. Boyle Peaking Reach include, prairie falcon, flammulated owl, and merlin). Surveys conducted by KRRC in May 2018 also documented several osprey nests on platforms located on top of electrical poles in the Iron Gate Reservoir area (CDM Smith 2018c); and
- Non-special-status mammals—western harvest mouse, montane vole, woodrat (dusky-footed, bushy-tailed), squirrel (western gray, California ground), black-tailed deer, elk, bobcat, beaver, mink, river otter, mountain lion, and Yuma myotis (bat).

Surrounding areas also support habitat for wild horse herds, bighorn sheep, and habitat components critical for deer to winter in the area. CDFW has identified areas north and south of Iron Gate Reservoir, Copco No. 2 Reservoir, Copco No. 1 Reservoir, and the Klamath River upstream to the Oregon-California state line as critical deer wintering habitat (CDFW 2014a). CDFW identifies wintering range to include habitat elements important to the survival of deer in the winter, which may include corridors essential for movement, staging areas where deer temporarily congregate, and high-quality winter forage (CDFW 2014a). This area represents one of the largest contiguous areas of deer winter range in the southern Oregon and northern California region. BLM's Pokegama Wild Horse Herd Management Area lies primarily in Oregon, but also includes portions in California north of the Klamath River. PacifiCorp reported that the wild horse herd roams throughout the area, from locations near Fall Creek to near J.C. Boyle Dam (PacifiCorp 2004a). Wild horse herds have also been documented along the western shore of Iron Gate Dam and based on data provided by CDFW in 2017, bighorn sheep are located along the north side of Copco No. 1 Reservoir and northeast of the confluence of Shovel Creek and the Klamath River (Figure 3.5-6).

Wildlife such as egrets, herons, raptors, river otters, and bears may forage on natural-origin or Iron Gate Hatchery-produced out-migrating salmonids (coho, fall-run Chinook, and steelhead) and adult returns (see Section 3.3.2.1 *Aquatic Species*). CDFW operates Iron Gate Hatchery, with an annual production goal of 75,000 coho salmon smolts, 6 million fall-run Chinook salmon yearlings and smolts, and 200,000 steelhead smolts (CDFW 2014b, detailed in Section 3.3.2.3 *Habitat Attributes Expected to be Affected by the Proposed Project*). However, the ability to meet the production goals varies annually based on adult returns and hatchery performance (e.g., no steelhead have been released since 2012 due to low returns of adult steelhead). While natural returns typically outnumber hatchery returns for all species, the proportion of the adult salmon escapement composed of Iron Gate Hatchery returns has historically been substantial. For fall-run Chinook salmon, around 35 percent of age 3 returning adults to the mid-Klamath River are Iron Gate Hatchery-produced (KRTT 2011, 2012, 2015), as well as approximately 30 percent of all coho salmon adult returns (CDFW 2014b, detailed in Section 3.3.5.9 *Aquatic Resource Impacts*). Under current conditions, no adult steelhead returning have been hatchery-produced since around 2012.

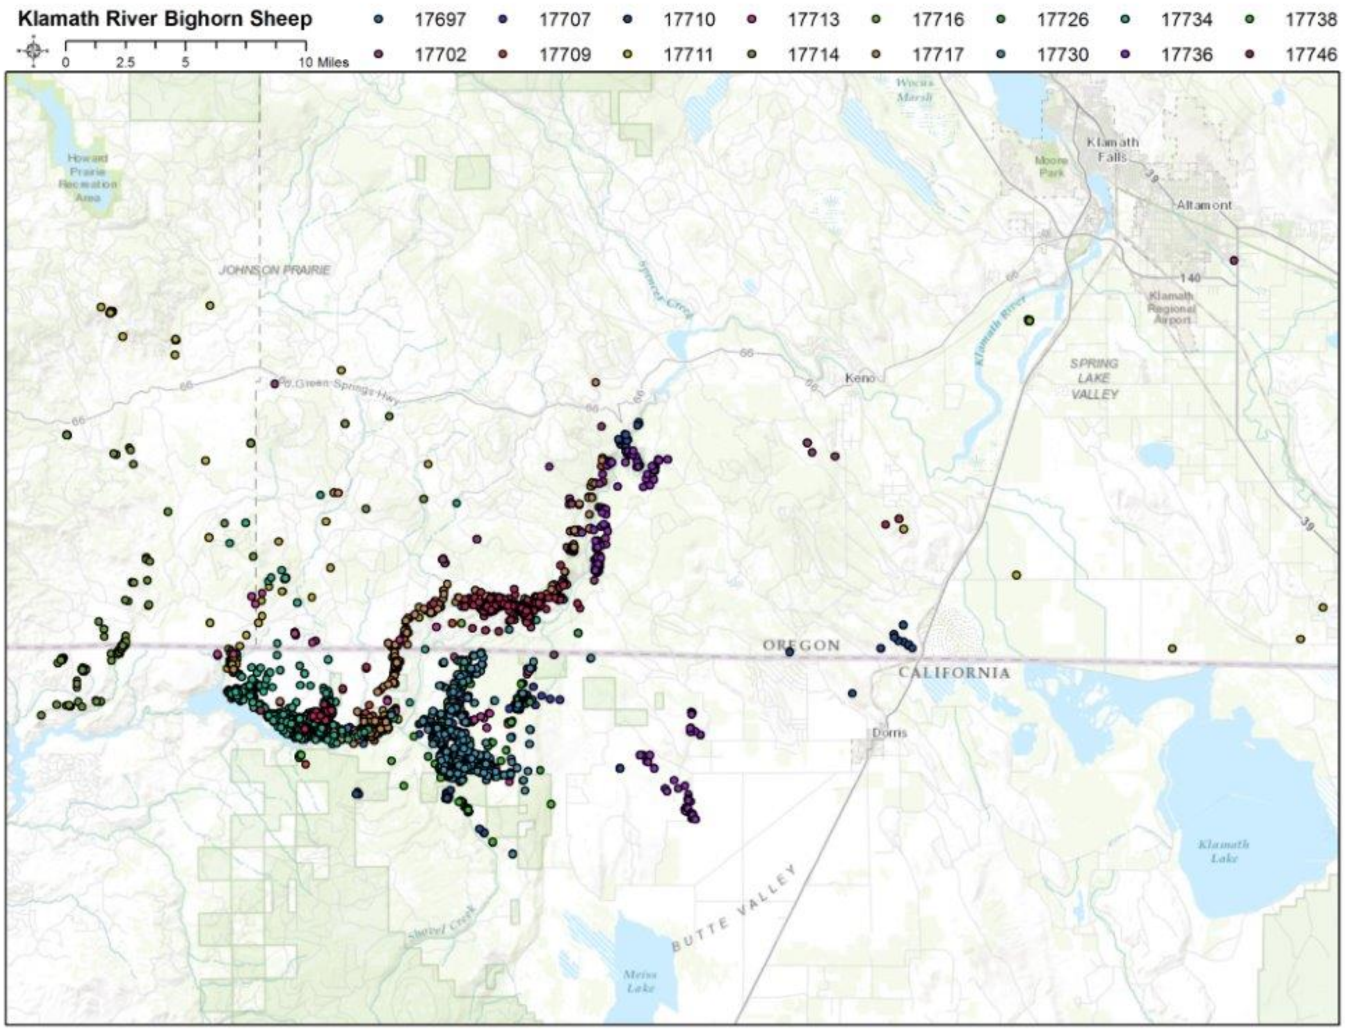

Figure 3.5-6. Bighorn Sheep 2017 Collar Data for the Klamath Basin (M. Harris, Senior Environmental Scientist, CDFW, pers. comm., October 2017).

3.5.2.5 Special-status Species

The list of special-status species known, or with the potential to occur, in the Primary Area of Analysis for terrestrial resources was developed by querying the following:

- CNDDB list of state and federal proposed endangered, threatened, candidate species, including those with BLM sensitive status (CDFW 2017a);
- USFWS list of federally listed and proposed endangered, threatened, and candidate species (USFWS 2017b);
- California Native Plant Society (CNPS) online Inventory of Rare and Endangered Vascular Plants of California (CNPS 2017);
- USDA Forest Service Pacific Southwest Region's (Region 5) documented occurrences of sensitive animals and sensitive and special interest plants (USDA Forest Service 2003 and 2017b);
- BLM species list (S. Acridge, Resource Management Supervisor, BLM, pers. comm., July 2017); and
- NMFS West Coast Region species list of endangered and threatened species and critical habitat (2017).

The database queries for CNDDB, USFWS, and CNPS were each based on a search of the Proposed Project Vicinity, which includes the USGS 7.5-minute quadrangles in which the Primary Area of Analysis for terrestrial resources is located and the adjacent quadrangles (Appendix I). Occurrence information for special-status species was based on studies conducted by PacifiCorp, KRRC, and available information on the presence of birds in the area from the eBird database (eBird 2018).

PacifiCorp conducted focused surveys for special-status species in 2002, 2003, and 2004 (PacifiCorp 2004a,b). These results are incorporated into Appendix J, which lists all positive occurrence data for special-status species within the Proposed Project Vicinity. PacifiCorp collected wildlife data in 2002 and/or 2003 which included, but was not limited to, the following types of surveys: breeding amphibians in ponds and wetlands; stream-dwelling amphibians in selected tributary streams; upland amphibian surveys; Oregon spotted frog surveys at four wetlands near J.C. Boyle and Keno reservoirs; foothill yellow-legged frog surveys at ten Klamath River mainstem and tributary sites meeting basic criteria for habitat suitability; western pond turtle basking surveys and suitable nesting habitat mapping; snake hibernacula surveys focused on areas located between roads/recreation sites and the river and selected rock talus areas; upland reptile surveys at 137 plots; small mammal trapping and track surveys with bat stations; bat roost surveys; bird surveys using avian point count and area searches in survey plots and along reservoir and shoreline habitats; protocol surveys for northern spotted owl and northern goshawk, and broadcast calls for great gray owls; and data collected opportunistically during other studies (e.g., fish electrofishing).

Results of wildlife surveys conducted by KRRC in 2017 and available data from 2018 are incorporated into this analysis and are also provided in Appendix B: *Definite Plan – Appendix J* and KRRC (CDM Smith 2018c,d); some surveys are anticipated to continue into 2019.

Special-status Plants

Table 3.5-4 lists the special-status plant species with potential to occur in the Primary Area of Analysis for terrestrial resources based on the CNDDB, USFWS, and CNPS database queries (plant species elevation information in CDFW 2017a and CNPS 2017 is provided in metric units). Fifty-three of these species are associated with wetland and/or riparian habitats. Species that were documented in the Proposed Project Vicinity but have an elevation range that is higher than the Primary Area of Analysis for terrestrial resources or that occur in habitats not represented in the Primary Area of Analysis were excluded. The number of species that have been documented in the Primary Area of Analysis for terrestrial resources and are included in the CNDDB, USFWS, and/or CNPS database includes 14 special-status vascular and three special-status bryophyte species. Although not present in the CNDDB, USFWS, and CNPS databases, Egg Lake monkey-flower (*Mimulus pygmaeus*) was documented in the vicinity of Fall Creek Dam A/B – City of Yreka Water Supply Diversion (Figure 2.7-15) during the CDM Smith's 2018 surveys (CDM Smith 2018b); this species has a California Rare Plant Rank (CRPR) status of 4.2 and is found on volcanic and clay soils in vernally mesic areas including Great Basin scrub, lower montane coniferous forest, meadows and seeps and pinyon and juniper woodlands. No federally listed or state-listed species have been documented within the Primary Area of Analysis for terrestrial resources but 11 have the potential to occur.

Table 3.5-4. Special-status Plant Species with the Potential to Occur in the Primary Area of Analysis for Terrestrial Resources.

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Vascular Plants						
Abronia umbellata var. *breviflora*	pink sand-verbena	–/–/–/BLMS/1B.1	June–October	0–10	Coastal dunes	Potential habitat within the Primary Area of Analysis
Allium siskiyouense	Siskiyou onion	–/–/–/–/4.3	(April) May–July	855–2,500	Rocky and sometimes serpentine soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Androsace elongata subsp. *acuta*	California androsace	–/–/–/–/4.2	March–June	150–1,305	Chaparral, cismontane woodland, coastal scrub, meadows and seeps, pinyon and juniper woodland, and valley and foothill grassland	Potential habitat within the Primary Area of Analysis
Angelica lucida	sea-watch	–/–/–/–/4.2	May–September	0–150	Coastal bluff scrub, coastal dunes, coastal scrub, and coastal salt marshes and swamps	Potential habitat within the Primary Area of Analysis
Antennaria suffrutescens	evergreen everlasting	–/–/–/–/4.3	January–July	500–1,600	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Arabis aculeolata	Waldo rockcress	–/–/–/–/2B.2	April–June	410–1,800	Serpentine soils in broadleafed upland forest, lower montane coniferous forest, and upper montane coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a).
Arabis mcdonaldiana	McDonald's rockcress	FE/CE/–/FSS/1B.1	May–July	135–1,800	Serpentine soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Arabis modesta	modest rockcress	–/–/–/–/4.3	March–July	120–800	Chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Arabis oregana	Oregon rockcress	–/–/–/–/4.3	May	600–1,830	Serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Arctostaphylos hispidula	Howell's manzanita	–/–/–/–/4.2	March–April	120–1,250	Serpentine or sandstone soils in chaparral	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Arctostaphylos nortensis	Del Norte manzanita	–/–/–/–/4.3	February	500–800	Often serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Arnica cernua	serpentine arnica	–/–/–/–/4.3	April–July	500–1,920	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Arnica spathulata	Klamath arnica	–/–/–/–/4.3	May–August	640–1,800	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Asarum marmoratum	marbled wild-ginger	–/–/–/–/2B.3	April–August	200–1,800	Lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Astragalus umbraticus	Bald Mountain milk-vetch	–/–/–/–/2B.3	May–August	150–1,250	Sometimes on roadsides in cismontane woodland and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Balsamorhiza lanata	woolly balsamroot	–/–/–/BLMS/1B.2	April–June	800–1,895	Rocky, volcanic soils in cismontane woodland	Potential habitat within the Primary Area of Analysis
Bensoniella oregana	bensoniella	–/CR/FSS/–/1B.1	May-July	915–1,400	Bogs and fens, lower montane coniferous forest, meadows and seeps	Potential habitat within the Primary Area of Analysis
Boechera koehleri	Koehler's stipitate rockcress	–/–/FSS/–/1B.3	(March) April–July	155–1,660	Serpentine, rocky soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Calamagrostis bolanderi	Bolander's reed grass	–/–/–/–/4.2	May–August	0–455	Mesic soils in bogs and fens, broadleafed upland forest, closed-cone coniferous forest, coastal scrub, meadows and seeps, freshwater marshes and swamps, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Calamagrostis crassiglumis	Thurber's reed grass	–/–/–/–/2B.1	May–August	10–60	Mesic soils in coastal scrub and freshwater marshes and swamps	Potential habitat within the Primary Area of Analysis
Calamagrostis foliosa	leafy reed grass	–/CR/–/BLMS/4.2	May–September	0–1,220	Rocky soils in coastal bluff scrub and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Callitropsis nootkatensis	Alaska cedar	Petition to list/–/–/–/4.3		650–2,500	Upper montane coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Calochortus greenei	Greene's mariposa lily	–/–/FSS/BLMS/1B.2	June–August	1,035–1,890	Volcanic soils in cismontane woodland, meadows and seeps, pinyon and juniper woodland, and upper montane coniferous forest	Documented during PacifiCorp surveys at Iron Gate Reservoir, Copco No. 1 & No. 2 (PacifiCorp 2004a; CDMB Smith 2018b). Several occurrences on CNDDB along Klamath River (2017a).
Calochortus monanthus	single-flowered mariposa lily	–/–/–/BLMS/1A	June	745–800	Meadows and seeps	Potential habitat within the Primary Area of Analysis
Calochortus persistens	Siskiyou mariposa lily	–/CR/FSS/BLMS/1B.2	June–July	1,000–1,860	Rocky, acidic soils in lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Calycadenia micrantha	small-flowered calycadenia	–/–/FSS/–/1B.2	June-September	5–1,500	Roadsides, rocky, talus, scree, sometimes serpentine soils and sparsely vegetated areas in chaparral, volcanic meadows and seeps, and valley and foothill grassland	Potential habitat within the Primary Area of Analysis
Cardamine angulata	seaside bittercress	–/–/–/–/2B.1	(January) March–July	25–915	Wet areas and streambanks in lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Carex buxbaumii	Buxbaum's sedge	–/–/–/–/4.2	March–August	3–3,300	Bogs and fens, mesic soils in meadows and seeps, and marshes and swamps	Potential habitat within the Primary Area of Analysis
Carex hystericina	porcupine sedge	–/–/–/–/2B.1	May–June	610–915	Streambanks in marshes and swamps	Potential habitat within the Primary Area of Analysis
Carex lenticularis var. *limnophila*	lagoon sedge	–/–/–/–/2B.2	June–August	0–6	Often gravelly soils along shores, beaches in bogs and fens, marshes and swamps, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Carex leptalea	bristle-stalked sedge	–/–/–/–/2B.2	March–July	0–700	Bogs and fens, mesic areas of meadows and seeps, marshes and swamps	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Carex lyngbyei	Lyngbye's sedge	–/–/–/–/2B.2	April–August	0–10	Brackish or freshwater marshes and swamps	Potential habitat within the Primary Area of Analysis
Carex praticola	northern meadow sedge	–/–/–/–/2B.2	May–July	0–3,200	Mesic areas of meadows and seeps	Potential habitat within the Primary Area of Analysis
Carex saliniformis	deceiving sedge	–/–/–/–/1B.2	June (July)	3–230	Mesic soils in coastal prairie, coastal scrub, meadows and seeps, and coastal salt marshes and swamps	Potential habitat within the Primary Area of Analysis
Carex scabriuscula	Siskiyou sedge	–/–/–/–/4.3	May–July	710–2,345	Mesic, sometimes serpentine soils in lower montane coniferous forest, meadows and seeps, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Carex serpenticola	serpentine sedge	–/–/–/–/2B.3	March–May	60–1,200	Mesic, serpentine soils in meadows and seeps	Potential habitat within the Primary Area of Analysis
Carex viridula subsp. *viridula*	green yellow sedge	–/–/–/–/2B.3	(June) July–September (November)	0–1,600	Bogs and fens, freshwater marshes and swamps, and mesic North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Castilleja ambigua var. *humboldtiensis*	Humboldt Bay owl's-clover	–/–/–/BLMS/1B.2	April–August	0–3	Coatal salt marshes and swamps	Potential habitat within the Primary Area of Analysis
Castilleja brevilobata	short-lobed paintbrush	–/–/–/–/4.2	April–July	120–1,700	Serpentine soils and edges and openings in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Castilleja elata	Siskiyou paintbrush	–/–/–/–/2B.2	May–August	0–1,750	Often serpentine soils in bogs and fens, and seeps in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Castilleja litoralis	Oregon coast paintbrush	–/–/–/–/2B.2	June	15–100	Sandy soils in coastal bluff scrub, coastal dunes, and coastal scrub	Potential habitat within the Primary Area of Analysis
Chaenactis suffrutescens	Shasta chaenactis	–/–/–/–/1B.3	May–September	750–2,800	Sandy, serpentine soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Chamaesyce hooveri	Hoover's Spurge	FT/–/–/–/1B.2	July–September (October)	25–250	Vernal pools	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Chrysosplenium glechomifolium	Pacific golden saxifrage	–/–/–/–/4.3	February–June	10–220	Streambanks, sometimes seeps, sometimes roadsides in North Coast coniferous forest, and riparian forest	Potential habitat within the Primary Area of Analysis
Cirsium ciliolatum	Ashland thistle	–/CE/–/BLMS/2B.1	June–August	800–1,400	Cismontane woodland and valley and foothill grassland	Potential habitat within the Primary Area of Analysis
Collomia tracyi	Tracy's collomia	–/–/–/–/4.3	June–July	300–2,100	Rocky, sometimes serpentine soils in broadleafed upland forest and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Coptis laciniata	Oregon goldthread	–/–/–/–/4.2	(February) March–May (September–November)	0–1,000	Mesic soils in meadows and seeps and streambanks in North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Cornus canadensis	bunchberry	–/–/–/–/2B.2	May–July	60–1,920	Bogs and fens, meadows and seeps, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Cypripedium californicum	California lady's-slipper	–/–/–/–/4.2	April–August (September)	30–2,750	Usually serpentine soils in bogs and fens, seeps and streambanks and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Cypripedium fasciculatum	clustered lady's-slipper	–/–/FSS/–/4.2	March–August	100–2,435	Usually serpentine soils in seeps and streambanks, lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Cypripedium montanum	mountain lady's-slipper	–/–/FSS/–/4.2	March–August	185–2,225	Broadleafed upland forest, cismontane woodland, lower montane coniferous forest, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Darlingtonia californica	California pitcherplant	–/–/–/–/4.2	April–August	0–2,585	Serpentine soils in bogs and fens, and meadows and seeps	Potential habitat within the Primary Area of Analysis
Dicentra formosa subsp. *oregana*	Oregon bleeding heart	–/–/–/–/4.2	April–May	425–1,485	Serrpentinite soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Draba carnosula	Mt. Eddy draba	–/–/FSS/–/1B.3	July–August	1,935–3,000	Serpentine, rocky soils in subalpine coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Empetrum nigrum	black crowberry	–/–/–/–/2B.2	April–June	10–200	Coastal bluff scrub and coastal prairie	Potential habitat within the Primary Area of Analysis
Epilobium oreganum	Oregon fireweed	–/–/FSS/BLMS/1B.2	June–September	500–2,240	Mesic soils in bogs and fens, lower montane coniferous forest, meadows and seeps, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Epilobium rigidum	Siskiyou Mountains willowherb	–/–/–/–/4.3	July–August	150–1,200	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Epilobium septentrionale	Humboldt County fuchsia	–/–/–/–/4.3	July–September	45–1,800	Sandy or rocky soils in broadleafed upland forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Erigeron bloomeri var. *nudatus*	Waldo daisy	–/–/–/–/2B.3	June–July	600–2,300	Serpentine soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Eriogonum congdonii	Congdon's buckwheat	–/–/–/–/4.3	(May) June–August (September)	800–2,345	Rocky, serpentine soils in lower montane coniferous forest openings	Potential habitat within the Primary Area of Analysis
Eriogonum hirtellum	Klamath Mountain buckwheat	–/–/FSS/–/1B.3	July–September	610–1,900	Serpentine soils in chaparral, lower montane coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Eriogonum nudum var. *paralinum*	Del Norte buckwheat	–/–/–/–/2B.2	June–September	5–80	Coastal bluff scrub and coastal prairie	Documented within the Primary Area of Analysis (CDFW 2017a)
Eriogonum siskiyouense	Siskiyou buckwheat	–/–/–/–/4.3	(June) July–September	970–2,740	Rocky, often serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Eriogonum ternatum	ternate buckwheat	–/–/–/–/4.3	June–August	305–2,225	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Eriogonum ursinum var. *erubescens*	blushing wild buckwheat	–/–/–/BLMS/1B.3	June–September	750–1,900	Rocky soils, scree, and talus in montane chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Erysimum concinnum	bluff wallflower	–/–/–/–/1B.2	February–July	0–185	Coastal bluff scrub, coastal dunes, and coastal prairie	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Erysimum menziesii	Menzies' Wallflower	FT/CE/–/–/1B.1	March–September	0–35	Coastal dunes	Potential habitat within the Primary Area of Analysis
Erythronium hendersonii	Henderson's fawn lily	–/–/FSS/–/2B.3	April–July	300–1,600	Lower montane coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Erythronium howellii	Howell's fawn lily	–/–/–/–/1B.3	April–May	200–1,145	Sometimes serpentine soils in lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Erythronium oregonum	giant fawn lily	–/–/–/–/2B.2	March–June (July)	100–1,150	Sometimes serpentine soils and in rocky openings in cismontane woodland and meadows and seeps	Documented within the Primary Area of Analysis (CDFW 2017a)
Erythronium revolutum	coast fawn lily	–/–/–/–/2B.2	March–July (August)	0–1,600	Bogs and fens, streambanks, broadleafed upland forest, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Eucephalus vialis	wayside aster	–/–/FSS/–/1B.2	June–September	910–1,545	Gravelly soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Fritillaria gentneri	Gentner's fritillary	FE/–/–/–/1B.1	April–May	1,005–2,970	Sometimes serpentine soils in chaparral, cismontane woodland, and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Galium serpenticum subsp. *scotticum*	Scott Mountain bedstraw	–/–/–/BLMS/1B.2	May–August	1,000–2,075	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Gentiana setigera	Mendocino gentian	–/–/FSS/–/1B.2	(April–July) August–September	335–1,065	Mesic soils in lower montane coniferous forest, and meadows and seeps	Potential habitat within the Primary Area of Analysis
Gilia capitata subsp. *pacifica*	Pacific gilia	–/–/–/–/1B.2	April–August	5–1,665	Coastal bluff scrub, openings in chaparral, coastal prairie, and valley and foothill grassland	Potential habitat within the Primary Area of Analysis
Gilia millefoliata	dark-eyed gilia	–/–/–/BLMS/1B.2	April–July	2–30	Coastal dunes	Potential habitat within the Primary Area of Analysis
Glehnia littoralis subsp. *leiocarpa*	American glehnia	–/–/–/–/4.2	May–August	0–20	Coastal dunes	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Helianthus bolanderi	serpentine sunflower	–/–/–/–/4.2	June-November	150–1,525	Serpentine seeps in chaparral and cismontane woodland	Documented during PacifiCorp surveys south of Iron Gate Reservoir (PacifiCorp 2004a)
Hesperocyparis bakeri	Baker cypress	–/–/–/–/4.2		820–1,995	Serpentine or volcanic soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Horkelia sericata	Howell's horkelia	–/–/–/–/4.3	May–July	60–1,280	Serpentine or clay soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Hymenoxys lemmonii	alkali hymenoxys	–/–/–/–/2B.2	June–August (September)	240–3,390	Great Basin scrub, lower montane coniferous forest, and subalkaline meadows and seeps	Potential habitat within the Primary Area of Analysis
Iliamna latibracteata	California globe mallow	–/–/FSS/–/1B.2	June–August	60–2,000	Montane chaparral, lower montane coniferous forest, mesic soils in North Coast coniferous forest, and streambanks in riparian scrub. Often in burned areas	Potential habitat within the Primary Area of Analysis
Iris bracteata	Siskiyou iris	–/–/–/–/3.3	May–June	180–1,070	Serpentine soils in broadleafed upland forest and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Iris innominata	Del Norte County iris	–/–/–/–/4.3	May–June	300–2,000	Serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Iris tenax subsp. *klamathensis*	Orleans iris	–/–/–/–/4.3	April–May	100–1,400	Lower montane coniferous forest, often in disturbed areas	Potential habitat within the Primary Area of Analysis
Juncus dudleyi	Dudley's rush	–/–/–/–/2B.3	July–August	455–2,000	Mesic soils in lower montane coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Juncus regelii	Regel's rush	–/–/–/–/2B.3	August	760–1,900	Mesic soils in meadows and seeps and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Kopsiopsis hookeri	small groundcone	–/–/–/–/2B.3	April–August	90–885	North Coast coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Lathyrus delnorticus	Del Norte pea	–/–/–/–/4.3	June–July	30–1,450	Often serpentine soils in lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Lathyrus japonicus	seaside pea	–/–/–/–/2B.1	May–August	1–30	Coastal dunes	Potential habitat within the Primary Area of Analysis
Lathyrus palustris	marsh pea	–/–/–/–/2B.2	March–August	1–100	Mesic soils in bogs and fens, coastal prairie, coastal scrub, lower montane coniferous forest, marshes and swamps, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Layia carnosa	beach layia	FE/CE/–/–/1B.1	March–July	0–60	Coastal dunes, and sandy soils in coastal scrub	Potential habitat within the Primary Area of Analysis
Lewisia cotyledon var. *heckneri*	Heckner's lewisia	–/–/–/BLMS/1B.2	May–July	225–2,100	Rocky soils in lower montane coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Lewisia cotyledon var. *howellii*	Howell's lewisia	–/–/–/–/3.2	April–July	150–2,010	Rocky soils in broadleafed upland forest, chaparral, cismontane woodland, and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Lewisia kelloggii subsp. *hutchisonii*	Hutchison's lewisia	–/–/–/–/3.2	(April) May–August	765–2,365	Openings, ridgetops, often slate, sometimes rhyolite tuff in upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Lewisia oppositifolia	opposite-leaved lewisia	–/–/FSS/–/2B.2	April-May (June)	300–1,220	Mesic soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Lilium bolanderi	Bolander's lily	–/–/–/–/4.2	June–July	30–1,600	Serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Lilium occidentale	western lily	FE/CE/–/–/1B.1	June–July	2–185	Bogs and fens, coastal bluff scrub, coastal prairie, coastal scrub, freshwater marshes and swamps, and openings in North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Lilium pardalinum subsp. *vollmeri*	Vollmer's lily	–/–/–/–/4.3	(June) July–August	30–1,680	Bogs and fens, and mesic soils in meadows and seeps	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Lilium pardalinum subsp. *wigginsii*	Wiggins' lily	–/–/–/–/4.3	June–August	485–2,000	Mesic soils in bogs and fens, broadleafed upland forest, lower montane coniferous forest, meadows and seeps, and riparian scrub	Potential habitat within the Primary Area of Analysis
Lilium rubescens	redwood lily	–/–/–/–/4.2	April–August (September)	30–1,910	Sometimes serpentine soils in broadleafed upland forest, chaparral, lower montane coniferous forest, North Coast coniferous forest, and upper montane coniferous forest. Sometimes roadsides	Potential habitat within the Primary Area of Analysis
Limnanthes floccosa subsp. *floccosa*	woolly meadowfoam	–/–/–/–/4.2	March–May (June)	60–1,335	Vernally mesic soils in chaparral, cismontane woodland, and valley and foothill grassland, and vernal pools	Potential habitat within the Primary Area of Analysis
Listera cordata	heart-leaved twayblade	–/–/–/–/4.2	February–July	5–1,370	Bogs and fens, lower montane coniferous forest, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Lomatium howellii	Howell's lomatium	–/–/–/–/4.3	April–July	110–1,705	Serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Lomatium martindalei	Coast Range lomatium	–/–/–/–/2B.3	May–June(August)	240–3,000	Coastal bluff scrub, lower montane coniferous forest, and meadows and seeps	Potential habitat within the Primary Area of Analysis
Lomatium peckianum	Peck's lomatium	–/–/–/–/2B.2	April–May (June)	700–1,800	Volcanic soils in chaparral, cismontane woodland, lower montane coniferous forest, and pinyon and juniper woodland	Documented within the Primary Area of Analysis (CDFW 2017a)
Lomatium tracyi	Tracy's lomatium	–/–/–/–/4.3	May–June	455–1,950	Serpentine soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Lupinus tracyi	Tracy's lupine	–/–/–/–/4.3	(May) June–July	895–2,000	Upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Lycopodiella inundata	inundated bog club-moss	–/–/–/–/2B.2	June–September	5–1,000	Coastal bogs and fens, mesic soils in lower montane coniferous forest, marshes and swamps and lake margins	Potential habitat within the Primary Area of Analysis
Lycopodium clavatum	running-pine	–/–/–/–/4.1	June–August (September)	45–1,225	Often edges, openings, and roadsides in mesic soils in lower montane coniferous forest and North Coast coniferous forest, and marshes and swamps	Potential habitat within the Primary Area of Analysis
Lysimachia europaea	arctic starflower	–/–/–/–/2B.2	June–July	0–15	Coastal bogs, fens, meadows, and seeps	Potential habitat within the Primary Area of Analysis
Micranthes marshallii	Marshall's saxifrage	–/–/–/–/4.3	March–August	90–2,130	Riparian forest, rocky steambanks	Potential habitat within the Primary Area of Analysis
Microseris laciniata subsp. *detlingii*	Detling's silverpuffs	–/–/–/–/2B.2	May–June	600–1,500	Clay soils in openings in cismontane woodland	Documented within the Primary Area of Analysis (CDFW 2017a)
Mitellastra caulescens	leafy-stemmed mitrewort	–/–/–/–/4.2	(March) April–October	5–1,700	Mesic soils in broadleafed upland forest, lower montane coniferous forest, meadows and seeps, and North Coast coniferous forest. Sometimes roadsides	Potential habitat within the Primary Area of Analysis
Moneses uniflora	woodnymph	–/–/–/–/2B.2	May–August	100–1,100	Broadleafed upland forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Monotropa uniflora	ghost-pipe	–/–/–/–/2B.2	June–August (September)	10–550	Broadleafed upland forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Montia howellii	Howell's montia	–/–/–/–/2B.2	(February) March–May	0–835	Meadows and seeps, North Coast coniferous forest, and vernal pools. Sometimes roadsides	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Oenothera wolfii	Wolf's evening-primrose	–/–/–/BLMS/1B.1	May–October	3–800	Sandy, usually mesic soils in coastal bluff scrub, coastal dunes, coastal prairie, and lower montane coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Opuntia fragilis	brittle prickly-pear	–/–/–/–/2B.1	April–July	820–880	Volcanic soils in pinyon and juniper woodland	Potential habitat within the Primary Area of Analysis
Orcuttia tenuis	Slender Orcutt Grass	FT/CE/–/–/1B.1	May–September (October)	35–1,760	Often in gravelly vernal pools	Potential habitat within the Primary Area of Analysis
Orthocarpus pachystachyus	Shasta orthocarpus	–/–/–/BLMS/1B.1	May	840–850	Great Basin scrub, meadows and seeps, and valley and foothill grassland	Potential habitat within the Primary Area of Analysis
Oxalis suksdorfii	Suksdorf's wood-sorrel	–/–/–/–/4.3	May–August	15–700	Broadleafed upland forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Packera bolanderi var. *bolanderi*	seacoast ragwort	–/–/–/–/2B.2	(Jan–April) May–July (August)	30–650	Coastal scrub and North Coast coniferous forest. Sometimes roadsides	Potential habitat within the Primary Area of Analysis
Packera hesperia	western ragwort	–/–/FSS/–/2B.2	April-June	500–2,500	Serpentine soils in meadows and seeps and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Packera macounii	Siskiyou Mountains ragwort	–/–/–/–/4.3	June–July	400–915	Sometimes serpentine, often in disturbed areas in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Penstemon cinicola	ash beardtongue	–/–/–/–/4.3	June–August (September)	730–2,685	Volcanic, sandy or rocky soils in lower montane coniferous forest, meadows and seeps, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Penstemon filiformis	thread-leaved beardtongue	–/–/–/BLMS/1B.3	May–August (September)	450–1,875	Rocky, often serpentine soils in cismontane woodland and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Phacelia greenei	Scott Valley phacelia	–/–/–/BLMS/1B.2	April–June	800–2,440	Serpentine soils in closed-cone coniferous forest, lower montane coniferous forest, subalpine coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Phlox hirsuta	Yreka phlox	FE/CE/–/–/1B.2	March–April	760–1,500	Serpentine soils, talus in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Pinguicula macroceras	horned butterwort	–/–/–/–/2B.2	April–June	40–1,920	Serpentine soils in bogs and fens	Potential habitat within the Primary Area of Analysis
Piperia candida	white-flowered rein orchid	–/–/–/BLMS/1B.2	(March) May–September	30–1,310	Sometimes serpentine soils in broadleafed upland forest, lower montane coniferous forest, and North Coast coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Pityopus californicus	California pinefoot	–/–/–/–/4.2	(March–April) May–August	15–2,225	Mesic soils in broadleafed upland forest, lower montane coniferous forest, North Coast coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Pleuropogon refractus	nodding semaphore grass	–/–/–/–/4.2	(March) April–August	0–1,600	Mesic soils in lower montane coniferous forest, meadows and seeps, North Coast coniferous forest, and riparian forest	Potential habitat within the Primary Area of Analysis
Poa piperi	Piper's blue grass	–/–/–/–/4.3	April–May	100–1,460	Serpentine, rocky soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Polemonium carneum	Oregon polemonium	–/–/–/–/2B.2	April–September	0–1,830	Coastal prairie, coastal scrub, and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Potamogeton foliosus subsp. *fibrillosus*	fibrous pondweed	–/–/–/–/2B.3	July–October	5–1,300	Shallow freshwater marshes and swamps	Potential habitat within the Primary Area of Analysis
Prosartes parvifolia	Siskiyou bells	–/–/FSS/–/1B.2	May–September	700–1,525	Often roadsides, disturbed areas, and burned areas in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Pyrrocoma racemosa var. *congesta*	Del Norte pyrrocoma	–/–/–/–/2B.3	August–September	200–1,000	Serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Ribes laxiflorum	trailing black currant	–/–/–/–/4.3	March–July(August)	5–1,395	North Coast coniferous forest, sometimes roadsides	Potential habitat within the Primary Area of Analysis
Romanzoffia tracyi	Tracy's romanzoffia	–/–/–/–/2B.3	March–May	15–30	Rocky soils in coastal bluff scrub and coastal scrub	Potential habitat within the Primary Area of Analysis
Rosa gymnocarpa var. *serpentina*	Gasquet rose	–/–/–/–/1B.3	April–June(August)	400–1,725	Serpentine soils, often roadsides, sometimes ridges, streambanks, and openings in chaparral and cismontane woodland	Potential habitat within the Primary Area of Analysis
Rubus nivalis	snow dwarf bramble	–/–/–/–/2B.3	June–August	1,085–1,350	North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Sabulina howellii	Howell's sandwort	–/–/–/BLMS/1B.3	April–July	550–1,000	Serpentine and xeric soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Salvia dorrii var. *incana*	fleshy sage	–/–/–/–/3	May–July	300–1,295	Great Basin scrub and pinyon and juniper woodland	Documented during PacifiCorp surveys at Iron Gate Reservoir and along Klamath River from Iron Gate Dam to Shasta River (PacifiCorp 2004a)
Sanguisorba officinalis	great burnet	–/–/–/–/2B.2	July–October	60–1,400	Often serpentine soils in bogs and fens, broadleafed upland forest, meadows and seeps, marshes and swamps, North Coast coniferous forest, and riparian forest	Potential habitat within the Primary Area of Analysis
Sanicula peckiana	Peck's sanicle	–/–/–/–/4.3	March, May, June	150–800	Often serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Sanicula tracyi	Tracy's sanicle	–/–/FSS/–/4.2	April–July	100–1,585	Openings in cismontane woodland, lower montane coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Schoenoplectus subterminalis	water bulrush	–/–/–/–/2B.3	June–August(September)	750–2,250	Bogs and fens, marshes and swamps and montane lake margins	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Scirpus pendulus	pendulous bulrush	–/–/–/–/2B.2	June, August	800–1,000	Mesic meadows and seeps, and freshwater marshes and swamps	Potential habitat within the Primary Area of Analysis
Sedum citrinum	Blue Creek stonecrop	–/–/–/–/1B.2	June	1,050–1,280	Serpentine and rocky soils in North Coast coniferous forest, talus, scree, or boulder crevices; sometimes roadsides	Potential habitat within the Primary Area of Analysis
Sedum laxum subsp. *flavidum*	pale yellow stonecrop	–/–/–/–/4.3	May–July	455–2,000	Serpentine or volcanic soils in broadleafed upland forest, chaparral, cismontane woodland, lower montane coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Sedum laxum subsp. *heckneri*	Heckner's stonecrop	–/–/–/–/4.3	June–July	100–2,100	Serpentine or gabbroic soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Sedum oblanceolatum	Applegate stonecrop	–/–/–/–/1B.1	June–July	400–2,000	Rocky soils and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Sedum obtusatum spp. paradisum	Canyon Creek stonecrop	–/–/FSS/–/1B.3	May-June	300–1,900	Granitic, rocky soils in broadleafed upland forest, chaparral, lower montane coniferous forest, and subalpine coniferous forest	Potential habitat within the Primary Area of Analysis
Sidalcea celata	Redding checkerbloom	–/–/–/–/3	April–August	135–1,525	Sometimes serpentine soils in cismontane woodland	Potential habitat within the Primary Area of Analysis
Sidalcea elegans	Del Norte checkerbloom	–/–/–/–/3.3	May–July	215–1,365	Serpentine soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Sidalcea malachroides	maple-leaved checkerbloom	–/–/–/–/4.2	(March) April–August	0–730	Often in disturbed areas in broadleafed upland forest, coastal prairie, coastal scrub, North Coast coniferous forest, and riparian woodland	Potential habitat within the Primary Area of Analysis
Sidalcea malviflora subsp. *patula*	Siskiyou checkerbloom	–/–/–/BLMS/1B.2	May–August	15–880	Often roadcuts in coastal bluff scrub, coastal prairie, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Sidalcea oregana subsp. *eximia*	coast checkerbloom	–/–/–/BLMS/1B.2	June–August	5–1,340	Lower montane coniferous forest, meadows and seeps, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Silene marmorensis	Marble Mountain campion	–/–/–/–/1B.2	June, August	170–1,250	Broadleafed upland forest, chaparral, cismontane woodland, and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Silene serpentinicola	serpentine catchfly	–/–/FSS/–/1B.2	May–July	145–1,650	SerpentineOpenings in serpentine gravelly or rocky soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Smilax jamesii	English Peak greenbrier	–/–/–/BLMS/4.2	May–July (August–October)	505–1,975	Streambanks and lake margins, mesic depressions, broadleafed upland forest, lower montane coniferous forest, marshes and swamps, North Coast coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Strepthanthus howellii	Howell's jewelflower	–/–/FSS/–/1B.2	July-August	305–1,500	Serpentine, rocky soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Strepthanthus oblanceolatus	Trinity River jewelflower	–/–/FSS/–/1B.2	April-June	20–420	Cismontane woodland	Potential habitat within the Primary Area of Analysis
Tauschia glauca	glaucous tauschia	–/–/–/–/4.3	April–June	80–1,700	Gravelly, serpentine soils in lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Thermopsis gracilis	slender false lupine	–/–/–/–/4.3	March–July	100–1,720	Chaparral, cismontane woodland, lower montane coniferous forest, meadows and seeps, and North Coast coniferous forest. Sometimes roadsides	Potential habitat within the Primary Area of Analysis
Thermopsis robusta	robust false lupine	–/–/FSS/–/1B.2	May–July	150–1,500	Broadleafed upland forest and North Coast coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Tiarella trifoliata var. *trifoliata*	trifoliate laceflower	–/–/–/–/3.2	(May) June–August	170–1,500	Edges, moist shady streambanks in lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Tracyina rostrata	beaked tracyina	–/–/FSS/–/1B.2	May-June	90–750	Chaparral, cismontane woodland, and valley and foothill grassland	Potential habitat within the Primary Area of Analysis
Trifolium siskiyouense	Siskiyou clover	–/–/–/–/1B.1	June–July	880–1,500	Mesic meadows and seeps, sometimes streambanks	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Trillium ovatum subsp. *oettingeri*	Salmon Mountains wakerobin	–/–/–/–/4.2	February–July	855–2,024	Mesic soils in lower montane coniferous forest, riparian scrub, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Triteleia grandiflora	large-flowered triteleia	–/–/–/–/2B.1	April–June	700–1,500	Great Basin scrub and Pinyon and juniper woodland	Potential habitat within the Primary Area of Analysis
Triteleia hendersonii	Henderson's triteleia	–/–/–/–/2B.2	May–July	760–1,200	Cismontane woodland	Potential habitat within the Primary Area of Analysis
Vaccinium coccineum	Siskiyou Mountains huckleberry	–/–/–/–/3.3	June–August	1,095–2,135	Often serpentine soils in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Vaccinium scoparium	little-leaved huckleberry	–/–/–/–/2B.2	June–August	1,036–2,200	Rocky soils in subalpine coniferous forest	Potential habitat within the Primary Area of Analysis
Veratrum insolitum	Siskiyou false-hellebore	–/–/–/–/4.3	June–August	45–1,635	Clay soils in chaparral and lower montane coniferous forest	Potential habitat within the Primary Area of Analysis
Viola howellii	Howell's violet	–/–/–/–/2B.2	May–June	655	North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Viola lanceolata ssp. *occidentalis*	western white bog violet	–/–/FSS/–/1B.2	April-September	100–990	Serpentine soils in bogs and fens, marshes and swamps	Potential habitat within the Primary Area of Analysis
Viola palustris	alpine marsh violet	–/–/–/–/2B.2	March–August	0–150	Coastal bogs and fens and mesic coastal scrub	Potential habitat within the Primary Area of Analysis
Viola primulifolia subsp. *occidentalis*	western white bog violet	–/–/–/–/1B.2	April–September	100–990	Serpentine bogs and fens and marshes and swamps	Potential habitat within the Primary Area of Analysis
Bryophytes						
Anomobryum julaceum	slender silver moss	–/–/–/–/4.2	N/A	100–1,000	Damp rock and soil on outcrops, usually on roadcuts in broadleafed upland forest, lower montane coniferous forest, and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Buxbaumia viridis	buxbaumia moss	–/–/FSS/BLMS/2B.2	N/A	975–2,200	Fallen wood or humus in lower montane coniferous forest, subalpine coniferous forest, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Discelium nudum	naked flag moss	–/–/–/–/2B.2	N/A	10–50	Clay banks in coastal bluff scrub	Documented within the Primary Area of Analysis (CDFW 2017a)

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Fissidens pauperculus	minute pocket moss	–/–/FSS/–/1B.2	N/A	10–1,024	Damp coastal soil in North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Mielichhoferia elongata	elongate copper moss	–/–/FSS/–/4.3	N/A	0–1,960	Metamorphic rock, usually acidic, usually vernally mesic, and sometimes carbonate soils in broadleafed upland forest, chaparral, cismontane woodland, coastal scrub, lower montane coniferous forest, meadows and seeps, and subalpine coniferous forest	Potential habitat within the Primary Area of Analysis
Orthotrichum holzingeri	Holzinger's orthotrichum moss	–/–/–/–/1B.3	N/A	715–1,800	Usually on rock in and along streams, and rarely on tree limbs in cismontane woodland, lower montane coniferous forest, pinyon and juniper woodland, and upper montane coniferous forest	Documented within the Primary Area of Analysis (CDFW 2017a)
Ptilidium californicum	Pacific fuzz wort	–/–/–/BLMS/4.3	May–August	1,140–1,800	Usually epiphytic on live or dead trees, fallen and decaying logs, and stumps and rarely on humus over boulders in lower montane coniferous forest and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Trichodon cylindricus	cylindrical trichodon	–/–/–/–/2B.2	N/A	50–2,002	Sandy, exposed soil, roadbanks in broadleafed upland forest, meadows and seeps, and upper montane coniferous forest	Potential habitat within the Primary Area of Analysis
Triquetrella californica	coastal triquetrella	–/–/–/–/1B.2	N/A	10–100	Coastal bluff scrub and coastal scrub.	Documented within the Primary Area of Analysis (CDFW 2017a).
Lichen						
Bryoria pseudocapillaris	false gray horsehair lichen	–/–/–/–/3.2	N/A	0–90	Conifers in North Coast coniferous forest along the coast	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Calicium adspersum	spiral-spored guilded-head pin lichen	–/–/FSS/–/2B.2	N/A	200	Often restricted to bark of conifers over 200 years old in lower montane coniferous forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Peltigera gowardii	western waterfan lichen	–/–/FSS/–/4.2	N/A	1,065–2,620	On rocks in cold water creeks with little or no sediment or disturbance in riparian forest	Potential habitat within the Primary Area of Analysis
Ramalina thrausta	angel's hair lichen	–/–/FSS/–/2B.1	N/A	75–430	On dead twigs and other lichens in North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Sulcaria badia	groovy beard lichen	–/–/FSS/–/–	N/A	0–670	Mesic mixed hardwood/mid-mature *Pseudotsuga menziesii* forest, with additional hardwoods (*Quercus kelloggii*) occasional in the vicinity[4]	Potential habitat within the Primary Area of Analysis
Usnea longissima	Methuselah's beard lichen	–/–/–/BLMS/4.2	N/A	50–1,460	Tree branches, usually on old growth hardwoods and conifers in broadleafed upland forest and North Coast coniferous forest	Potential habitat within the Primary Area of Analysis
Fungi[5]						
Cudonia monticola		–/–/FSS/–/–	fruits primarily in spring	160–1,827	Common under conifers in mature moist coniferous forests in northern CA and the Pacific Northwest. Typically associated with very rotten wood	Potential habitat within the Primary Area of Analysis
Dendrocollybia racemosa	branched Collybia	–/–/FSS/–/–	fruits in autumn	Unknown	Grows on the remains of decayed mushrooms, or in duff of mixed hardwood-conifer woods in Pacific Northwest	Potential habitat within the Primary Area of Analysis
Otidea smithii		–/–/FSS/–/–	fruits August-December	381–1,144	Usually under conifer forests in Pacific Northwest and Norther California	Potential habitat within the Primary Area of Analysis
Phaeocollybia olivacea	Olive Phaeocollybia	–/–/FSS/–/–	fruits September-December	6–962	Grows on ground in mixed woods and under conifers in southern Oregon and northern California	Potential habitat within the Primary Area of Analysis

Scientific Name	Common Name	Status[1] Federal/ State/USDA Forest Service/ BLM/CRPR	Blooming Period[2,3]	Elevation Range (m)	California Habitat Associations[2]	Potential Habitat Or Documented Occurrence?
Rubroboletus pulcherrimus [Boletus pulcherrimus]	red-pored Bolete	–/–/FSS/–/–	fruits July–December	13–1,713	In mixed hardwood-conifer forests. Often found growing under conifers	Potential habitat within the Primary Area of Analysis
Tricholomopsis fulvescens		–/–/FSS/–/–	Unknown	above 1,000	Grows on rotting conifer logs in the Pacific Northwest and northern California	Potential habitat within the Primary Area of Analysis

[1] Status:
Federal
FE Federally Endangered
FT Federally Threatened
– No federal status
State
CE California State Endangered
CR California State Rare
– No state status
USDA Forest Service
FSS USDA-FS Sensitive
– No USDA-FS status
BLM
BLMS BLM Sensitive
– No BLM status
California Rare Plant Rank (CRPR; formerly known as CNPS Lists)
List 1B Plants rare, threatened, or endangered in California and elsewhere
List 2B Plants rare, threatened, or endangered in California, but more common elsewhere
List 3 More information needed about this plant, a review list
List 4 Plants of limited distribution, a watch list
– No CRPR status
CNPS Threat Ranks:
0.1 Seriously threatened in California (high degree/immediacy of threat)
0.2 Fairly threatened in California (moderate degree/immediacy of threat)
0.3 Not very threatened in California (low degree/immediacy of threats or no current threats known)

[5] Information sources include Aurora 1986, USDA_FS and BLM 2017.

Special-status Wildlife

To assess the possible effects of the Proposed Project on special-status species analyzed in this EIR, all special-status terrestrial wildlife species identified in the querying process described above (Section 3.5.2.5 *Special-status Species*) were evaluated for the potential to occur in the Proposed Project Vicinity (see Appendix Table J-3 for all wildlife species reviewed in the querying process) to determine inclusion for further analysis based on the following considerations: previously documented (including sightings from 1954) and known to occur in the Primary Area of Analysis for terrestrial resources, designated critical habitat is present in the Primary Area of Analysis, suitable habitat present in the Primary Area of Analysis, and/or potential to be affected by the Proposed Project. The 46 terrestrial special status determined to be appropriate for further analysis are six invertebrates, six amphibians, two reptiles, 23 birds, and nine mammals (Table 3.5-5). Habitat and occurrence information from CNDDB and 2002 and 2003 survey results from PacifiCorp (2004a) and 2018 surveys from KRRC (as referenced in Section 3.5.2.4 *Non-Special Status Wildlife*) are provided in Table 3.5.-5.

(see Section 3.3.2 *Environmental Setting* and Appendix Table A-1 for a discussion of aquatic special-status wildlife species such as Shasta crayfish, sea turtles, sea lion, and whales.)

Table 3.5-5. Suitable Habitat and Occurrence Information for Special-status Wildlife Species.

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Invertebrates			
Hooded lancetooth *Ancotrema voyanum*	--/--/BLMS	Limestone substrates, mostly in an elevation range of 550–3,100 feet	• Species was documented in 1992 approximately 4 miles southwest of Orleans and approximately 0.2 miles from the Klamath River (greater than 100 river miles (RM) downstream of Iron Gate Dam) (CDFW 2017a).
Oregon shoulderband *Helminthoglypta hertleini*	--/--/BLMS	Found on basaltic talus slopes where ground cover/moisture is present; adapted to dry conditions during a portion of the year	• Single occurrence has been documented approximately 100 RM downstream of Iron Gate Dam (no documentation date) (2017a).
Trinity shoulderband *Helminthoglypta talmadgei*	--/--/BLMS	Limestone rockslides, litter in coniferous forests, old mine tailings, and along shaded streams	• Single occurrence documented at mine tailings in 1954 more than 100 RM downstream of Iron Gate Dam (2017a).
Siskiyou shoulderband *Monadenia chaceana*	--/--/BLMS	Lower reaches of major drainages. Talus and rock slides, under rocks and woody debris in moist conifer forests, caves, and riparian corridors in shrubby areas	• Single occurrence has been documented approximately 0.25 RM downstream of Copco No. 2 Dam in a lava rockslide (no documentation date) (2017a).
Tehama chaparral *Trilobopsis tehamana*	--/--/FSS, BLMS	Rocky talus and under leaf litter or woody debris within approximately 330 feet of limestone outcrops	• Two occurrences in 1990 and 1994—one sighting near the Klamath River and another along the hill slope. Both occurrences are more 20 RM downstream of Iron Gate Dam (2017a).
Western bumblebee *Bombus occidentalis*	–/–/FSS	Shrub, chaparral, and open grassy areas (urban parks, mountain meadows)	• Six sightings from 1969 and earlier are located more than 70 RM downstream of Iron Gate Dam (2017a).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Amphibians			
Southern torrent (southern seep) salamander *Rhyacotriton variegatus*	–/SSC/FSS	In and adjacent to cold, permanent, well-shaded mountain springs, waterfalls, and seeps with rock substrate	• Not observed in California during the PacifiCorp surveys (PacifiCorp 2004a). • Approximately 10 sightings have been recorded, approximately 50 RM or more downstream from Iron Gate Dam typically along tributaries or at the confluence to the Klamath River; the most recent sighting was from 2007. • Found to be widespread in the tributaries of the Lower Klamath River (Green Diamond Resources Company 2006), but due to lack of suitable habitat, would not be expected to occur in the mainstem of the Lower Klamath River.
Scott Bar salamander *Plethodon asupak*	--/ST/--	Rocky forested areas, especially thick moss-covered talus; elevation range of 1,500–2,000 feet	• Not documented in California during the PacifiCorp surveys (PacifiCorp 2004a,b). • Documented at four locations approximately 30 RM downstream of Iron Gate Dam between 1996 and 2005 (CDFW 2017a).
Siskiyou Mountains salamander *Plethodon stormi*	--/ST/FSS	Loose rock talus on north-facing slopes or in dense wooded areas; also under bark near talus	• Not documented in California during the PacifiCorp surveys (PacifiCorp 2004a). • Documented at five locations approximately 30 RM downstream of Iron Gate Dam between 1972 and 2003 (CDFW 2017a).
Pacific tailed frog *Ascaphus truei*	–/SSC/–	In and adjacent to cold, clear, moderate- to fast-flowing, perennial mountain streams in conifer forest	• Not documented in California during the PacifiCorp surveys (PacifiCorp 2004a). • Observed at the confluence of a tributary approximately 60 RM downstream from Iron Gate Dam in 1989. Farther downstream, five additional sites are documented along tributaries to the Klamath or at the confluence (2017a). • Found to be widespread in the tributaries of the Lower Klamath River (Green Diamond Resources Company 2006), but due to lack of suitable habitat for these species, would not would be expected to occur in the mainstem of the Lower Klamath River.

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Foothill yellow-legged frog *Rana boylii*	Petition to list/ SCT, SSC/FSS, BLMS	Shallow tributaries and mainstems of perennial streams and rivers, typically associated with cobble or boulder substrate	• Documented on tributaries to the Klamath River (CDFW 2017a). • Documented in 2017 on the Lower Klamath River, approximately 13 RM upstream of the estuary (M. Wikaira Yurok Tribe to Parker Thaler, pers. comm., January 2018), approximately 20 RM upstream of the estuary by landowner Green Diamond in 1994 (CDFW 2017a), and approximately 50 RM downstream from Iron Gate Dam in 1970 and farther downstream in 1976 (CDFW 2017a). • Detections are rare in the Klamath Basin (AmphibiaWeb 2017) • PacifiCorp targeted surveys in 2003 at most likely habitat locations (including Bogus and Cottonwood Creek, approximately 0.2 and 7 miles downstream of Iron Gate Dam, respectively) detect no occurrences (PacifiCorp 2004a). • Historical localities were restricted to a relatively small area that consisted of the mainstem Klamath River in the Klamath River Canyon, California, and its nearby tributaries (Borisenko and Hayes 1999). • One frog observed at Boise Creek in 1999 (Hayes et al. 2016).
Northern red-legged frog *Rana aurora*	–/SSC/FSS	Breeds in still or slow-moving water with emergent and overhanging vegetation, including wetlands, wet meadows, ponds, lakes, and low-gradient, slow-moving stream reaches with permanent pools; uses adjacent uplands for dispersal and summer retreat	• Not documented in California during the PacifiCorp surveys (PacifiCorp 2004a). • A 1995 sighting was documented approximately 20 RM upstream of the Klamath River Estuary; species located along the north bank of the Klamath River along mats of vegetation (CDFW 2017a).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Reptiles			
Western pond turtle *Actinemys marmorata*	Petition to list/SSC/FSS, BLMS	Permanent, slow-moving fresh or brackish water with available basking sites and adjacent open habitats or forest for nesting	• Documented in 2018 at Iron Gate Reservoir with majority of observations along the northern half of the reservoir (Mirror Cove and near Camp Creek and Jenny Creek) and throughout Copco No. 1 Reservoir with majority of observations occurring in the northern Beaver Creek and Raymond Gulch coves. Also observed near the Copco Rd bridge at the upstream end of the reservoir (CDM Smith 2018c). • Considered common to abundant in many Lower Klamath Project reservoirs and reaches with suitable nesting habitat being present. During PacifiCorp 2002 and 2003 surveys, 6 turtles were documented in California portion of the J.C. Boyle peaking reach (12 at Copco No. 1 Reservoir, 18 in the beaver dam pond/wetland between Fall Creek and Iron Gate Reservoir, and 17 at Iron Gate Reservoir. Surveys downstream of the Iron Gate Dam to Shasta River documented one site with 9 turtles; however, it was noted that the survey had several gaps due to sites being inaccessible (PacifiCorp 2004a). • Documented basking during May 2018 wildlife surveys in the reservoirs-9 in Iron Gate Reservoir and between 31-36 in Copco No. 1 Reservoir (K. Stenberg, Principal, CDM Smith, pers. comm., July 2018). • Approximately 10 miles RM downstream of Iron Gate Dam, an individual was observed basking approximately 0.5 miles upstream of Williams Creek at the confluence of a tributary in November 2005 (CDFW 2017a).PacifiCorp (2002) indicated that most basking probably occurs in Iron Gate Reservoir when water levels decrease, and the turtles use emerging rocks and boulders; however low water levels reduce the amount of aquatic habitat and make bordering emergent wetlands less accessible due to increased distance (PacifiCorp 2004a).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Northern sagebrush lizard *Sceloporus graciosus*	–/–/BLMS	Inhabits sagebrush, chaparral, juniper woodlands, and dry conifer forests	• Documented during PacifiCorp surveys near the edge of a forested wetland along Iron Gate Reservoir (PacifiCorp 2004a). • Documented during 2018 surveys in several areas surrounding Copco No. 1 Reservoir including a large population in a rocky area to the east of Fall Creek, and Iron Gate Reservoir including Bogus Creek fish hatchery, Long Gulch Cove shoreline, Jenny Creek shorelines, and recreational areas (CDM Smith 2018c,d).
Birds			
American white pelican *Pelecanus erythrorhynchos*	–/SSC/–	Nests at lakes and marshes and uses almost any lake outside of the breeding season	• Documented during PacifiCorp surveys—55 pelicans on Copco No. 1 Reservoir and 107 pelicans on Iron Gate Reservoir (PacifiCorp 2004a). • Documented at Copco No. 1 and Iron Gate reservoirs (eBird 2018), • Documented during 2018 surveys throughout Copco No. 1 Reservoir near the dam and in Keaton Cove and at Iron Gate Reservoir, including Mirror Cove, Juniper Point, upstream extent of the reservoir, and near the boom in front of Iron Gate Dam (CDM Smith 2018c,d).
Barrow's goldeneye *Bucephala islandica*	–/SSC/–	May be found in northern California during the winter (non-breeding season) along open water and riverine habitat. Nests in cavities, including artificial nest boxes	• Documented during PacifiCorp surveys at Copco and Iron Gate reservoirs primarily between January and April (PacifiCorp 2004a), prior to northward migration. • Documented at Iron Gate Reservoir and on the Klamath River downstream of Iron Gate Dam (eBird 2018).
Common loon *Gavia immer*	–/SSC/–	Freshwater lakes, rivers, estuaries, and coastlines	• Documented during PacifiCorp surveys at Iron Gate Reservoir (PacifiCorp 2004a).
Bald eagle *Haliaeetus leucocephalus*	–, Bald and Golden Eagle Protection Act (BGEPA), SFP/SE, BLMS, FSS	Large bodies of water or rivers with abundant fish; uses adjacent snags or other perches; nests and winter communal roosts in advanced-successional conifer forest within approximately 1 mile of open water	• Documented during the KRRC surveys, two inactive bald eagle nests—one within 0.5 miles of Copco Reservoir and one located between 0.5–2 miles of Iron Gate Reservoir (S. Leonard, AECOM, Senior Water Resources Engineer, pers. comm, October 2018). • Documented in 1997 along the Klamath River, and approximately 2 miles from Copco No. 1 and No. 2 dams (CDFW 2017a). • Documented during PacifiCorp surveys at J.C. Boyle and Copco No. 1 reservoirs. The highest number of bald eagles (12) was found at Copco No.1 Reservoir (PacifiCorp 2004a,b).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Northern harrier *Circus cyaneus*	–/SSC/–	Nests, forages, and roosts in wetlands or along rivers or lakes, but also in grasslands, meadows, or grain fields	• Documented during PacifiCorp surveys along the Klamath River from Iron Gate Dam to Shasta River (PacifiCorp 2004a). • Documented along Copco No. 1 Reservoir, along Iron Gate Reservoir and tributaries, and Klamath River downstream of Iron Gate Dam (eBird 2018).
Northern goshawk *Accipter gentilis*	–/SSC/FSS, BLMS	Mature and old-growth stands of coniferous forest, middle and higher elevations; nests in dense part of stands near an opening	• Documented during PacifiCorp surveys flying over J.C. Boyle peaking reach (PacifiCorp 2004a). • Documented in 1981 more than 80 RM downstream of Iron Gate Dam (CDFW 2017a).
Swainson's hawk *Buteo swainsoni*	–/ST/BLMS	Nests in oaks or cottonwoods in or near riparian habitats; forages in grasslands, irrigated pastures, and grain fields	• Documented occurrences within the Project Vicinity near agricultural fields approximately 10 miles east of Copco No. 1 Reservoir (CDFW 2017a).
Golden eagle *Aquila chrysaetos*	–/SFP/–	Open woodlands and oak savannahs, grasslands, chaparral, sagebrush flats; nests on steep cliffs or large trees	• Documented during PacifiCorp surveys along the lower reaches of the J.C. Boyle peaking reach and along Iron Gate and Copco No. 1 reservoirs (PacifiCorp 2004a). • Also documented along the Klamath River, downstream of Iron Gate Dam (eBird 2018). • Two active golden eagle nests were documented during the KRRC surveys within two miles of Copco No. 1 Reservoir and three inactive nests were documented within 2 miles of Iron Gate Reservoir (S. Leonard, AECOM, Senior Water Resources Engineer, pers. comm, October 2018). In May 2018, a golden eagle was observed at Copco No. 1 Reservoir perched on a slope on the northern shoreline, a pair was observed near a northern cove, and one was observed bathing in the shallow water (CDM Smith 2018c).
American peregrine falcon *Falco peregrinus*	–/SFP/–	Wetlands, woodlands, cities, agricultural lands, and coastal area with cliffs (and rarely broken-top, predominant trees) for nesting; often forages near water	• Documented around Iron Gate Reservoir (CDFW 2017a). • Documented of Iron Gate Dam along the Klamath River (eBird 2018).
Greater sandhill crane *Grus canadensis tabida*	–/ST, SFP/FSS, BLMS	Forages in freshwater marshes and grasslands as well as harvested rice fields, corn stubble, barley, and newly planted grain fields	• Documented nesting habitat at J.C. Boyle Reservoir in May 2018 (Appendix B: *Definite Plan – Appendix J*). • Documented during the PacifiCorp surveys at J C. Boyle Reservoir (PacifiCorp 2004a). Other sightings in ponds and near agricultural fields east of Yreka (CDFW 2017a).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Black tern *Chlidonias niger*	–/SSC/–	Nests semi-colonially in protected areas of marshes	• Documented during PacifiCorp surveys at J.C. Boyle Reservoir (PacifiCorp 2004a).
Western yellow-billed cuckoo *Coccyzus americanus*	FT/SE/FSS, BLMS No critical habitat proposed within the Primary Area of Analysis	Summer resident of valley foothill and desert riparian habitats; nests in open woodland with clearings and low, dense, scrubby vegetation	• Although not documented in the area, it has been noted that the species has the potential to be in the vicinity (PacifiCorp 2004a). • In coordination with state agencies, it has been noted that breeding habitat is unlikely in the area.
Northern spotted owl *Strix occidentalis caurina*	FT/ST, SSC/– Critical habitat designated approximately 0.5 miles south east of Copco No. 1 Reservoir	Typically in older forested habitats; nests in complex stands dominated by conifers, especially coastal redwood, with hardwood understories; some open areas are important for foraging	• Detected during PacifiCorp surveys southeast of Copco No. 1 Reservoir (PacifiCorp 2004a). • Activity center is located approximately 1.7 miles southeast of Copco No. 1 Reservoir (CDFW 2017c). • Designated critical habitat approximately 0.5 miles southeast of Copco No. 1 Reservoir and along the Klamath River approximately 40 RM downstream of Iron Gate Dam. • Critical habitat is located north of the Lower Klamath Project in the Jenny Creek basin, upstream of Copco No. 1 Reservoir, and along portions of the Lower Klamath River. Also documented on National Forest lands and along the Lower Klamath River on lands managed by Green Diamond Resources Company.
Great gray owl *Strix nebulosi*	–/SE/FSS	Dense, coniferous forest, usually near a meadow for foraging; nests in large, broken-topped snags	• Documented during PacifiCorp surveys east of Fall Creek near Jenny Creek (PacifiCorp 2004a).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Black swift *Cypseloides niger*	–/SSC/–	Nests in moist crevices behind or beside permanent or semi-permanent waterfalls in deep canyons, on perpendicular sea cliffs above surf, and in sea caves; forages widely over many habitats	• Not documented in California during the PacifiCorp surveys (PacifiCorp 2004a). • Single occurrence is known from 1982 along the banks of the Klamath River, over 100 RM downstream of Iron Gate Dam (CDFW 2017a).
Vaux's swift *Chaetura vauxi*	–/SSC/–	Redwood and Douglas-fir habitats with large snags, especially forest with larger basal hollows and chimney trees	• Documented during PacifiCorp surveys at Copco No. 1 and Iron Gate reservoirs, along the J.C. Boyle peaking reaches, along Fall Creek, and along Klamath River from Iron Gate Dam to Shasta River (PacifiCorp 2004a).
Black-backed woodpecker *Picoides arcticus*	Petitioned for listing filed in 2012. In October 2017, USFWS released a finding indicating listing of the species is not warranted (USFWS 2017b)/ Petitioned for listing filed in 2012. In May 2013, the Fish and Game Commission released a finding indicating listing of the species is not warranted (CDFW 2013)/–/–	Affinity to boreal and montane coniferous forests post-burn or following outbreaks of wood-burning beetles	• Not documented in the area; however, potential for the species to occur due to the presence of suitable habitat (coniferous forest).
Olive-sided flycatcher *Contopus cooperi*	–/SSC/–	Primarily advanced-successional conifer forests with open canopies	• Documented during PacifiCorp surveys along Iron Gate Reservoir and along J.C. Boyle peaking reach (PacifiCorp 2004a). • Observed during 2018 surveys at the northern coves and riparian woodlands at Copco No. 1 Reservoir (CDM Smith 2018c)

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Willow flycatcher *Empidonax traillii*	–/SE/FSS	Dense brushy thickets within riparian woodland often dominated by willows and/or alder, near permanent standing water; uses brushy, early-succession forests (e.g., clearcuts) in the Pacific Northwest	• Documented during PacifiCorp surveys in riparian and wetland habitats located along the shoreline of Copco No. 1 and Iron Gate reservoirs, along the J.C. Boyle peaking reach, and along Klamath River from Iron Gate Dam to Shasta River (PacifiCorp 2004a). • Documented Iron Gate Reservoir at Jenny Creek in 2008 (CDFW 2017a). • Observed during 2018 surveys at Copco No. 1 Reservoir in the northern cove at the confluence of West Fork Beaver Creek, Beaver Creek, and East Fork Beaver Creek in fringe willow (CDM Smith 2018c).
Purple martin *Progne subis*	–/SSC/–	Conifer, valley-foothill, montane-hardwood forests with large snags in open areas; most nest sites located in upper slopes of hilly terrain; also may nest in human-made structures with cavities	• Documented during PacifiCorp surveys upstream of the upper falls at Fall Creek (PacifiCorp 2004a). • Documented a few locations along the Klamath River, downstream of Iron Gate Dam (eBird 2018).Observed nesting during 2018 survey on a utility pole near the intersection of Copco Road and the dam access spur road (CDM Smith 2018c).
tricolored blackbird *Agelaius tricolor*	Petition to list/SCE, SSC/–	Feeds in grasslands and agriculture fields; nesting habitat components include open accessible water, a protected nesting substrate (including flooded or thorny vegetation), and a suitable nearby foraging space with adequate insect prey	• A single sighting in 2011 (eBird 2018) at Copco No. 1 Reservoir and potential for the species to occur due to the potential presence of suitable habitat (open foraging area adjacent to aquatic habitat). • Flock of approximately 25 observed in an agricultural field along Yreka Ager Road, located approximately 12 miles southwest of the Bogus Creek Fish Hatchery (CDM Smith 2018c).
Yellow warbler *Setophaga petechia*	–/SSC/–	Open-canopy, deciduous riparian woodland close to water, along streams or wet meadows	• Documented during PacifiCorp surveys at all Lower Klamath Project reservoirs and reaches (PacifiCorp 2004a). • Documented along the Klamath River downstream of Iron Gate Dam (eBird 2018). • Observed around Copco No. 1. Reservoir and most frequent in riparian woodlands and hillside seep areas and also at Iron Gate Reservoir, including Bogus Creek fish hatchery, Brush Creek, Camp Creek, and Jenny Creek (CDM Smith 2018c).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Yellow-breasted chat *Icteria virens*	–/SSC/–	Early-successional riparian habitats with a dense shrub layer and an open canopy	• Documented during PacifiCorp surveys in wetland and riparian habitats along J.C. Boyle peaking reach, at Copco No. 1 Reservoir, along Fall Creek, and along Klamath River from Iron Gate Dam to Shasta River (PacifiCorp 2004a). • Documented during 2018 surveys in the northern cove of Iron Gate Reservoir near Camp Creek and Horseshoe Ranch Wildlife Area, and at Fall Creek and along the southern portion of Copco No. 1 Reservoir, near Ager Beswick Road east of Keaton Cove (CDM Smith 2018c).
Mammals			
Western mastiff bat *Eumops perotis californicus*	–/SSC/–	Variety of habitats including desert scrub, chaparral, oak woodland, ponderosa pine, mid-elevation conifer (e.g., giant sequoia). Roosting habitat mostly associated with significant rock features. Forages seasonally at high elevations	• Not documented in California during PacifiCorp surveys (PacifiCorp 2004a). • Documented at Medicine Lake, Siskiyou County (Pierson and Rainey 1998). • Range includes the Primary Area of Analysis (CDFG 1997).
Townsend's western big-eared bat *Corynorhinus townsendii*	–/SSC/FSS, BLMS	Roosts in cavities, usually tunnels, caves, buildings, and mines, but also rock shelters, preferentially close to water. Caves near water's edge are favored.	• Not documented in California during the PacifiCorp surveys (PacifiCorp 2004a). • Two documented occurrences in 1997 at bridges approximately 40 RM downstream of Iron Gate Dam (CDFW 2017a). • Suitable habitat (e.g., man-made structures) are present in the Limits of Work. Structures providing habitat for a non-special-status bat species (Yuma myotis) were documented at the Copco No. 1 powerhouse and the Iron Gate south gatehouse (PacifiCorp 2004a), which may support other bat species.
Spotted bat *Euderma maculatum*	–/SSC/BLMS	Roosts in cracks, crevices, and caves, usually high in fractured rock cliffs solitary or in small groups	• Suitable habitat for this species (e.g., large dam faces) may be present in the Limits of Work. • Although not documented during PacifiCorp roost surveys, species speculated to be rare, but widely distributed, and as a result may be in Area of Analysis (PacifiCrop 2004a).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Pallid bat *Antrozous pallidus*	–/SSC/FSS, BLMS	Roosts in rock crevices, live or dead tree hollows, mines, caves, and a variety of vacant and occupied structures or buildings	• Not documented in California during PacifiCorp surveys (PacifiCorp 2004a); however, it was noted that species presence of a roost site was documented by one dead individual (Yuma myotis), and that it is possible that sites with confirmed evidence of bat use support aggregations of more than one species. • No CNDDB occurrences are documented within the Primary Area of Analysis. • Suitable habitat are present in the Limits of Work. Structures providing habitat for a non-special-status bat species (Yuma myotis) were documented at the Copco No. 1 powerhouse and the Iron Gate south gatehouse (PacifiCorp 2004a), which, along with other structures, trees, rock crevices in the area, may support other bat species.
Fringed myotis *Myotis thysanodes*	–/–/BLMS, FSS	Roosts in crevices, cavities, and foliage in a wide variety of habitats including rock crevices, caves, mines, buildings and bridges, and large-diameter snags	• Not documented in California during PacifiCorp surveys; however, it was noted that species presence of a roost site was documented by one dead individual (*Yuma myotis*), and that it is possible that sites with confirmed evidence of bat use support aggregations of more than one species. (PacifiCorp 2004a). • No CNDDB occurrences are documented within the Primary Area of Analysis. • Suitable habitat are present in the Limits of Work. Structures providing habitat for Yuma myotis were documented at the Copco No. 1 powerhouse and the Iron Gate south gatehouse (PacifiCorp 2004a), which, along with other structures, trees, rock crevices in the area, may support other bat species. • Habitat for myotis species inside Copco No. 1 C-12 gate house as a maternity roost of more than 2,000 Myotis spp. (species not noted) was confirmed in June 2018 and several hundred bats (species not noted) also roosting at Copco 1 diversion tunnel and Iron Gate diversion tunnel (KRRC 2018b).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
Long-eared myotis (*Myotis evotis*)	–/–/BLMS	Roosts in bridges, buildings, under exfoliating tree bark, and in hollow trees, caves, mines, cliff crevices, sinkholes, rocky outcrops on the ground	• Not documented in California during PacifiCorp surveys; however, it was noted that species presence of a roost site was documented by one dead individual (Yuma myotis), and that it is possible that sites with confirmed evidence of bat use support aggregations of more than one species. (PacifiCorp 2004a). • Suitable habitat (e.g., man-made structures) are present in the Limits of Work. • Habitat for myotis species inside Copco No. 1 C-12 gate house as a maternity roost of more than 2,000 Myotis spp. (species not noted) was confirmed in June 2018 and several hundred bats (species not noted) also roosting at Copco 1 diversion tunnel and Iron Gate diversion tunnel (KRRC 2018b).
Yuma myotis *Myotis yumanensis*	–/–/BLMS	Roosts in bridges, buildings, cliff crevices, caves, mines, and trees	• Structures providing habitat for Yuma myotis were documented at the Copco No. 1 powerhouse and the Iron Gate south gatehouse (PacifiCorp 2004a). • Habitat for myotis species inside Copco No. 1 C-12 gate house as a maternity roost of more than 2,000 Myotis spp. (species not noted) was confirmed in June 2018 and several hundred bats (species not noted) also roosting at Copco 1 diversion tunnel and Iron Gate diversion tunnel (KRRC 2018b).
Gray wolf *Canis lupus*	FE/SE/– No critical habitat designated	Range of habitats including temperate forests, mountains, tundra, taiga, and grasslands	• The Lower Klamath Project is not within or near the area of current wolf activity; however, have been previously documented in the area (CDFW 2017a; M. Harris, Senior Environmental Scientist, CDFW, pers. comm., October 2017). • Since December 2011, at least two packs of gray wolves and three separate individual wolves have been detected in California. Key wolf use areas to date have included western Lassen and eastern Siskiyou counties, although wolves have also been known to utilize parts of Modoc, Plumas, Shasta, and Tehama counties (M. Harris, Senior Environmental Scientist, CDFW, pers. comm., November 2017).

Common Name Scientific Name	Status[a] Federal/ State/USDA Forest Service, BLM	Habitat Association	Available Habitat and Occurrence Information within the Primary Area of Analysis
American badger *Taxidea taxus*	–/SSC/–	Shrubland, open grasslands, fields, and alpine meadows with friable soils	• Not documented in California during PacifiCorp surveys (PacifiCorp 2004a). • A single occurrence (unknown date) was documented approximately 2 miles upstream of Copco No. 1 Reservoir (CDFW 2017a).

[a] Status codes:

Federal
FT = Listed as threatened under the federal Endangered Species Act
BGEPA = Federally protected under the Bald and Golden Eagle Protection Act
FSS = USDA Forest Service Sensitive species
BLMS = Bureau of Land Management Sensitive Species

State
SE = Listed as Endangered under the California Endangered Species Act
ST = Listed as Threatened under the California Endangered Species Act
SCT = State Candidate Threatened
SSC = CDFW Species of Special Concern
SFP = CDFW Fully Protected species

3.5.2.6 Wildlife Corridors and Habitat Connectivity

Project reservoirs and waterways create substantial breaks in the connectivity of riparian habitat. Large mammals such as elk and deer are likely able to traverse narrow reservoirs, while these waterways may create barriers to small mammals, reptiles, and amphibians. In addition, canals, roads, powerhouses, and other facilities can block movement of amphibians and reptiles (PacifiCorp 2004a).

Riparian corridors facilitate dispersal of both aquatic and terrestrial wildlife. Riparian areas provide shade, cooler temperatures, and substrate for cover, breeding, or foraging for amphibians such as western toads and many bird species such as western yellow-billed cuckoo and yellow-breasted chat. Continuous riparian connectivity plays an important role during dispersal of juvenile birds, and reservoirs may support dispersal of juvenile birds in some areas (PacifiCorp 2004a).

Transmission power lines have the potential to cause bird mortality from collisions, particularly when transmission lines cross flight paths that birds use during seasonal migration or daily movements between foraging and nesting areas. PacifiCorp assessed transmission line configurations for raptor-safe design by evaluating electrocution and collision hazards relative to standards and guidelines for power lines described in the Edison Electric Institute’s publications, Suggested Practices for Raptor Protection on Power Lines: The State of the Art in 1996 (APLIC 1996) and Mitigating Bird Collisions with Power Lines: The State of the Art in 1994 (APLIC 1994) (PacifiCorp 2004a). PacifiCorp determined that there are three segments of transmission lines in California near areas of high waterfowl and wading bird use: one segment near the upstream end of Iron Gate Reservoir and two segments that cross Iron Gate Reservoir. The probability of avian collision is reduced at these sites as the lines do not pass between the reservoirs, rivers, major wetlands, or cropland that would attract foraging birds. Based on the date of this writing, no collisions or electrocutions have been documented by PacifiCorp personnel for any of the FERC Project-related transmission lines since a Memorandum of Understanding to document bird mortalities was filed in the 1980s between PacifiCorp and CDFW, ODFW, and USFWS (PacifiCorp 2004a).

3.5.3 Significance Criteria

Criteria for determining significant impacts on terrestrial resources are based upon Appendix G of the CEQA Guidelines (California Code of Regulations title 14, section 15000 et seq.) and professional judgment informed by best available data. Effects on terrestrial resources are considered significant if the Proposed Project would:

- Result in population-level impacts on state species of special concern, USDA Forest Service sensitive wildlife species on USDA Forest Service lands, or BLM sensitive species on BLM lands.

- Result in any of the following to the other types of special-status species[112]: not listed above: direct mortality or physical harm to individuals; degradation of habitat or a change in habitat conditions that would result in physiological impairment or that may affect the ability to perform essential behaviors such as migration, feeding, or reproducing; or abandonment of active bird nests or hibernacula or maternity bat roosts due to noise or structure removal (i.e., buildings, vegetation).
- Result in substantial removal or degradation of any riparian habitat or rare natural community.
- Result in substantial modifications of federally protected wetlands as defined by Section 404 of the Clean Water Act through direct removal, filling, hydrological interruption, or other means.
- Result in population-level impacts to culturally significant plant species, or a substantial change in habitat conditions that support these plants.
- Result in a substantial reduction of acreage or degradation of habitat that supports rare natural communities, for instance, through the introduction or spread of invasive plants.
- Result in substantial interference with the movement of any native resident or migratory wildlife species or with documented native resident or migratory wildlife corridors.
- Conflict with any local policies protecting biological resources, such as a tree preservation policy, where the conflict would result in an adverse impact on terrestrial resources.
- Conflict with the provisions of an adopted Habitat Conservation Plan (HCP), Natural Community Conservation Plan, or other approved local, regional, or state habitat conservation plan, where the conflict would result in an adverse impact on terrestrial resources.

3.5.4 Impact Analysis Approach

The impact analysis focused on the Primary Area of Analysis for terrestrial resources (area surrounding the Limits of Work and Klamath River downstream to the Pacific Ocean [see Section 3.5.1 *Area of Analysis*]). Property within the Secondary Area of Analysis for terrestrial resources would eventually be transferred to the respective states (i.e., California or Oregon) and managed for public interests (e.g., creation of open space, wetland and riverine restoration, river-based recreation, and grazing). Given that future land uses are speculative and potential impacts will vary, potential impacts to the Secondary Area of Analysis are not analyzed in this section. However, since the vegetation types, geology, climate, and hydrology of the Secondary Area of Analysis are similar to the Primary Area of Analysis, potential impacts from ground and noise

[112] Based on coordination with CDFW, significant impacts would occur if there is direct mortality or physical harm to special-status species which are defined as those species listed, proposed, or under review as endangered or threatened under the federal Endangered Species Act (ESA) or the California Endangered Species Act (CESA); those designated by the USDA Forest Service as sensitive or watch list species; those listed as rare under the California Native Plant Protection Act and/or included on CDFW's most recent *Special Vascular Plants, Bryophytes, and Lichens List* with a California Rare Plant Rank (CRPR) of 1, 2, 3, or 4 (CDFW 2017a); those designated as a Species of Special Concern by CDFW, designated as Fully Protected under the California Fish and Game Code (Sections 3511, 4700, 5050, and 5515), and/or protected under the federal Bald and Golden Eagle Protection Act.

disturbance activities (e.g., wetland and riverine restoration activities, recreation activities) in the Secondary Area of Analysis are expected to be similar to those in the Primary Area of Analysis.

Evaluation of the Proposed Project considered both short- and long-term effects on terrestrial resources. Short-term effects were defined as impacts that have the potential to occur within two years of the action and long-term effects were defined as impacts that have the potential to occur two years or more after the activity is completed. The analysis considered the timing of the action as identified in Appendix H of the Definite Plan (e.g., pre-dam removal period [one to two years prior to drawdown], reservoir drawdown period [January to March, year of drawdown], dam removal period [spring, summer, and fall immediately after drawdown], post-dam removal period [after dam removal is complete], plant establishment period [Year 1], and maintenance and monitoring period [Years 2 to 5]). Short-term impacts on nesting birds were evaluated as a result of construction-related noise greater than ambient conditions, and species-specific noise impacts on northern spotted owl were assessed for a 1-mile buffer around all dams to account for the loudest noise disturbance distance associated with blasting, 0.5-mile buffer around all reservoirs to account for the loudest noise disturbance distance associated with helicopter use, and 0.25-mile buffer around all other areas within the Limits of Work to account for noise disturbance associated with heavy equipment. These northern spotted owl noise disturbance distances were developed in coordination with the Arcata USFWS office based on an estimation of auditory and visual disturbance effects (USFWS 2006).

There are some terrestrial species (amphibians, reptiles) that have an aquatic life history aspect in riverine habitats (river and on river banks) and thus impacts from flow and sediment were also evaluated. Outputs of sediment transport and hydrologic models were used to predict modifications to terrestrial vegetation communities and how those would affect riparian zones, wetlands, and aquatic habitats, as well as special-status wildlife and plant species. Additional information on hydrologic modeling is provided in Section 3.1.6 *Summary of Available Hydrology Information for the Proposed Project*. The terrestrial resources analysis also incorporated impacts due to upland habitat modification during construction (e.g., staging areas).

There are terrestrial special-status species that may inhabit upland habitat (plants, invertebrates, birds, mammals) along the Middle Klamath River, Lower Klamath River, and Klamath River Estuary. As discussed in Section 3.6 *Flood Hydrology*, anticipated flow rates would stay below historical peak flows and would not alter the 100-year floodplain in the Middle Klamath River downstream of Humbug Creek. Therefore, flow-related impacts on terrestrial upland species would be similar to those under existing conditions and are not analyzed further.

The evaluation of potential impacts on terrestrial resources due to the Proposed Project included development of measures to reduce significant impacts to the extent feasible. Where the State Water Board can implement the measures, they are analyzed as mitigation measures. In some cases, implementation of such terrestrial resources measures would be not be considered feasible for the purposes of CEQA because the State Water Board cannot ensure that they would occur. In these cases, recommended measures are provided that would reduce potential impacts if implemented by KRRC. However, the impact analysis herein does not rely on the implementation of these measures. Both the terrestrial resources mitigation measures and the recommended measures are consistent with widely accepted professional best management practices for environmental protection and many of the measures were developed in consultation with CDFW and USFWS. In other cases, there are mitigation measures the State Water Board can ensure through the water quality certification. In these cases, the mitigation measure is considered as part of the impact analysis and determination of significance.

The following sources were assessed to determine the scope of existing local policies relevant to the Proposed Project:

- Del Norte County General Plan (Mintier & Associates et al. 2003):
  - Section 1 (Natural Resources/Conservation), Wildlife Habitat Resources, Policies 1.E.1, 1.E.2, 1.E.8, 1.E.9, 1.E.11, 1.E.12, 1.E.28, 1.E.29 and 1.E.33
- Humboldt County General Plan for Areas Outside of the Coastal Zone (Humboldt County 2017):
  - Conservation and Open Space Element, Biological Resources Policies BR-P7, BR-P9, BR-P10, and BR-P12
- Klamath County Comprehensive Plan (Klamath County 2010):
  - Goal 5 (Open Space, Scenic, and Historic Area and Natural Resources), Policies 3, 4, 10, 11, 12, and 16
- Siskiyou County General Plan (Siskiyou County 1980):
  - Deer Wintering Area Policies 28 and 29 (Siskiyou County n.d.)
  - The Conservation Element (Siskiyou County 1973), Wildlife Habitat, Objectives 1, 5–8

Most of the aforementioned policies (and objectives) are stated in generalized terms, consistent with their overall intent to protect terrestrial resources, including special-status wildlife and plant species as well as wetland, riparian, and rare natural communities. By focusing on the potential for impacts to specific special-status wildlife and plant species, as well as defined wetland, riparian, and rare natural communities within the terrestrial resources Area of Analysis, consideration of the more general local policies listed above is inherently addressed by the specific, individual analyses presented in Section 3.5.5 *[Aquatic Resources] Potential Impacts and Mitigation*. A subset of the existing local policies listed above contain more detailed information, including Del Norte County's General Plan Policy 1.E.29, which requires on-site mitigation for impacts on riparian vegetation, and Humboldt County's General Plan Policy BR-P9, which requires that oak mitigation be consistent with the provisions of CEQA, specifically Public Resources Code Section 21083.4. Del Norte County's General Plan Policy 1.E.29 is consistent with the Proposed Project actions regarding riparian vegetation (i.e., Reservoir Area Management Plan [Appendix B: *Definite Plan – Appendix H*]). The areas where there may be an impact on oaks due to Proposed Project construction activities (i.e., Limits of Work plus a 0.25-mile buffer, see also Section 3.5.1 *Area of Analysis*) are not within Humboldt County, so there would be no conflict with Humboldt County's General Plan Policy BR-P9.

The following sources were assessed to determine the scope of existing HCPs relevant to the Proposed Project and potential for overlap with the Primary Area of Analysis for Terrestrial Resources: (a) PacifiCorp's Interim Operations Habitat Conservation Plan for the Klamath Hydroelectric Project (PacifiCorp 2012) and (b) Green Diamond Forest

Habitat Conservation Plan (Green Diamond Resource Company 2018). These HCPs also provide generalized terms for protection of terrestrial resources, including special-status wildlife and plant species as well as wetland, riparian, and rare natural communities. By focusing on the potential for impacts to specific special-status wildlife and plant species, as well as defined wetland, riparian, and rare natural communities within the terrestrial resources Area of Analysis, the specific, individual analyses presented in Section 3.5.5 *[Aquatic Resources] Potential Impacts and Mitigation* address the HCPs.

3.5.5 Potential Impacts and Mitigation

3.5.5.1 Vegetation Communities

Potential Impact 3.5-1 Construction-related impacts on wetland and riparian vegetation communities.

Disturbances associated with construction areas, disposal sites, and haul roads where clearing, grading, and staging of equipment would occur could have short-term impacts on sensitive habitats, including wetlands and riparian habitats along reservoirs and river reaches. Heavy machinery traversing wetland and riparian areas could change local topography and impact wetland and riparian vegetation and could introduce increased levels of dust and runoff pollution to wetland and riparian areas that could degrade plant community conditions. Several of the bridges required for access to and from the dam sites would be replaced or upgraded prior to reservoir drawdown (see Potential Impact 3.22-2). Adjacent riparian vegetation under or adjacent to the existing or new bridges could be impacted during these activities. Additionally, removal of recreation sites could result in impacts on wetland and riparian vegetation (e.g., the Palustrine Forested Wetland at Iron Gate Reservoir). Wetland and riparian vegetation are likely to be present in the areas where construction activities are planned to occur; without surveys to document these habitats and measures to adequately protect them, these habitats would be likely to be degraded or removed and thus construction-related activities would result in a significant short-term impact.

Based on existing data for the Primary Area of Analysis for terrestrial resources (Section 3.5.2.1 *Vegetation Communities*), wetland and riparian habitats (Estuarine, Montane Riparian, Palustrine, and Wet Meadow) account for approximately five percent of the total acreage. The Proposed Project identifies a number of pre-construction measures to reduce impacts on these habitats. First, a wetland delineation would be conducted within the limits of construction around the dams and facilities, access and haul roads, and disposal sites in accordance with the 1987 USACE Wetland Delineation Manual (USACE 1987) and applicable Regional Supplements (i.e., Western Mountains, Valleys, and Coast Region [USACE 2010] and Arid West [USACE 2008]). The results of the wetland delineation would be incorporated into the Proposed Project design to avoid and minimize direct impacts on wetlands to the maximum extent feasible, and wetland areas adjacent to the construction Limits of Work would be fenced to prevent inadvertent entry. There could be impacts on wetlands if the fencing does not include an appropriate buffer (i.e., a prescribed distance from the edge of the wetland in which construction activities are prohibited); however, with implementation of Mitigation Measure TER-1, short and long-term impacts on wetland communities would be reduced to less than significant.

Additionally, the Proposed Project includes construction best management practices (Appendix B: *Definite Plan – Appendix J*) to reduce potential impacts on water quality in wetlands and other survey waters during construction. The combination of these measures and implementation of Mitigation Measure WQ-1, as described in Potential Impact 3.2-4, would reduce potential impacts on wetlands to less than significant.

The Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) includes details for the installation of native plants and aerial, barge, or hand seeding in appropriate areas to re-vegetate all areas disturbed during construction, including reservoir areas, demolition and disposal sites, staging, access and haul roads, and turn-arounds, with a goal of no net loss of wetland or riparian habitat acreage and functions. Wetlands established in restored areas would be monitored for five years or until the performance criteria (as defined in Appendix B: *Definite Plan – Appendix H*, Section 6.1.4) have been met. To minimize the introduction of invasive plant species into construction areas, construction vehicles and equipment would be cleaned with compressed water or air within a designated containment area to remove pathogens, invasive plant seeds, or plant parts, and disposed of in appropriate disposal facilities. The Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) also includes a five-year monitoring plan with metrics to evaluate success of minimizing invasive exotic vegetation (i.e., percent relative cover by medium and low priority invasive plants [as defined in the Reservoir Area Management Plan] shall be less than the average at designated reference locations as follows: 25 percent in Year 1; 40 percent in Year 2; 55 percent in Year 3; 70 percent in Year 4; 90 percent in Year 5; and no high-priority invasive plants [as defined in the Reservoir Area Management Plan] shall be present in the Limits of Work at any time during the five-year monitoring).

Mitigation Measure TER-1 Establish a 20-foot buffer around delineated wetlands.
The KRRC shall establish a minimum of a 20-foot buffer around all delineated wetlands potentially affected by construction impacts to ensure there will not be any significant environmental impacts to wetlands by deterring heavy machinery from traversing the wetland and preventing runoff pollution from directly entering the wetland where doing so would not result in a significant environmental impact. The State Water Board has the authority to include this mitigation measure in its water quality certification for the project, and the measure is therefore feasible and used in this analysis to make a significance determination.

With the implementation of these measures, potential short-term impacts on wetlands and riparian areas from construction would be less than significant.

<u>Significance</u>
No significant impact in the short term with mitigation

Potential Impact 3.5-2 Short-term and long-term impacts on wetland and riparian vegetation communities along existing reservoir shorelines due to reservoir drawdown.
Under the Proposed Project, there would be reduction of existing wet habitat at Copco No. 1, Copco No. 2, and Iron Gate reservoirs (currently 15.8 acres of Montane Riparian and 52.3 acres of Palustrine habitat, Table 3.5-2) due to reservoir drawdown, as detailed below:

- Copco No. 1 Reservoir: The shoreline of Copco No. 1 Reservoir currently supports Palustrine Scrub-shrub Wetland where tributary channels enter the reservoir, and Palustrine Forested Wetland occurs along the northwest shore. Small patches of

Palustrine Emergent Wetland also currently exist along the shoreline. These communities would be lost due to reservoir drawdown.

- Copco No. 2 Reservoir: The southern slope of Copco No. 2 Dam currently supports a Palustrine Scrub-shrub Wetland and Palustrine Forested Wetland. Reservoir drawdown would reduce the extent of these wet habitats. These features are not anticipated to be entirely lost because Copco No. 2 Reservoir is relatively small and, therefore, the features will be in close in proximity to the newly exposed river channel.
- Copco No. 2 penstock: Currently, Copco No. 2 penstock leaks water that supports small, local patches of Palustrine Emergent Wetland. Dam and penstock removal would result in the loss of this vegetation.
- Iron Gate Reservoir: Vegetation along the shores of Iron Gate Reservoir includes some Montane Riparian and Palustrine habitat including Palustrine Forested Wetland in the day use and campground areas, and Palustrine Emergent Wetland and Palustrine Scrub-shrub Wetland along Jenny, Scotch, and Camp creeks where tributaries join the reservoir. Reservoir drawdown would reduce the extent of these wet habitats.

Degradation or removal of wetland and riparian habitat in the areas listed above would be a significant short-term and long-term impact.

The Proposed Project includes several actions to encourage rapid revegetation with native riparian species in the reservoir footprints as defined in the Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) that would ensure no net loss of wetland or riparian habitat acreage and functions. Six locations in Copco No. 1 Reservoir and three locations in Iron Gate Reservoir would be targeted for restoration; these areas would undergo barge-mounted pressure washing/sediment jetting during reservoir drawdown and subsequently would be excavated to the historical floodplain elevation to help create wetlands, floodplain areas, and off-channel habitat features. As depicted in Figures 2.7-11 and 2.7-12, approximately 50 acres of riparian bank would be targeted for revegetation and approximately 100 acres of wetlands, floodplain, and off-channel habitat features would be targeted for restoration. The resulting acreage of restored riparian and wetland vegetation will vary depending on field conditions including the presence of cultural resources and human remains, changes in the topography following drawdown that affect the extent of restorable areas, and changes in topography that affect access; however, given that the proposed acreage to be restored (150 acres) is well above the total acreage potentially impacted (68 acres) the policy of no net loss is anticipated to be achieved.

In addition to restoration in these nine focus areas within Copco No. 1 and Iron Gate reservoirs, prior to drawdown, revegetation activities would include invasive plant species control within the Limits of Work, collection of native plant seed, and propagation of native plants. During the reservoir drawdown period (January to March) and directly afterward, proposed actions within the Limits of Work would include seeding (aerial or potentially barge) of exposed soils, salvaging and planting of existing wetland and riparian vegetation, and evaluation of restoration sites. Following reservoir drawdown (i.e., summer through fall), proposed actions within the Limits of Work would include additional seeding and weed control, and installation of live plants (poles, container plants) as well as acorns. After dam removal is complete and throughout the first year of plant establishment, activities would include additional seeding as necessary, invasive species control, continued plant installation, plant maintenance, and adaptive management of installed habitat features within the Limits of Work.

During the maintenance and monitoring period (years 2 to 5 after revegetation is complete), additional re-seeding and re-planting will be performed in areas that failed to establish and previously seeded and planted areas will be maintained through weed control and irrigation system upkeep. Therefore, short-term impacts on wetland and riparian vegetation would be less than significant, as riparian and wetland vegetation would be actively reestablished along the new river channel and tributaries within the reservoir area in order to meet the proposed success criteria (i.e., percent relative cover at designated reference locations as follows: 70 percent in Year 1; 75 percent in Year 2; 80 percent in Year 3; 85 percent in Year 4; and 90 percent in Year 5).

Following drawdown of the reservoirs, existing upland vegetation is expected to remain unchanged and contribute to successional processes on newly exposed areas. Existing wetland-dependent vegetation along the margins of the reservoirs is expected to die out and transition to upland communities. Wetland species that occur near confluences are expected to conform to the riparian corridor width of the tributaries and over the subsequent years extend down the newly exposed mainstem river channel riparian corridor. Therefore, implementation of the Proposed Project may result in a long-term net increase in the areal extent of riparian and wetland habitat within the terrestrial resources Primary Area of Analysis, largely as part of natural recruitment along newly-exposed mainstem river channel riparian corridor within the former reservoir footprints, but also as a result of active restoration management. Moreover, restored wetlands would benefit from receiving marine-derived nutrients in salmon and other anadromous fish that would have access to Klamath River reaches upstream of Iron Gate Dam once the Lower Klamath Project reservoirs are removed (see also Potential Impact 3.5-27).

The Reservoir Area Management Plan (Appendix B: *Definite Plan – Appendix H*) also includes control of invasive plant species (referred to as invasive exotic vegetation [IEV] in the Reservoir Area Management Plan); actions would include invasive plant surveys during pre-dam removal years 1 and 2, invasive plant control during and after drawdown, and monthly inspections for compliance through year 5 and quarterly inspections from years 5 to 10 post-dam removal (Table 2.7-2). Control methods would include manual weed pulling, mowing or cutting, tilling and disking, grazing, solarization, and the potential use of herbicides. Herbicides would be applied as last resort and only use herbicides that have been approved by BLM, CDFW, RWQCB, USFWS, and NMFS. These control measures and monitoring efforts would ensure that impacts on native plant species would be less than significant.

Significance

No significant impact in the short term and long term

Potential Impact 3.5-3 Short-term and long-term impacts on wetland habitat downstream of the Lower Klamath Project dams due to erosion or sediment deposition.
